REMOTE CONTROL. The ability to operate equipment, apparatus, and processes from a distance. A high percentage of industrial control systems fall into this category, where the indicating, recording, and controlling instruments will be located up to several hundred feet from the equipment that is being controlled. Commonly, the instrumentation will be placed on a control panel or console where the operator can take readings on all points of a large installation quickly and efficiently. Otherwise, several operators would be required to physically move about the plant. Without remote control, the coordination of complex processes would be chaotic. Frequently, instruments and controllers will be contained within a separate control house or control room, a facility often air conditioned for protection of the equipment and to provide comfort for the operator. In installations of this type, the signals of information flowing from a control house to the process and back are either electric or pneumatic. Without the use of boosters, however, pneumatic transmission is distance-limited.

There are varying degrees of *remoteness*. Where telecommunications are used, the ability to control remotely, as in the case of space vehicles and probes, is essentially limitless. Solid wire and microwave communications commonly are used to carry control signals and information over long distances as encountered, for example, in pipeline management. Telephone lines are commonly used for such industrial communications purposes. Some interesting arrangements of remote control have been developed in connection with the manipulation of robots for undersea and radioactive applications.

REMSEN, IRA (1846–1927). An American chemist born in New York. He began his career in medical practice but abandoned it for chemistry and went to Germany to study. He received his doctorate in chemistry from the University of Gottingen in 1870. He returned to the U.S. where he taught physics and chemistry at Williams. He was later invited to join the staff of John Hopkins University where he became head of the department of chemistry. There he established the first graduate curriculum in chemistry in the U.S. based on the system then in use in Germany. In 1879, saccharin was discovered in his research laboratory. He wrote several widely used textbooks and founded the *American Journal of Chemistry*, which later merged with JACS. Remsen served as President of Johns Hopkins from 1901–1912. He was also recognized as one of the great teachers of chemistry.

REPEATABILITY. With reference to industrial and scientific instruments, the Instrument Society of America defines *repeatability* as the closeness of agreement among a number of consecutive measurements of the output for the same value of the input under the same operating conditions, approaching from the same direction, for full range traverses. See Fig. 1. Repeatability is usually measured as a *nonrepeatability* and expressed as repeatability in percent of span. Repeatability does *not* include hysteresis. See also **Reproducibility**.

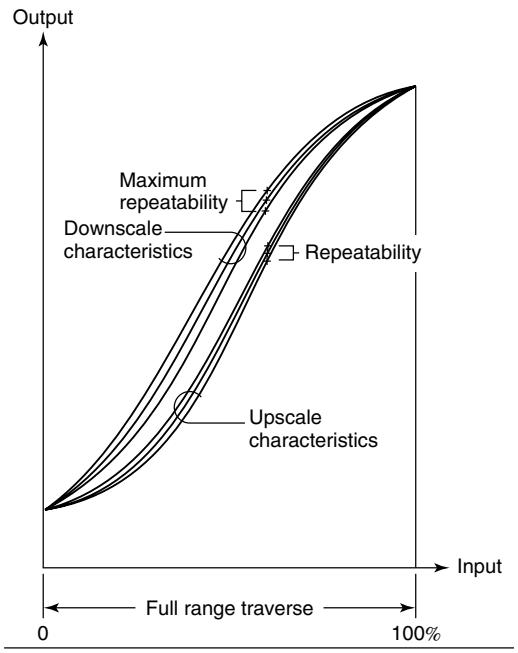

Fig. 1. Graphic description of repeatability.

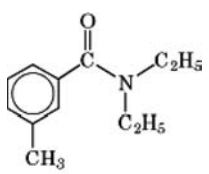
REPELLENTS. Repellents are materials that affect insects and other organisms by disrupting their natural behavior of bloodseeking through biting of humans and animals, and are the first line of defense that can be readily used for this purpose. The best overall standard repellent is *N*,*N*-diethyl-*m*-toluamide [CAS: 134-62-3] (DEET), systematically named *N*,*N*-diethyl-3-methylbenzamide (1);



(1)

however, many other compounds are presently in use. One database search showed 27 active ingredients in 212 products registered by the U.S. EPA for human use as repellents or feeding depressants, including octyl bicycloheptene dicarboxamide (*N*-2-ethylhexyl bicyclo[2.2.1]-5-hepten-2,3-dicarboxamide), dipropyl isocinchomeronate (2,5-pyridine dicarboxylic

acid, dipropyl ester), dimethyl phthalate, oil of citronella, cedarwood oil, pyrethrins, and pine tar oil. Repellent–toxicant or biting depressant systems are available which are reasonably comfortable for the user and can protect completely against a number of pests for an extended period of time.

Newer, cosmetically appealing formulations of chemical repellents have become popular in the United States since the mid-1980s, and interest in personal protection against biting arthropods has been renewed. Children and adults may be exposed daily to risks of Lyme disease, and those exposed should be particularly interested in reducing exposure to nymphs of the deer tick *Ixodes scapularis*. The tick, which carries the bacterium *Borellia burgdorferi*, is the same tick species previously called *I. dammini* by some entomologists. Destruction of ticks by spraying is expensive, works only locally, and is not very effective on a large scale. Not only is this disease difficult to diagnose and treat, but treatment of Lyme disease using expensive antibiotics has no effect on the next infective bite. See also **Lyme Disease**.

The use of insecticides has led to the rise of widespread resistance in areas where residual insecticides were applied for malaria eradication, and in some locations that have widespread irrigation, as in California, or that practice flooding for rice production. Mosquito resistance to insecticides is prevalent in Southeast Asia, India, and East Africa. Use of personal protection and repellents is recommended for travelers to malarious areas for avoiding serious health risks. Insect species that can be vectors of diseases are listed in Table 1.

TABLE 1. INSECT VECTORS OF DISEASE

Insect	Scientific Name	Disease
Biting midges	*Ceratopogonidae*	Bluetongue virus
Blackflies	*Simulium*	River blindness
Sandflies	*Phlebotamus, Leptoconops*	Leishmaniasis
Tsetse flies	*Glossina*	African trypanosomiasis or sleeping sickness
Tabanids or horseflies	*Tabanus*	
Clegs	*Haemotopota*	
Deerflies	*Chrysops*	
Snipe flies and stableflies	*Stomoxys*	
Cattle ticks	*Rhipicephalus*	Heartwater fever and blackwater fever
Soft ticks	*Dermacentor, Amblyomma*	Rocky Mountain and spotted fever
Mites or chigger mites	*Trombidiidae*	Scrub typhus
Bedbugs	*Cimex*	
Lice	*Pediculus*	Typhus
Kissing bugs	*Pentatomid*	Chagas disease
Fleas	*Xenopsylla, Pulex*	Plague

Evaluation of Repellents

The candidate chemical is dissolved in ethanol and spread over one forearm of the human subject, as DEET (**1**) is similarly applied to the other forearm. Each arm is then exposed to 1500 avid *A. aegypti* female mosquitoes for 3 min at 30-min intervals. Effectiveness is based on complete protection, ie, the time until the first confirmed bite (one bite followed by another within 30 min).

Each candidate repellent is applied to a knit cotton stocking or cloth patch at 3.3 g/m^2 cloth, usually as a 1% solution of active ingredient (AI) in acetone. Two hours later, the stock or cloth patch is placed over an untreated nylon stocking on the arm of a subject, the hand covered, and the arm exposed to 1500 female mosquitoes for one minute. If fewer than five bites are counted, the test is repeated at 24 h, then weekly until failure, which is, by definition, five bites per minute. The standard mosquitoes used are *Aedes aegypti*, *Anopheles quadrimaculatus*, or *A. albimanus*. Candidate repellents in cloth tests are in one of the following classes: class 1, effective 0 d; class 2, 1–5 d; class 3, 6–10 d; class 4, 11–21 d; and class 5, >21 d.

Air is drawn over a human arm through a 9.5-cm disk of cotton netting having 0.64-cm holes and treated with a solution of the candidate repellent; air is then drawn into an olfactometer cage containing 125 avid female *A. aegypti*. The number of days the repellent prevents >10% of the mosquitoes from passing through the netting constitutes effectiveness.

Small areas of human forearms are marked and treated with small amounts of repellent on a unit area basis to ensure that the treatment rate is always the same between subjects. The patches are tested at 0 and 4 hours against small numbers (ca 15) of mosquitoes. This method does not consider creep, movement of repellent across the skin surface, or the interaction between two chemicals owing to such lateral movement of chemical.

A treated strip of fabric and a control strip are lowered into a container of crawling arthropods such as ticks, fleas, and mites. After a predetermined time, the strips are lifted, the animals remaining are counted, and the percentage repellency is determined.

Machines have been constructed by several groups to measure the intrinsic (initial) repellency of a compound when it is added to a warm, moist airstream to overcome the attractiveness of the airstream to mosquitoes. Such machines remove the factor of human odor in attempts to simplify the measurement of repellency.

Numerous methods have involved the use of animals as attractants, followed by evaluation of repellents as skin treatments or attached cloth treatments, often against crawling arthropods such as fleas, ticks, and mites. Animals such as gerbils, guinea pigs, camels, mice, shaved rabbits, and hairless dogs have been used, particularly when the toxicity is unknown.

Arthropod Repellents

Mosquito Repellents. Clothing impregnants may be applied to socks, head nets, gloves, or conventional apparel by dipping into emulsions, manual application of liquid, or surface spraying with aerosols. Repellents may be applied to cotton cloth using technical material dissolved in acetone, although this solvent may be unavailable or incompatible with some synthetic fabric blends. Repellents may be applied to clothing on a large scale using 10% of a nonionic emulsifier and 90% technical material at 5 wt % of the cloth. Repellent jackets made of 0.64-cm cotton mesh are impregnated with a repellent such as DEET (1). There are several advantages in this. For instance, the repellent is applied to the mesh, not directly on skin. Repellents other than DEET may be used, such as repellents more effective than DEET, against biting flies or other mosquitoes. The jacket may be retreated as necessary simply by the addition of a measured quantity of concentrated repellent, such as 75 wt % DEET, to the jacket while in its storage pouch. An effective skin repellent such as DEET is lost much more slowly from the mesh jacket than from skin. This jacket has been added to the army supply system and is meant to be retreated with standard military-issue 75 wt % DEET. The DEET-treated jacket has been effective against mosquitoes in northern and southern states, blackflies in Maine, biting midges in Florida, and sandflies in Panama. The jacket is effective against heavy pressures of small insects that are capable of passing through mesh. Also, the jacket's wide spaces allow passage of air and moisture, making it a more comfortable alternative than either wearing long-sleeved, heavily repellent-treated clothing or having repellents applied to skin, particularly in warm, humid climates with heavy insect populations.

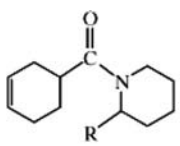
Since its initial report as a promising repellent in 1954, DEET has been considered the best all-around repellent having generally acceptable characteristics, despite a continuing search for a superior chemical. Improvements include many commercial products with added cosmetic agents that use slow release technology. DEET is the principal or only component in most of the effective mosquito repellents on the market. Muskol (100% DEET) and a number of other products containing 100% DEET were popular in the 1980s, with reports in outdoor magazines and *Consumer Reports* claiming that 100% DEET was perhaps more desirable, and had to be applied less often than more dilute formulations. However, the use of 100% DEET on skin is usually not justified because of the possibility of skin irritation, and not for reasons of better or worse repellent activity.

Dimethyl phthalate [CAS: 131-11-3] (DMP) is a clear oil insoluble in water and soluble in organic solvents, and is synthesized from phthalic

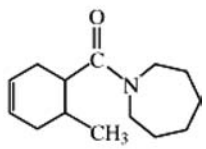
acid esterified with methanol. DMP is an effective repellent, used as a standard against *A. aegypti*, and is effective for 11–22 d on cloth. The famous repellent Rutgers 6–12, 2-ethyl-1,3-hexanediol [CAS: 94-96-2], is a clear oil that is insoluble in water and miscible with organic solvents such as ethanol. Screened during World War II, this repellent is exceptionally effective against *A. aegypti*, lasting 196 d on cloth. Tests have been run against the newer pests *A. albopictus* and *A. aegypti*, including five repellents containing DEET (test standard), a controlled release formulation containing DEET, two dosages of DEET in ethanol, and Avon Skin-So-Soft. On the skin, the repellent chemicals provide significant protection from biting; however, *A. albopictus* is more sensitive to repellents than *A. aegypti*.

Biting Midge Repellents. The genus *Culicoides* is found in fresh water, salt water, and tide water environments in the southeastern United States and Caribbean, where they may be properly called biting midges, or more commonly sandflies, sand fleas, sand gnats, punkies, no-see-ums, or flying teeth. Because of their small size, they can pass easily through ordinary mosquito screens. Commonly used repellents are of varying effectiveness, depending on the species involved.

Among the 117 compounds synthesized, structures that have been found especially active include the 1-piperidyl-(**2**) and 1-[hexahydro-1*H*-azeipinyl] (**3**) derivatives where the cyclohexenyl ring can either be mono unsaturated or have methyl branches such as in the 2-position. The use of Avon Skin-So-Soft, a scented mineral oil cosmetic, has been claimed to repel biting midges at Parris Island, South Carolina, and it is reportedly widely used for mosquitoes as well. When applied liberally, it apparently traps the midges or fouls their mouthparts and thus inhibits biting. Tests of several commercial mineral oil preparations, both scented and unscented, show interference with biting behavior and therefore a repellent effect. This is because when applied thickly to skin, the small biting midges tend to become thickly coated and drown in the oil.



(**2**)



(**3**)

Phlebotomine Sandfly Repellents. Phlebotomine sandflies are found primarily in relatively underdeveloped tropical and subtropical regions of the world. They are vectors of the various forms of leishmaniasis, bartonellosis, and numerous arboviruses, including the medically important sandfly fever group. However, personal protection against phlebotomine sandflies has had little attention as compared to repellents for mosquitoes. Only a few tests of repellents for Old World phlebotomine flies have been documented, but none of them as recently as the 1990s.

Skin applications of the five selected repellents including DEET provide a mean coefficient of protection (CP) of 99.2% against the attack of at least three species of *Lutzomyia*. All of these repellents tested at the highest dosage give good protection from the bites of at least three species of phlebotomine sandflies, two of which are important vectors of leishmaniasis. However, the azepine (**3**, saturated) gives complete protection and warrants further study.

Horseflies, Greenheadflies, Deerflies, Stableflies. Field trials of permethrin-treated clothing against highly susceptible tsetse flies have shown good effectiveness. There are no published tests exhibiting the effectiveness of clothing treatments against North American species of horseflies and deerflies. Bath oils are commonly used by lifeguards on the Florida Gulf Coast for protection against biting stableflies, and have been used effectively on horses; however, as usual, repellents fail at high fly populations. This repellent effect is difficult to demonstrate in cage tests with stableflies, where biting attacks occur despite treatment with this material. It is likely that use of repellent-treated mesh jackets and hats for mosquitoes and sandflies would be most effective against these large biting flies.

Tick and Chigger Repellents. Prevention of tick attachment is possible by mechanically preventing access of the ticks to bare skin bordering or beneath the clothing, such as zippered long pants with bloused cuffs tucked into boot or sock tops and a long-sleeved shirt tucked into the pants. Repellents are best impregnated into clothing, on wrist skin under the sleeve, on and above the socks, and around the neck on the exposed skin and under the collar. DEET products are available as a 50% liquid and may be mixed with isopropyl alcohol (59 mL DEET and 1 L 2-propanol) to produce sufficient material to impregnate clothing with a 5% solution and, depending on tick density, give 80–98% protection.

Permethrin was developed as a clothing impregnant for military use by several countries worldwide, including the United States. It first became available in 1982 as a clothing treatment under EPA label 24C in an aerosol formulation called Permanone Tick Repellent. The same formulation is widely available in products registered with approved labeling under such trade names as Duranon Tick Repellent and Coulston's Permethrin Arthropod Repellent. A topical permethrin treatment of clothing has shown good effectiveness against crawling insects when applied as a water-based formulation of 0.5 wt % permethrin. It gives extremely effective protection against ticks. Permethrin-treated cloth is practically odorless; a single treatment of ca 20-s spray (ca 0.2 g/m^2) adsorbs to the outer surface of clothing, does not contact skin, and is long lasting. Permethrin as a clothing treatment acts more as a toxicant than as a repellent, and though ticks may crawl on the clothing, the visit is only temporary and usually fatal within a few minutes. The lethal barrier provided has been shown to give 100% protection in tests against ticks in Oklahoma, Kentucky, and Florida. The materials named above are likewise effective repellents against chigger mites (*Trombiculidae*), also called chiggers or redbugs.

Body and Head Lice. The human body louse, *Pediculus humanus* L., is an important health threat in gyms and schools of the United States and in many areas of the world. Most populations of body lice are resistant to the organochlorine insecticides, including lindane. Fabric patches treated with permethrin have been evaluated against natural and laboratory strains of human body lice in Peru. Permethrin-treated fabric is toxic to lice on contact and quickly affects feeding behavior, even when washed up to 20 times. Thus permethrin-treated clothing interrupts disease transmission, and offers a passive louse control not previously feasible.

Cockroach Repellents. Transport of goods and materials also provides rapid transport of cockroaches in corrugated cardboard boxes, empty beer and soft-drink bottles, cases in recycling locations, and commercial trucks used for transporting commodities such as bananas, laundry, dry cleaning, and paper bags. Repellents may be helpful in preventing transport of cockroaches into uninfested areas. Some logical uses of repellents are on cardboard cartons for food and soft drinks, on beer crates, and in coin-operated vending machines, all of which provide excellent shelter and food for cockroaches. Recycling of beer cans and soft-drink containers offers cockroaches another opportunity for shelter and transport, and control is probably difficult. A good repellent can be used either alone or in conjunction with an insecticide as a residual treatment in business establishments or homes. Such effective, long-term repellents can become more useful in the future if the only toxicants available are short-term biodegradable materials. This is especially problematic when retreatment is expensive and rapidly becomes ineffective. Also, the cockroach's opportunistic nature of feeding and shelter-finding permits survival and flourishing when most but not all sites are treated. Similarly, the use of slow-acting toxicants such as borax and boric acid is not effective for long unless insects can be confined to dry, treated surfaces. This tends to describe a laboratory environment and is not applicable to the real world in which cockroaches may quickly leave an effectively treated area and fully recover from the sublethal effects. Many

repellents are found among amides, sulfonamides, cyanoacetic acids, and carboxamides, but two good ones are *N,N*-diethylcyclohexaneacetamide and *N,N*-diethylcyclohexanepropaneamide both better than fencholic acid when tested against the common North American cockroaches, *Blattella germanica* and *Periplaneta Americana.*

Dibutyl succinate or Tabutrex [141-03-7]; R-11; R-55 [23885-27-0]; and R-874 [3547-33-9] have been available for industry as cockroach repellents since the 1960s.

Another problem lies in the overlap of repellent–toxicant definition, in that many toxicants are known to have repellent effects. Pyrethrins are often used on ships to flush cockroaches from harborages during a treatment with another, less activating toxicant. In a survey of the components, eg, toxicants, synergists, solvents, flushing agents, and emulsifiers, making up commercially available formulations of insecticides for cockroach control in the United States, 121 different materials were examined. Tests show that pyrethrins which have been considered repellents for some years, MGK 264 [CAS: 113-48-4] and the emulsifier Triton X100 [CAS: 9002-93-1], are noticeably repellent to both German and American cockroaches.

Other Insects. Bark beetle management in European forests has been successful using combinations of sex pheromones and tree volatiles. Repellents that were tested in Louisiana to deter attacks of the southern pine beetle afforded protection of high value loblolly pines by using the host tree compound 4-allylanisole [CAS:140-67-0]. The aggregation inhibitor 4-allylanisole eliminated tree deaths for the length of the 30-d test by placing nine vials with wicks containing 20 g each of repellent vertically on the lower trunk of each tree being protected, using the tree as a flagpole. A patent has been issued on this technology (U.S. Pat. 5,403,836).

Bird Repellents

Blackbirds, starlings, and sparrows are North American birds that cause serious damage to growing crops. Nonchemical techniques using repelling devices such as propane cannons, shiny Mylar ribbons, scarecrows, metallic pinwheels, and recorded distress calls give temporary results, but when the birds become accustomed to the devices, the effect is generally lost.

Some bird repellents are composed of viscous, sticky materials that birds dislike having on their feet. These compounds, eg, Tanglefoot, Roost-No-More, and TackTrap, are often based on incompletely polymerized isobutylene and thinned with aromatic solvents.

Intoxicating chemicals are those that are not necessarily lethal but operate as primary repellents or secondary repellents, eg, emetics causing sickness or distress. Primary bird repellents are those whose mode of action is having a bad taste; immediate rejection of food is the desired result. However, they are effective only if other foods are available; they are not effective in times of food shortages, because large flocks of migrating birds would be forced to feed or starve.

Avitrol [CAS: 504-24-5] (4-aminopyridine), mp 155–158 °C, bp 273 °C, has repellent–toxicant properties for birds and is classed as a severe poison and irritant. This secondary bird repellent can be used as a broadcast bait, causing uncoordinated flight and distress calls and escape responses in nearby birds.

Methyl anthranilate [CAS: 140-20-3], the grape flavoring used in food products, has been shown effective as a waterfowl repellent.

Methiocarb [CAS: 2032-65-7] (3,5-dimethyl-4-(methylthio) phenol methylcarbamate) is classed as an insecticide and acaricide and is used as a slug and snail bait, but is no longer registered for use as a bird repellent in the United States.

Anthrahydroquinones have been patented in Japan as bird repellents, and anthraquinone [CAS: 84-65-1] is used widely in Europe as a spray to protect growing crops and as a wood dressing. The synthetic pyrethroid deltamethrin [CAS: 52918-63-5] was evaluated, as were other materials, including bendiocarb and 20,25-diazocholesterol dihydrochloride [CAS: 1249-84-9] (Ornitrol), a steroid that inhibits embryo development when adsorbed or ingested as a seed treatment of bait corn.

Mammalian Pests

The concept of employing a nonlethal repellent to control wildlife depredation on crops arose early in agricultural history and has been pursued vigorously ever since. Although the continued interest in repellents may reflect public opinion about the impact on endangered or protected species, feeding inhibitors and modern lethal treatments remain practical solutions. A food repellent has been defined as "a compound or combination of compounds that, when added to a food source, acts through the taste system to produce a marked decrease in the utilization of that food by the target species". The action can be primary, where the animal reacts to the taste of the repellent alone, or secondary, where the animal uses the taste of the repellent as a cue to later adverse effects. A useful repellent is meant to stop a hungry animal from feeding on a readily accessible, abundant, and palatable food, forcing the pest animal to leave the area or make a change in food habits, both unlikely choices.

Although no consistently effective chemical repellent has been developed for vertebrate pests, some promising materials have been tested as repellents that are based on predator avoidance, specifically compounds from the secretions of predators.

Area repellents are materials that are intended to keep animals away from a broad area. They include predator scent such as lion or tiger manure, blood meal, tankage such as putrefied slaughterhouse waste, bone tar oil, rags soaked in kerosene or creosote, and human hair. Although few controlled tests have been run on these materials in the past, more recent investigations of predator odors have shown promise.

Health and Safety Factors

Toxicological testing has been carried out on many of the older, widely used materials, all of which require re-registration with the EPA. As a result of EPA regulations, many of the materials submitted as cloth repellents since 1970 have been tested at the USDA Agriculture Research Service, Medical and Veterinary Entomology Research Laboratory in Gainesville, Florida. Effective compounds, after further testing, are then submitted to the U.S. Army Environmental Health Agency for extensive toxicological testing. Compounds are tested as repellents on human skin only after passing the four standard toxicological tests: rabbit eye irritation, rabbit skin dermal, rat inhalation, and rat acute ingestion. All of these, plus EPA regulations in the United States classifying repellents as pesticides, have drastically reduced the number of candidate chemicals submitted to the USDA laboratory in Gainesville for general screening since about 1975, and virtually eliminated chemicals submitted as candidate repellents.

Labels for repellent products sold in the United States are recommended for purposes of efficacy and safety of use. Newer products containing DEET may contain less active ingredient but feature a cosmetic that makes the compound less objectionable on the skin and more acceptable to use.

REPOSE (Angle of). The maximum angle with the horizontal at which an object on an inclined plane will retain its position without tending to slide. The tangent of the angle of repose equals the coefficient of static friction.

The term angle of repose is also used with the closely related meaning of the maximum angle with the horizontal at which loose material such as grain, sand, coal, or stone will retain its position without tending to slide. The moisture content and the distribution of the fine and coarse particles have a marked effect on the value of this angle. The angle of repose is an important factor in the design of retaining walls, earth dams,

and embankments and is particularly valuable in the design of storage bins and bunkers since the allowable surcharge as well as the active horizontal pressure depends upon its value.

Angles of repose for some materials include: ashes (wet), 38–45°; bentonite (pulverized), 45°; cement (portland), 40°; clay (loose dry lump), 25–45°; coal (bituminous, slack, dry), 37°; coke (sized), 30°; earth (common loam, dry), 30–40°; feldspar (crushed), 45°; Fuller's earth, 23°; gravel (dry), 30–40°; malt, 33°; salt (cake), 36°; sand (dry, loose), 25–35°; sand (wet), 30–45°; slag (granulated), 45°; soda ash, 37°; and stone (crushed), 30–40°.

REPPE PROCESS. Any of several processes involving reaction of acetylene [CAS: 74-86-2] (1) with formaldehyde [CAS: 50-00-0] to produce 2-butyne-1,4-diol [CAS: 110-65-6] which can be converted to butadiene [CAS: 106-99-0]; (2) with formaldehyde under different conditions to produce propargyl alcohol [CAS: 107-19-7] and, form this, allyl alcohol [CAS: 107-18-6]; (3) with hydrogen cyanide [CAS: 7490-8] to yield acrylonitrile [CAS: 107-13-1]; (4) with alcohols to give vinyl ethers; (5) with amines or phenols [CAS: 64743-03-9] to give vinyl derivatives; (6) with carbon monoxide [CAS: 60-08-0] and alcohols to give esters of acrylic acid [CAS: 79-10-7]; (7) by polymerization to produce cyclooctatetraene [CAS: 629-20-9]; and (8) with phenols to make resins. The use of catalysts, pressures up to 30 atm, and special techniques to avoid or contain explosions are important factors in these processes.

See also **Acetylene**.

REPRODUCIBILITY. With reference to industrial and scientific instruments, the Instrument Society of America defines *reproducibility* as the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions. Reproducibility is usually measured as a *nonreproducibility* and expressed as reproducibility in percent of span for a specified period of time, but under certain conditions the period may be a short time during which drift may not be included. Reproducibility, in contrast to repeatability, does include hysteresis, drift, and also repeatability. See also **Repeatability**.

REPTILIA. The reptiles, including the lizards and snakes, crocodiles, alligators and related forms, and turtles and tortoises. A class of the phylum *Chordata*.

The class is characterized as follows: (1) The skull articulates with the spinal column by a single process. (2) The mandibles are made up of several bones, joined with the skull by the quadrate bone. (3) The skin is covered with scales. (4) The heart is 4-chambered but the separation of the ventricles is incomplete. (5) The members are poikilothermal. (6) The members have extraembryonic membranes during development, a fundamental requirement of terrestrial life in the vertebrates; hence, the reptiles are grouped with the birds and mammals as *Amniota*.

Although the group is the lowest class of vertebrates to attain the capacity for entirely terrestrial life, many reptiles are now amphibious or aquatic. Even the aquatic species, however, come to the land to deposit their eggs.

Reptiles are economically important to a rather limited extent. The flesh of some turtles, lizards, and even snakes is used as food, and the skin of the alligator makes an excellent, if conspicuous, leather. In some regions, crocodiles have been known to kill human beings. Usually, it seems that the danger from them is very limited. Poisonous snakes also may destroy human life, but here again the danger is usually encountered only under special conditions and snake bites may be regarded as accidental.

There are a number of extinct groups, but the classification of the living groups is briefly as follows:

Order *Prosauria*. A single living species, the tuatara of New Zealand, makes up this order. It is a lizardlike animal with a few primitive structural characteristics, including a well-developed pineal eye. The order also bears the name *Rhynchocephalia*.

Order *Chelonia (Testudinata)*. The turtles, tortoises, and related species. Characterized by the shell, consisting of an upper carapace and a lower plastron, formed of bony plates with a horny sheath.

Order *Crocodilia*. Large reptiles resembling lizards in form. The jaws are elongated. The thick skin is provided with bony plates. The crocodiles, alligators, garial, and related species.

Order *Sauria*. The lizards and snakes. In some classifications these forms are included in separate orders, and in some the lizards constitute the suborder *Sauria* and the snakes the suborder *Serpentes* of the order *Squamata*. The order including the lizards is also named *Lacertilia*. All of these animals have elongate bodies. The skin bears horny scales and in some cases bony plates.

Numerous species of reptilia are described throughout this encyclopedia.

REPULSIVE FORCES. Forces between bodies which tend to move them apart. The existence of such forces between molecules is shown by their collision diameters and similar properties; while in the case of crystals these forces, in equilibrium with forces of attraction, result in the formation of stable ionic systems.

REQUIEM SHARKS. See **Sharks**.

RESIDUE. If $f(z)$, a function of the complex variable, has a pole at $z = z_0$ so that it may be expanded in a Laurent series $\Sigma a_n(z - z_0)n$, then the coefficient a_{-1} is the *residue* of the function at the point z_0. Determination of the residues of a function makes it possible to evaluate an integral in the complex plane by the Cauchy theorem (see **Calculus**). However, expansion in a Laurent series is not always easy so the following procedures are often used.

1. Let the function be given in the form $w = f(z)/g(z)$ with a simple pole at $z = z_0$. If the denominator can be factored so that $g(z) = (z - z_0)F(z)$, its residue $R = f(z_0)/F(z_0)$.

2. If the denominator is not easily factored and there are n simple poles at $z_1, z_2, z_3, \ldots$ the sum of the residues is

$$S = \sum_{i=1}^{n} f(z_i)/g'(z_i)$$

where the prime means differentiation.

3. There are simple poles at $z = 0, z_1, z_2, \ldots$ and the function has the form $w = f(z)/zg(z)$. The sum of the residues is

$$S = f(0)/g(0) + \sum_{i=1}^{n} f(z_i)/z_i g'(z_i)$$

4. The function w has a pole of order k at $z = z_0$, then its residue is

$$R = \frac{1}{(k-1)!}\left[\frac{(z - z_0)^k f(z)}{g(z)}\right]_{z=z_0}^{(k-1)}$$

the $(k - 1)$th derivative to be evaluated at $z = z_0$.

Modifications of these methods can be made to care for other cases.

RESILIENCE. The resilience of a body measures the extent to which energy may be stored in it by elastic deformation. The implication of the word "stored" in the above definition is that this energy may be released in the form of mechanical work when the force causing the elastic deformation is removed, and that resilience is a property of a material within its elastic limit. The "modulus of resilience" is the maximum energy storage in a unit volume of the material. In practical units, it is the inch-pounds of energy stored in a cubic inch of the material stressed to the elastic limit. The modulus of resilience is directly proportional to the square of the stress, and inversely proportional to the modulus of elasticity. It is equal to the area under the stress-strain diagram up to the elastic limit, or

$$\frac{1}{2}\frac{\sigma^2}{E}$$

in which E is the modulus of elasticity and σ is the elastic limit.

RESINS (Acetal). These are thermoplastic resins, obtainable both as homopolymers and copolymers, and produced principally from formaldehyde [CAS: 50-00-0] or methanal [CAS: 50-00-00] either directly or through its cyclic trimer, trioxane [CAS: 110-88-3] or 1,3,5-trioxacyclohexane [CAS: 110-88-3].

Formaldehyde polymers have been known for some time and early investigations of formaldehyde polymerization contributed significantly to the development of several basic concepts of polymer science. Polymers of higher aliphatic homologues of formaldehyde are also well known and frequently referred to as aldehyde polymers. Some have curious properties, but none are commercially important.

Formaldehyde homopolymer is composed exclusively of repeating oxymethylene units and is described by the term polyoxymethylene (POM) [CAS: 9002-81-7]. Commercially significant copolymers, for example [CAS: 95327-43-8], have a minor fraction (typically less than 5 mol %) of alkylidene or other units, derived from cyclic ethers or cyclic formals, distributed along the polymer chain. The occasional break in the oxymethylene sequences has significant ramifications for polymer stabilization.

Acetal resins were first commercialized by Du Pont in 1960 under the tradename Delrin (registered trademark of E. I. du Pont de Nemours and Co., Inc.) Introduction of the then new engineering plastics followed development of suitable processes for the preparation of high molecular weight formaldehyde homopolymer and for the requisite conversion of the homopolymer's unstable end groups by a procedure known as end-capping. Development and commercialization of copolymers of trioxane with cyclic ethers (eg, ethylene oxide) by Celanese quickly followed in 1962. The copolymers did not require end-capping. Rather, good polymer stability could be achieved by ablation of unstable polymer fractions by a suitable process. Today there are ten producers of acetal resins, mostly copolymers.

Acetal resins have the highest fatigue endurance of commercial thermoplastics. A variety of ionic initiators, such as tertiary amines and quaternary ammonium salts, are used to effect polymerization of formaldehyde. Chain transfer, shown by the following reactions, controls the molecular weight of resulting resins:

Step 1, initiation of new chain:

$$-CH_2OCH_2O^- + H_2O \rightarrow -CH_2OCH_2OH + OH^-$$

Step 2, reaction of growing chain with H_2O, releasing hydroxyl ion:

$$OH^- + CH_2O \rightarrow HOCH_2O^-$$

Step 3, end-capping of high-molecular-weight polyoxymethylene glycol to provide stable commercial resin:

$$HOCH_2O^- + nCH_2O \rightarrow HOCH_2O(CH_2O)_{n-1}CH_2O^-$$

Starting ingredients may be formaldehyde or the cyclic trimer trioxane, $CH_2OCH_2OCH_2O$. Both form polymers of similar properties. Boron trifluoride of other Lewis acids are used to promote polymerization where trioxane is the raw material.

Acetals provide excellent resistance to most organic compounds except when exposed for long periods at elevated temperatures. The resins have limited resistance to strong acids and oxidizing agents. The copolymers and some of the homopolymers are resistant to the action of weak bases. Normally, where resistance to burning, weathering, and radiation are required, acetals are not specified.

The mechanical strength, friction and wear characteristics, predictable long and short term properties, and generally excellent solvent resistance of acetal resins make them ideal candidates for industrial applications. Conveying devices and gears are excellent examples of this type of application. Information on the design of such devices is available from suppliers. Optimization of design and molding of gears from acetal resins has been discussed in the technical literature. Acetal resins compete effectively with nylons and thermoplastic polyester among other resins in many industrial applications.

Molding of parts for a wide variety of plumbing and irrigation applications consumes as much acetal resin as the industrial applications. Rod and slab stock can be machined into components for precision flow control devices.

Acetal resins are also used extensively in transportation, especially automotive. Handles and internal components (gears, gear racks, cables) for window lifts and other similar devices are examples. Most of the applications which do not involve painting or plating are below the window line. Many common consumer items are manufactured essentially entirely from acetal resin (eg, disposable lighters) or have critical components molded from acetal resin (eg, hubs and platforms for videocassettes). The properties that make acetal resins useful in industrial applications make them useful for internal components, especially mechanical drive systems, of many household appliances.

RESINS (Acrylonitrile-butadiene-styrene) (ABS). [CAS: 9003-56-9]. acrylonitrile-butadiene-styrene resins are commonly referred to as ABS resins. These materials are thermoplastic resins that are produced by grafting styrene and acrylonitrile onto a diene-rubber backbone. The usually preferred substrate is polybutadiene because of its low glass-transition temperature (just above $-80\,^{\circ}C$). Where ABS resin is prepared by suspension or mass polymerization methods, stereospecific diene rubber made by solution polymerization is the preferred diene. Otherwise the diene used normally is a high-gel or cross-linked latex made by a "hot-emulsion" process.

Manufacture

In most ABS polymerization approaches, a rubber substrate is manufactured in an initial stage, with the styrene/acrylonitrile copolymer matrix being generated in one or more subsequent stages. An example of one approach is shown in block diagram format in Fig. 1.

Step 1. Polybutadiene rubber is formulated by feeding butadiene, water, an emulsifier, and catalyst into a glass-lined reactor. This is an exothermic reaction. About 80% conversion is achieved in a period of about 50 hours. The residual butadiene monomer is recovered by steamstripping and recycled.

Step 2. Polybutadiene rubber is further polymerized, but in the presence of styrene and acrylonitrile monomers. This is done in low-pressure reactors under a nitrogen atmosphere. In this operation, the monomers are grafted onto the rubber backbone through the residual desaturation remaining from the first step.

Step 3. In a separate step, styrene-acrylonitrile (SAN) resin [CAS: 9003-54-7] is prepared by emulsion, suspension, or mass polymerization by free-radical techniques. The operation is carried out in stainless-steel reactors operated at about $75\,^{\circ}C$ ($167,\,^{\circ}F$) and 5 psig for about 7 hours. The final chemical operation is the blending of the ABS graft phase with the SAN resin, plus adding various antioxidants, lubricants, stabilizers, and pigments. Final operations involve preparation of a slurry of fine resin particles (via chemical flocculation), filtering, and drying in a standard fluid-bed dryer at $121–132,\,^{\circ}C$ ($250–270,\,^{\circ}F$) inlet air temperature.

It should be noted that many different polymerization techniques are used commercially to generate substrate, graft, and rigid backbone during the manufacture of ABS. These include emulsion, suspension, solution, and bulk polymerization. Also, twin-screw extruders, continuous mixers, and intensive internal fluxing mixers are used in addition to single-screw extruders as compounding devices.

Properties

These resins incorporate a desirable balance of impact resistance, hardness, chemical resistance, a range of surface gloss levels, and non-staining properties. The dimensional stability of ABS is good; creep resistance is excellent. The resins have relatively low water absorption or change in volume over a range of humidity. Commercial forms of ABS include custom color-matched compounded pellets, natural pellets (non-pigmented), and granular resins for use in compounding or alloying with other plastics.

Conversion

A wide range of standard converting processes is applicable to ABS resins, including injection molding; compression molding; sheet extrusion

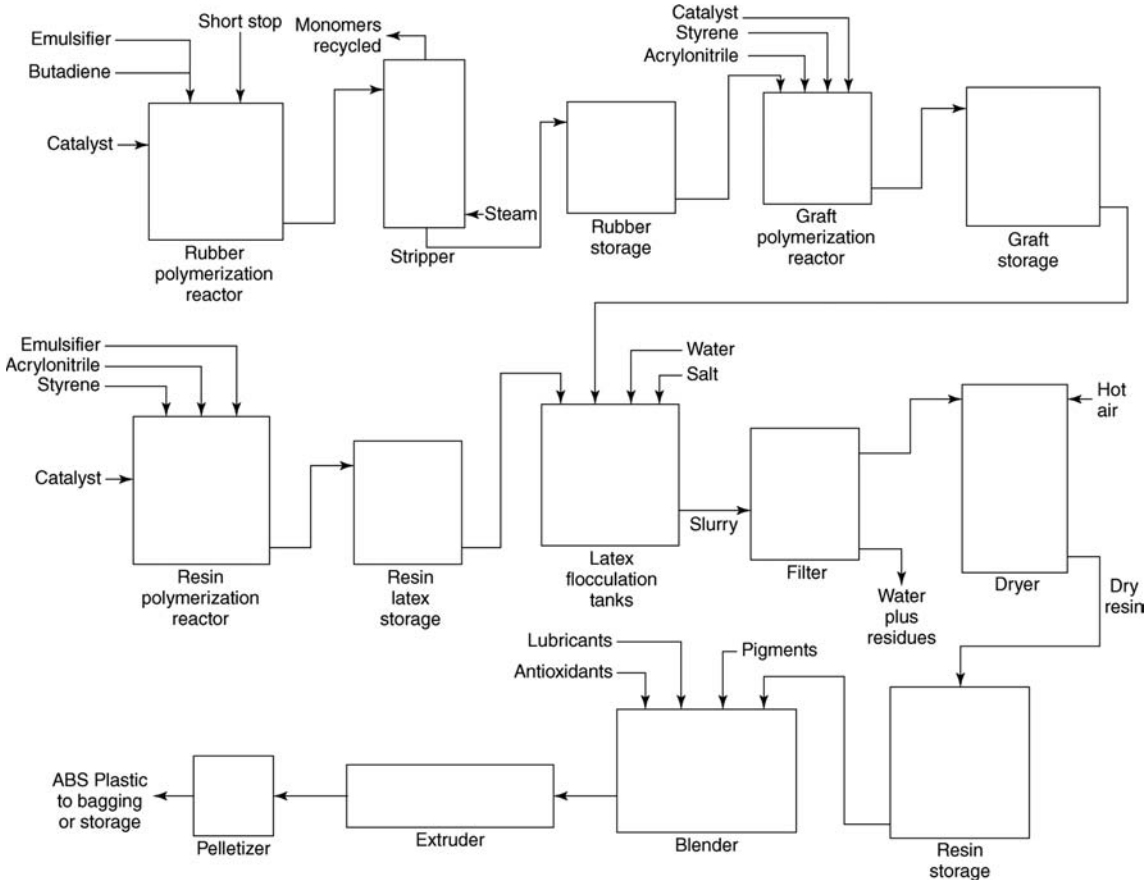

Fig. 1. Acrylonitrile-butadiene-styrene (ABS) resin manufacturing process. (*BorgWarner Chemicals*.)

followed by either pressure forming or vacuum forming; pipe extrusion; profile extrusion; and blow molding. ABS is slightly hygroscopic and should be dried prior to processing. Common fabricating techniques, such as drilling, sawing, riveting, solvent or ultrasonic welding, and insertion of metal fasteners can be used with ABS. Also, ABS can be hot stamped, painted, laminated, embossed, and, depending upon the grade of resin, electroplated or vacuum metalized.

Typical ABS Products

Injected molded parts can be found in telephone sets, refrigerator parts, plumbing fixtures and fittings, radios, televisions, small household appliances, business machines and personal computers, and numerous products for the automotive industry, including interior/exterior trim and bumpers. Examples of ABS extrusion grade product uses include refrigerator door and tank liners, bathtub surrounds, and boat hulls. These parts are made by extruding ABS into sheets and subsequently vacuum forming or pressure forming the sheet into the desired shape. ABS can also be directly extruded into the desired part, as with the extrusion of drain waste and vent (DWV) piping and profile extrusion of refrigerator breaker strips. Blow molding is an extrusion grade processing approach that is gaining in popularity and involves applications such as water tanks, interior and exterior doors, and some automotive parts. For these various applications, either general-purpose or specialty grades of ABS may be used. Some of the special properties that can be imparted to ABS follow.

Flame retardation (FR) is a characteristic frequently needed in the manufacture of business machine and personal computer housings, some small appliances, and telecommunications equipment, among others. Flame retardation can be imparted to ABS either by alloying with an inherently flame-retardant polymer, such as PVC (polyvinyl chloride), or by the use of a halogenated (predominantly bromine-related compounds) additive system. These FR grades of ABS can be designed to meet various flammability standards, such as those of Underwriters Laboratories, depending upon the needs of the application. In addition to flame retardation, some business machine applications require RFI/EMI (radio frequency/electromagnetic interference) shielding. This is accomplished with ABS by giving the surface of the material a conductive coating via processes such as painting, electroplating, or vacuum metalizing.

High temperature resistance is a property of particular importance in the automotive interior trim area. Elevated temperature resistance is accomplished by either incorporating alpha methyl styrene or maleic anhydride in the basic formula, or by alloying ABS with polycarbonate. Heat deflection temperatures of 240 °F (116 °C) are possible by using these approaches.

Transparency can be imparted to ABS by using methyl methacrylate as the fourth monomer. The major use of transparent ABS is in the manufacture of refrigerator crisper trays.

Foamed ABS. The resin can be foamed either through the use of a chemical blowing agent, or by direct injection of nitrogen into the melt during processing. Structural foam grades of ABS are available in either general-purpose or flame-retardant formulas. Foam core pipe is manufactured by co-extruding solid inner and outer skins around a structural foam wall interior. This is a widely practiced technique used by pipe extruders to reduce DWV pipe specific gravity, while not compromising pipe performance characteristics.

Other special characteristics can be imparted to ABS by various formula modifications. Some grades with specific thermal elongation characteristics can be electroplated or sputter coated. These materials find wide application in the automotive trim market. Gloss variations from matte-finish to high gloss are available to meet specific requirements. ABS can be reinforced with materials such as glass fibers, aluminum flake, mica, or barium ferrite. Although the ultraviolet (UV) stability of ABS has been historically poor, significant progress has recently been made by using special pigments, UV stabilizers, and paint systems. The use of polyelectrolytes in the formula has made it possible to offer grades of ABS with some antistatic qualities.

Engineering Staff, BorgWarner Chemicals, Washington, WV

RESINS (Natural). Complex compounds composed of carbon, hydrogen, and relatively small amounts of oxygen, which are secreted in various tissues of many plants. In the pine family, where resins are very common, they are secreted as oleoresins in resin canal cells, which break down finally, producing resin canals. These canals appear as longitudinal ducts in the sapwood and inner bark, connected laterally by resin canals in the compound wood rays, thus forming an extensive network. A common name given to the oleoresin in this group is pitch, the sticky juice that exudes from the plant wherever it is wounded. On exposure to the air the volatile oil in this pitch (oil of turpentine) gradually evaporates, leaving a clear hard glassy substance, the resin, which forms a protective coating over the wound.

Most resins have the same physical properties, being clear, translucent, and of a yellow or brownish color. Amber, a fossil resin, is a more or less familiar example. Resins are insoluble in water, but soluble in common organic solvents such as ether and alcohol. All resins burn with a sooty flame. Resins seem to be mainly of value to the plan in that they form protective coverings against the entrance of disease-producing organisms and also prevent excessive loss of water from the thin-walled tissues exposed in the wound.

Resins are separated into several classes. Many of the resins contain almost no volatile oil and are hard, without taste or odor. These are the varnish or hard resins. Other resins, when removed from the plant in which they are formed, and dissolved in volatile oils, form a thick semi-solid mass: these are the oleoresins. In still other cases the resin occurs in combination with a gum, forming a gum resin.

Hard Resins. Several of the hard resins, used mainly for making varnishes, are called copals. Most of them come from Africa and are either found in fossil form or obtained from living plants. Other copals come from Australia, New Zealand and East Indian Islands. The plants that form them are members of the legume and pine families. The African copals are products of several species of *Trachylobium*, fairly large trees growing in east Africa and Madagascar. The best resin from these trees occurs in a fossil form, often deeply buried in the ground — sometimes in regions where the trees no longer grow. These resins dissolve slowly and are used in making varnishes, which are very durable. A South American tree of large size, *Hymenaea courbaril*, also of the Leguminoseae, yields a very similar resin, which is also found in lumps in the ground around the trees, and used in varnishes.

Another copal is obtained from *Agathis australis*, a very large coniferous tree native in Australia and New Zealand, where it is known as the Kauri pine. Like the other copals, that from the Kauri pine is found in lumps buried in the ground. Most of these lumps are 1 or 2 inches in diameter, but some are much larger, weighing up to 100 pounds. Nearly all of this resin comes from the northern part of North Island of New Zealand. It is frequently called Kauri gum, though it is not a gum, but a true copal resin. Another group of hard resins, known as dammar resins, is obtained from many different trees growing in southern Asia and the East Indian Islands. These resins dissolve readily in alcohol, forming spirit-varnishes.

One of the commonest and most important of the hard resins is rosin, obtained by distilling the pitch, or turpentine, which is a product of several of the native pines of the southeastern United States. This rosin, also known as colophony, is a very important product of that region. Originally the turpentine was obtained by chopping a deep hollow in the base of the trunk of the tree and allowing it to fill up with the turpentine, which was then scooped out. This method was very destructive and wasteful, since much of the oleoresin, turpentine, was lost during the process. The weakened trees were easily blown down.

Now turpentine is obtained by cutting V-shaped gouges in the bark and inserting metal gutters beneath the gouges. These gutters carry the turpentine to a cup placed underneath. As soon as the cut is made, turpentine begins to flow and continues to do so for two or three days, gradually slowing as the drying turpentine allows resin to accumulate and plug the wounds. A new flow is obtained by cutting off a narrow strip of bark from the upper edge of the cut. The process is continued as long as the pitch will flow, which is usually all summer and well along into the late fall. Each tree may be turpentined for 6 to 7 successive years or even longer before it ceases to be profitable.

The crude turpentine collected in the cups and the product that has dried on the wound of the tree are removed and carried to the still. Here the turpentine, to which a little water is added, is carefully heated to drive off the oil of turpentine present, together with the water added. The distillate is condensed by passing it through a coil around which cold water is flowing. It is collected in a barrel or any suitable container. The two substances, water and oil of turpentine, which make up the distillate, are immiscible and soon separate, the lighter oil of turpentine rising to the top and floating on the water, which is drawn off from the bottom. Oil of turpentine is often called spirits of turpentine, or, in the paint trade, turpentine. In medicine the word turpentine is reserved for the oleoresin which upon distillation yields oil of turpentine and rosin.

The residue remaining in the tank at the end of the distillation is skimmed to remove any impurities such as twigs, bits of bark and dirt, and run into vats to cool. Then it is put into barrels and allowed to harden, forming rosin.

Oil of turpentine is used principally as a solvent for paints and varnishes, because it mixes readily with the various substances used and also because it evaporates quickly, causing the paint or varnish to dry. It is also used in making such things as sealing wax and shoe polish. Very pure grades of turpentine (the oleoresin) are used medicinally.

Large quantities of rosin are used in sizing paper, which makes it take ink without spreading or blotting, gives it a smoother surface and makes it heavier. Rosin is also used in cheaper varnishes, in paints, and in soap making. It is furthermore used as an adulterant of the more expensive resins. Linoleum manufacturers use large amounts of rosin.

In early times, large quantities of crude turpentine were used to waterproof the rigging of the sailing vessels and to calk the seams of the hull.

Mastic is a hard resin exuding from the branches of one of the Pistachio trees, *Pistacia lentiscus*, native of Mediterranean Europe and southern Asia. Formerly, it was extensively used medicinally, for stomach troubles and dysentery, as well as other ailments. Now it is used in making varnishes and in lithographic work. Natives of the region in which it is found chew mastic, which has a pleasant taste.

Since turpentine is a mixture of a volatile substance, spirits of turpentine and a hard resin, it is one of the oleoresins.

Oleoresins. Canada balsam is one of the oleoresins. It is obtained from the bark of *Abies balsamea*, the common balsam fir of northern North America. Canada balsam, because its refractive index is so near that of glass, is much used in optical work and in preparing materials for examination with a microscope.

Little used today is Dragon's blood, an oleoresin obtained from the fruits of *Daemonorops draco*, a native palm of southeastern Asia and the Molucca Islands. The resins exudes from the surface of the ripening fruits. It is removed from them by boiling in water. The resin is then moulded into balls or long sticks. It is sometimes used in making varnishes and lacquers.

True lacquer, obtained from the juice of *Rhus verniciflua*, a sumac tree of southeastern Asia, is another oleoresin. To obtain the juice lateral cuts are made in the bark. The exuded sap is collected not only from these cuts but from small branches which are cut off and soaked in water. The juice is cleaned of any foreign substances by straining it through hemp cloth. By slow heating, either artificial or by the sun, the juice is evaporated and stored until used. Lacquer is a poisonous substance, causing intense irritation of the skin in many people. Others seem to be immune. Lacquer is usually applied over some soft wood, commonly soft pine, the pores of which have first been filled by rubbing in a paste of rice and resin, followed by a paste of soft clay and resin. The surface is then covered with cloth and layer after layer of lacquer put over that. Each layer is allowed to dry and rubbed down very smooth before the next layer is added. Any color to be added is mixed with the lacquer, with each colored layer covered by a clear layer before another is put on. The final product is a thick covering composed of many thin layers of lacquers. If this is carved the edges of the carving, on careful examination, will show the fine lines separating the different layers. Lacquering is a very old industry, having been carried on in China since the sixth century.

Certain resins occur in combination with fragrant volatile oils. One of these is benzoin, obtained from *Styrax benzoin* by cutting notches in

the bark and allowing the resin to collect in them. It is used in making perfumes, in incense, and as a source of benzoic acid, used medicinally.

Another fragrant oleoresin is storax, obtained from *Liquidambar orientalis*, a medium-sized tree growing in southwestern Asia. The resin is obtained by boiling the bark and wood of young branches. It is used medicinally and also in incense.

Gum Resins. Gum resins include myrrh, which exudes from the trunk and branches of *Commiphora myrrha*, a tree growing in the region around the Red Sea. The lumps of resin are used medicinally, and also in making incense. Another gum resin is frankincense, obtained by cutting notches in the stem of *Boswellia carterii*, which grows in northeastern Africa and in Arabia. This resin is used in incense. *Asafoetida* is also a gum resin. See also **Gums and Mucilages**.

RESINS (Synthetic). A manufactured high polymer resulting from a chemical reaction between two (or more) substances, usually with heat or a catalyst. This definition includes synthetic rubbers and silicones (elastomers), but excludes modified, water soluble polymers (often called resins). Distinction should be made between a synthetic resin and a plastic; the former is the polymer itself, whereas the latter is the polymer plus such additives as filters, colorant, plasticizers etc. See also **Elastomers**; and **Plasticizers**.

The first truly synthetic resin was developed by Baikeland in 1911 (phenol–formaldehyde). This was soon followed by a petroleum-derived product called *coumarone-indene*, which did indeed have the properties of a resin. The first synthetic elastomer was polychloroprene (1931) originated by Nieuwland and later called neoprene. Since then many new types of synthetic polymers have been synthesized perhaps the most sophisticated of which, are nylon and its congeners (polyamides, by Carothers), and the inorganic silicone group (Kipping). Other important types are alkyds, acrylics, aminoplasts, polyvinyl halides, polyester, epoxies, and polyolefins. In addition to their many applications in plastics, textiles, and paints, special types of synthetic resins are useful as ion-exchange media. See also **Paints and Coatings**.

Note: Because the term *resin* is so broadly used as to be almost meaningless, it would be desirable to restrict its application to natural, organ-soluble, hydrocarbon-based products derived from trees and shrubs. But in view of the tendency of inappropriate terminology to "gel" irreversibly, it is a losing battle to attempt to replace "synthetic resin" with the more precise "synthetic polymer." See also **Gums and Mucilages**; and **Resins (Natural)**.

RESISTANCE. The uses of this term in physics are in accordance with its general meaning of "that which tends to oppose motion."

1. Mechanical resistance is the opposition offered by a material body to forces that tend to produce motion. This mechanical resistance may arise from friction, from stresses set up in rigid anchors, or from inertia. Whenever the power dissipated in friction is proportional to the square of the velocity, mechanical resistance may be defined as the real part of mechanical impedance, the unit of which is the mechanical ohm.

2. Acoustic resistance is defined as the real component of acoustic impedance, the commonly used unit being the acoustic ohm. Acoustic flow resistance (D.C. acoustic resistance) is defined as the quotient of the pressure difference between the two surfaces of a sound-absorbing material by the volume current through the material.

3. Fluid resistance is the opposition offered by gases or liquids to the passage of bodies through them.

4. Electric conductors are believed to contain free electrons, the movement of which through the substance constitutes electric conduction. In this migration the moving particles evidently meet with some restraint, since heat is generated. Electrical resistance is the factor by which the square of the instantaneous conduction current must be multiplied to give the power lost by dissipation as heat or other permanent radiation of energy away from the electric circuit. (Consider the "radiation resistance" of an antenna.) The unit of electrical resistance is the ohm. The measure of the resistance of a given conductor is the electromotive force required per unit current, and is usually expressed in ohms. The resistance of a wire or other linear conductor of uniform cross section is proportional to the length l and inversely proportional to the cross section a: $R = \mathbf{r}/a$. The constant $\mathbf{r}$ is the "resistivity" of the substance, usually expressed in ohm-centimeters; and its reciprocal is the "electric conductivity." The dependence of resistivity of metals upon temperature is one of the major problems of electron physics.

Pieces of wire may be cut off at such lengths as to have definite resistances, and mounted with convenient connections to form a "resistance box," used in many electrical measurements. A "rheostat" is usually a rugged conductor, often with adjustable resistance, used to introduce a resistance load into a circuit. Resistances are commonly measured by means of some form of bridge, of which the Wheatstone bridge is most familiar.

Some typical resistivities are given in Table 1:

TABLE 1. RESISTIVITIES OF SOME COMMON MATERIALS
(In ohm-centimeters at 20 °C)

Aluminum	2.83×10^{-6}	Mercury	95.78×10^{-6}
Brass	7.0	Nickel	7.8
Copper	1.72	Platinum	10.0
German silver	33.0	Silver	1.63
Iron (pure)	10.0	Tin	11.5
Lead	22.0	Tungsten	5.51

For some purposes, it is convenient to express the resistivity as the resistance of one foot of wire of the given metal having a cross-section of one circular mil [a circular mil is the area of a circle 0.001 foot (0.0003 meter) in diameter]. This value may be obtained by multiplying the resistivity in ohm-centimeters by the factors 6.015×10^6.

The dependence of resistance of many metallic conductors upon temperature is expressed with fair approximation by the linear equation

$$R = R_0(1 + At)$$

in which R_0 is the resistance at 0 °C and t is the centigrade temperature. The temperature coefficient A is a constant characteristic of the metal.

5. There remains yet another type of resistance for consideration — heat resistance. This might be said to be the property of offering opposition to the flow of heat. This property is desirable in a heat insulator such as pipe covering, but undesirable in heat transfer equipment. The term resistivity is rarely used in connection with heat flow, as its reciprocal, thermal conductivity, is quite satisfactory, and enjoys the advantage of common usage.

RESISTANCE THERMOMETER. The fact that the electrical resistance of a metal wire increases with rising temperature is the basis of a very useful class of thermometers. One has only to calibrate a given length of wire, as to its resistance in relation to its temperature, enclose it in a suitable protecting tube, and keep it connected with the resistance-measuring bridge, to have a resistance thermometer adapted to a variety of uses over a very wide temperature range. The metal nearly always employed is platinum. The variation of resistivity with temperature of platinum is very nearly linear, being closely approximated by the formula $\mathbf{r} = 0.000000037t + 0.000011$, in ohm-centimeters and centigrade degrees. Callendar found that for any given platinum resistance thermometer there is a slight systematic departure from this formula, characteristic of the particular sample of wire. It is best, therefore, to calibrate each instrument throughout the range for which it is intended.

Care must be taken, in mounting the platinum wire, that it does not come in contact with materials that will contaminate it at high temperatures. Compensation is also necessary for the change of resistance in the wires leading to the platinum spiral. This is commonly effected by balancing against these wires a pair of "dummy" wires similar to and laid alongside them. The instrument is usually provided with a suitably designed resistance bridge, such as the Callendar and Griffiths or the Mueller bridge; which for practical purposes should be portable and self-contained, with battery, galvanometer, balancing rheostat, etc., all in one case, and with a cable leading to the thermometer proper. The resistance thermometer is also called a resistance pyrometer.

Only a few of the pure metals have a characteristic relationship suitable for the fabrication of sensing elements used in resistance thermometers. The metal must have an extremely stable resistance-temperature relationship so that neither the absolute value of the resistance R_0 nor the coefficients a and b drift with repeated heating and cooling within the thermometer's specified temperature range of operation. The relationship may be expressed by:

$$R_t = R_0(1 + at + bt^2 + ct^3 + \cdots)$$

where R_0 = resistance at reference temperature (usually at ice pint, 0 °C), ohms
R_t = resistance at temperature t, ohms
a = temperature coefficient of resistance, ohm/ohm-degree C
b and c = coefficients calculated on the basis of two or more known resistance-temperature (calibration) points.

The material's specific resistance in ohms per cubic centimeter must be within limits that will permit fabrication of practical-size elements. The material must exhibit relatively small resistance changes for nontemperature effects, such as strain and possible contamination which may not be totally eliminated from a controlled manufacturing environment. The material's change in resistance with temperature must be relatively large in order to produce a resultant thermometer with inherent sensitivity. The metal must not undergo any change of phase or state within a reasonable temperature range. Finally, the metal must be commercially available with essentially a consistent resistance-temperature relationship to provide reliable uniformity.

Industrial resistance thermometers, often referred to as resistance temperature detectors (RTD), usually are made with elements of platinum, nickel, or copper. The entire resistance thermometer is an assembly of parts which include the sensing element, internal leadwires, internal supporting and insulating materials, and protection tube or case. A platinum industrial resistance thermometer assembly is shown in Fig. 1.

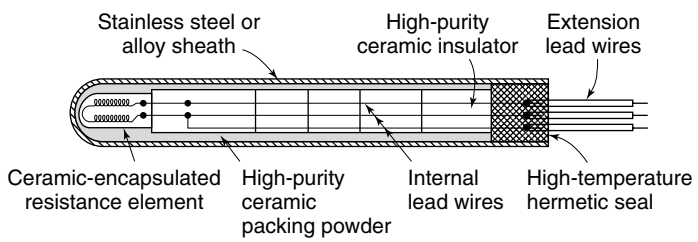

Fig. 1. Platinum industrial resistance thermometer assembly.

RESISTANCE TRANSDUCER. A large number of transducers for the measurement of several variables (temperature, pressure, flow, and so on) are designed around some aspect of Ohm's law, wherein the electrical resistance of a material or device can be caused to change when the material is subjected to some condition or situation that is the object of measurement.

As in the case of a potentiometer, the resistance of the device can be altered in accordance with the input from some external force to be measured by moving a contact and thus change the resistance value between two points. Inasmuch as resistance changes with the cross section of a conductor, that cross section can be altered as in the case of a strain gage. Resistance also is a function of temperature. Hence, resistance transducers can be used as temperature sensors. Similarly, resistance often is affected by humidity changes and by chemical composition changes.

Numerous transducers of the resistance type are described throughout this volume.

RESISTIVE-WALL AMPLIFIER. An electron-beam amplifier in which the beam flows near a resistive wall. Gain is obtained through interaction between the stream-charge and the wall-charge, which is induced by the stream. The wall-charges act on the stream so as to cause larger and larger bunches to be formed, which result in exponential growth of the original signal with distance. Gain and gain-bandwidth are comparable to other forms of traveling wave tubes, and the stability is inherently greater.

RESISTIVITY (Specific Resistance). A proportionality factor characteristic of different substances equal to the resistance that a centimeter cube of the substance offers to the passage of electricity, the current being perpendicular to two parallel faces. It is defined by the expression:

$$R = \rho \frac{l}{A}$$

where R is the resistance of a uniform conductor, l is its length, A is its cross-sectional area, and ρ is its resistivity. Resistivity is usually expressed in ohm-centimeters.

RESISTOR TRANSISTOR LOGIC. A form of logic circuit using transistors and resistors. The abbreviation RTL is sometimes used to refer to this class of circuits. A circuit for performing the logical operation NOT OR (NOR) is shown in Fig. 1. Although the circuit values are chosen to bias the transistor beyond cutoff when A, B, and C are all at ground potential (0 logic state), change to the positive voltage associated with 1 operation of either of the three inputs will result in the transistor being brought into full conduction. Its collector will then be close to ground potential corresponding to a 0 (NOT 1) output. Thus, the circuit effects the operation NOT (A OR B OR C).

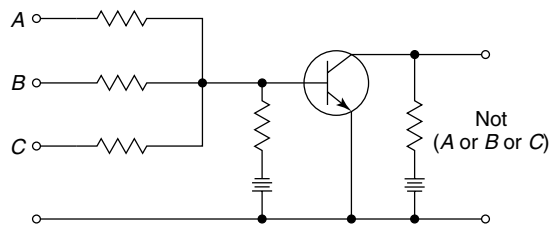

Fig. 1. Resistor transistor logic (RTL) circuit effecting NOT-OR (NOR) function.

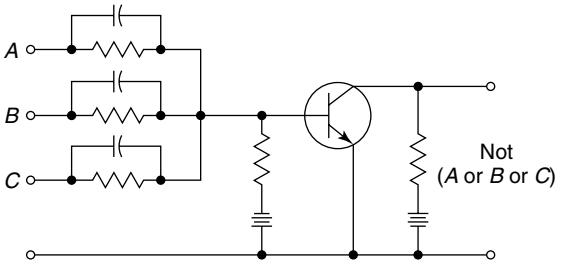

Fig. 2. Resistor capacitor transistor logic (RCTL) circuit effecting NOT-OR (NOR) function.

A variation of this arrangement, known as *Resistor Capacitor Transistor Logic* (RCTL), is shown in Fig. 2. Operation is the same as RTL except that higher speeds of operation are possible because the switching time of the transistor from one state to the other is reduced markedly by the use of the capacitors.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

RESOLUTION. A term used in a number of specific cases in science to denote the process of separating closely related forms or entities or the degree to which they can be discriminated. The term is most frequently used in optics to denote the smallest extension which a magnifying instrument is able to separate or the smallest change in wavelength which a spectrometer can differentiate. In this last sense, it is defined as the ratio

of the average wavelength (wave number or frequency) of two spectral lines, which can just be detected as a doublet, to the difference in their wavelengths (or wave numbers or frequencies). The term resolution is also applied to such varied processes as the separation of a racemic mixture into its optically active components or as the breaking up of a vectorial quantity into components.

RESOLUTION (Computer System). In systems where either the input or output of the subsystem is expressed in digital form, the resolution is determined by the number of digits used to express the numerical value. In a digital-to-analog converter, the output analog signal takes on a finite number of discrete values, which correspond to the discrete numerical input. The output of an analog-to-digital converter is discrete although the analog input signal is continuous.

In digital equipment, resolution is typically expressed in terms of number of digits in the input or output digital representation. In the binary system, a typical specification is that "resolution is x bits." As an example, if V_{fs} is the fullscale input- or output-voltage range, this specification states that the resolution is $V_{fs}/2^x$. If $x = 10$ and $V_{fs} = 5V$, the resolution is $5/2^{10}$, or $0.00488V$. It is also common to express resolution in terms of "parts." A 4-digit decimal converter may be said to have a resolution of "1 part in 10,000" and a 10-bit binary converter may be said to have a resolution of "1 part in 1,024." The term *least significant bit* (LSB) also is used. It may be stated, for example that the binary resolution is "$\pm\frac{1}{2}$ LSB." Also used is the term *least significant digit* (LSD). This term is used with relation to decimal or other nonbinary digital equipment.

RESOLVING POWER (Microscope). This is given by the relation $d = 1.22\lambda/2$ N.A., where d is the linear separation of two points, λ is the wavelength used, and N.A. is the numerical aperture of the object lens. Most telescopes have large objective lenses in order to have large light-gathering power, and to have high resolution. This high resolution may produce resolved images too close together to be resolved by the human eye. Hence an eye-lens or ocular is included in the system for the purpose of magnifying the initial image so that the eye can see it as resolved. Note that no amount of magnification of the initial image can increase the resolving power of the telescope over the resolving power of the objective lens.

RESOLVING POWER (Telescope). The ability of a telescope to separate the images of the two stars of a double star, for example. Most studies of resolving power are based on the Rayleigh criterion of resolving power. Most telescopes have large objective lenses in order to have large light-gathering power, and to have high resolution. This high resolution may produce resolved images too close together to be resolved by the human eye. Hence an eye-lens or ocular is included in the system for the purpose of magnifying the initial image so that the eye can see it as resolved. Note that no amount of magnification of the initial image can increase the resolving power of the telescope over the resolving power of the objective lens. See also **Telescope (Astronomical-Optical)**.

RESONANCE. (1) In chemistry, resonance (or mesomerism) is a mathematical concept based on quantum mechanical considerations (i.e., the wave functions of electrons). It is also used to describe or express the true chemical structure of certain compounds that cannot be accurately represented by any one valence-bond structure. It was originally applied to aromatic compounds such as benzene, for which there are many possible approximate structures, none of which is completely satisfactory. See also **Benzene**.

The resonance concept indicates that the actual molecular structure lies somewhere between these various approximations, but is not capable of objective representation. The idea can be applied to any molecule, organic or inorganic in which and electron pair bond is present. The term *resonance hybrid* denotes a molecule that has this property. Such molecules do not vibrate back and forth between two or more structures, nor are they isotopes or mixtures. The resonance phenomenon is rather an idealized expression of an actual molecule that cannot be accurately pictured by any graphic device.

(2) In the terminology of spectroscopy, resonance is the condition in which the energy state of the incident radiation is identical with that of the absorbing atoms, molecules or other chemical entities. Resonance is applied in various types of instrumental analysis such as nuclear resonance absorption and nuclear magnetic resonance. See also **Absorption (Process)**; and **Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)**.

Note: The multiple meanings of *nucleus* and *resonance* can be a source of confusion, especially when these terms are closely associated, as in *nuclear magnetic resonance* and *resonance of molecular nucleus*. In the first of these expressions, *nucleus* is used in sense (1) under "nucleus," and *resonance* in sense (2) under "resonance." In the second expression, *nucleus* is used in sense (3) under "nucleus" and resonance in sense (1) under *resonance*.

RESONANCE RADIATION. A process of reemission of radiation by gases and vapors. The process involves excitation, by incident photons, of atoms to higher energy levels, from which they may return to the ground state, or to other states. Therefore the radiation emitted, while characteristic of the particular atom, is not necessarily of the same frequency as that absorbed. Resonance radiation appears to be a species of fluorescence, except that it may take place with no change in frequency. For example, Wood found that sodium vapor, upon absorption of D-light (16,973 cm^{-1}), re-emitted the same frequency and therefore the name resonance radiation was adopted. But when Strutt excited sodium vapor by light of wave number 30,273 cm^{-1} (second line of the principal sodium series), the emitted radiation was D-light (16,973 cm^{-1}).

RESONATOR. 1. A device used to utilize or exhibit the effects of resonance. 2. A group of electrons which absorbs electromagnetic radiation of certain frequencies.

RESORPTION. The absorption, or less commonly, the adsorption by a body or system of material previously released from absorption or adsorption by that same body or system.

RESPIRATION (Plants). Plant cells, like all living cells, require energy to maintain the organization of materials and activities we associate with life. In plant cells, as in animal cells, this energy is provided by the oxidation of foods, commonly carbohydrates, in the process known as respiration. This oxidation is a sequence of enzyme-controlled reactions, in which the energy of the food is released a little at a time. The net result of the breakdown of a carbohydrate, commonly glucose, is the production of carbon dioxide and water, and the utilization of oxygen. The following equation expresses the overall result:

$$C_6H_{12}O_6 + 6\ O_2 \longrightarrow 6\ CO_2 + 6\ H_2O + \text{useful energy}$$

Thus oxygen is absorbed from the atmosphere and carbon dioxide is released.

The net results of this process are the opposite of those in photosynthesis, in which carbon dioxide is used and oxygen is produced. When green parts of plants are exposed to light, ordinarily photosynthesis proceeds much faster than respiration, so that respiration cannot be detected by the gaseous exchanges. In the dark, however, the green tissues as well as those lacking chlorophyll demonstrate the gas exchange characteristic of respiration.

Sometimes other foods, such as proteins, fats, or organic acids, may be oxidized in plant cells. In such cases the respiratory quotient (R.Q.) or respiratory ratio (ratio of amount of CO_2 released to amount of O_2 used) is not 1, as it is when carbohydrates are oxidized. Proteins and fats contain relatively less oxygen than do the carbohydrates, so more oxygen is required to bring about their complete oxidation, and the R.Q. is less than 1. When certain of the organic acids are respired, the R.Q. is greater than 1.

The sequence of chemical reactions in respiration results in a stepwise breakdown of the carbohydrate molecule. Phosphate groups are incorporated as a part of the sugar molecule, and are exceedingly important in the energy relationships of the cell. In certain types of phosphate-containing

organic compounds, the phosphate is attached through "energy-rich" bonds. When these bonds are broken, the energy thus released may drive a chemical reaction or may perform useful work within the cell. Several of the steps in the respiratory process produce these energy-rich compounds. This represents a means of transferring energy within the cell, from respiration to other chemical processes or to any site where energy is required.

The separate reactions in the sequence of respiration are controlled by enzymes. A large number of enzymes are required for the whole process. A number of these depend for their activity upon coenzymes that are vitamins of the B complex, or derivatives of these compounds. For example, thiamine (vitamin B_1) serves as a coenzyme in the release of carbon dioxide.

The energy released in respiration may be used in a variety of ways. Protoplasm must be made continually, especially where there is rapid growth. The manufacture of protoplasm requires energy. The synthesis of many other compounds within the cell also requires energy. The accumulation of mineral ions by plant cells, the "pumping" of water by root pressure, and the maintenance of the semipermeability of the plasma membrane all require some of the respiratory energy. Unfortunately for the plant, the energy transfers are not completely efficient, and some of the energy is lost as heat. The release of heat is frequently demonstrated by placing germinating seeds in a thermos bottle and noting the increase in temperature of the seeds with a thermometer.

The foregoing discussion refers primarily to aerobic respiration, or respiration at the expense of atmospheric oxygen. *Anaerobic respiration* also may occur in plant cells. A familiar example is the fermentation which occurs when yeast cells act upon a sugar solution:

$$C_6H_{12}O_6 \longrightarrow 2\ CO_2 + 2C_2H_5OH$$

The sugar is partially oxidized, releasing carbon dioxide and alcohol and liberating some of the energy stored in the sugar. The process can occur in the absence of oxygen. Sometimes other products, such as acetic acid or lactic acid, result from similar processes. Some of the initial enzymes and chemical reactions in these processes are the same as those in aerobic respiration. In most plant cells aerobic respiration occurs in preference to anaerobic respiration if oxygen is available. This is advantageous to the plant because the aerobic reaction releases considerably more of the available energy of the food being oxidized.

RESPIRATORY SYSTEM. The assemblage of organs by which air or water is brought into contact with tissues which can absorb part of its contents of oxygen.

Many animals absorb oxygen through the surface of the body. This is particularly true of small and simple forms, but the skin of the earthworms and that of some amphibians absorb all of the oxygen required by the animals, and any moist skin may absorb small quantities. The simplest modification to be introduced as a respiratory system is some extension of the surface to provide for the needs of a more bulky body. Tufted or thin plate-like structures called gills project into the water from the surface of many aquatic animals. Such structures are not adapted for air breathing because their epithelium must be moist for the ready passage of oxygen and their extensive surface favors drying when exposed to air.

In aquatic insects gills contain gas-filled tubes (*tracheae*) and are known as tracheal gills, but in most animals the blood or body fluids circulate through them. Gills of this kind are found in many annelid worms and in the crustaceans. In the latter group they are sometimes protected by a fold of the body wall. This fold encloses them in a chamber through which water is propelled by special appendages.

In many terrestrial arthropods, the respiratory system consists of air tubes or tracheae, metamerically arranged. In the primitive state each segment contains a pair of tracheae opening to the surface of the body separately through small pores called spiracles or stigmata. The openings are usually guarded by some closing device or by a grating formed from the cuticula. The tracheae have coiled chitinous filaments (*taenidia*) in their walls which keep them distended, and at their inner ends they communicate with finer tracheoles which lack these filaments. These fine tubules lead to the various tissues of the body, although oxygen probably passes from them into the body fluids, rather than directly to the cells. The gas-filled tubes form a closed system in aquatic insects. In these forms the oxygen content is renewed by diffusion from the surrounding water in tracheal gills, as mentioned above.

Spiders have a pair of lung books formed of many thin leaves in depressions in the abdomen. Blood circulates in these leaves and air between them.

The respiratory system of vertebrates is associated with the pharynx. In primitive chordates, cyclostomes, fishes, and larval amphibians the gill slits persist along this passage, so that water taken into the mouth may be expelled from the pharynx without being swallowed. Finely divided blood vessels in the walls of the pharynx or in special outgrowths known as gills along the walls of the pharyngeal clefts receive oxygen from the water as it flows over the surfaces. The gill surface is elaborately folded into numerous gill lamellae.

In some fishes and in terrestrial vertebrates generally, a saccular outgrowth of the ventral wall of the pharynx forms lungs for the reception of air. In the simplest forms the outgrowth branches to form two saclike lungs. In more complex lungs the surface is increased by ridges projecting into the cavities from their walls, and in the most highly developed organs of this type there are many minute chambers (alveoli) in a spongy mass of tissue containing muscle and elastic fibers. The original connection with the pharynx persists, leading into a single tube, the trachea, supported by cartilage rings. The principal branches of the trachea are the bronchi or bronchial tubes. They lead into finer bronchioles whose branches communicate with the alveoli.

Lungs in Humans. The lungs are the most important organs of respiration. They are paired structures, containing thousands of small sacs, the *alveoli*. See Fig. 1. The lungs are conical in shape. The right lung is composed of three lobes; the left has two. Each lobe is subdivided, in turn, into two or more bronchopulmonary segments, each segment representing the lung tissue supplied by one of the main branches of the lobar bronchi. In diseases, such as pneumococcal pneumonia, atelectasis, and lung abscess, the lesions are typically confined to a single lobe or segment.

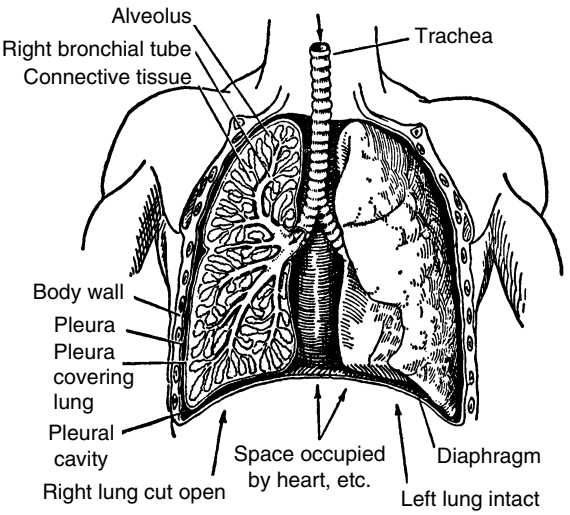

Fig. 1. Human respiratory system.

The lungs are soft and spongy in texture; in the adult, they are gray, mottled with black, or even totally black in color, but in the infant they are pink. The dark color of the lungs in adults living in cities is the result of carbon deposits produced from the atmosphere.

Sounds produced by the lungs during respiration may be heard by the physician through a stethoscope. The value of listening to sounds in the chest area was known to Hippocrates in the fifth century B.C. The conventional type of stethoscope was invented by Dr. George Cammann of New York in the mid-1800s. Each lung is covered with a membrane called the *pleura*. This membrane extends over the inner chest wall and down to the upper surface of the diaphragm. The two layers, therefore, are a closed sac, one on either side of the chest. The space enclosed by the pleural membrane is known as the *pleural cavity*. When a person is

free from disease, no real space is present. Instead, these two coverings for the lungs lie next to each other, separated only by a thin coating of fluid, which permits the surfaces to slide easily over one another during the breathing processes. The lungs are housed in the thoracic cavity which is composed of twelve vertebrae, twelve pairs of ribs, the breastbone, muscles, and fibrous tissue. It is the expansion of this cavity, triggered by nerve impulses from the brain, that causes the lungs to expand and air to be drawn into the lungs. Collapse of the cavity causes expiration.

The pleural cavity is walled off from the abdominal cavity by a sheet of muscle called the *diaphragm*. When a person inhales, the diaphragm moves downward toward the abdominal cavity. Conversely, it moves upward when the person exhales. The up-and-down piston-like movements of this organ account for 60% of the air breathed. The diaphragm is attached in the rear to the spine, at the sides to the lower six ribs, and in front to the breastbone (*sternum*).

During strenuous exercise, the amount of oxygen used by the body increases to 10 or more times that normally used. An increase in carbon dioxide also occurs in the blood. This results in a gasping for breath, a feeling of fatigue, aching muscles, and other signs of shortage of air. These symptoms may appear to be caused by an inadequacy of the respiratory system, but actually they result from failure of the body to increase the amount of blood pumped into the heart. When the body adjusts to this condition, and panting and other symptoms cease, a so-called "second wind" occurs.

The thought that a person completely fills the lungs with fresh air when inhaling and completely empties them of used air when exhaling is erroneous. Only part of the air inhaled, which is about a pint at one time, enters the lungs. The remainder stays in the passageways that lead to the lungs. This is known as "dead air" inasmuch as it does not enter into an exchange of gases in the tissues of the body. When respiratory failure occurs, as in electrocution or drowning, the mechanical act of breathing often can be simulated artificially.

There are several diseases which involve the respiratory system. Some of these are described in separate entries in this encyclopedia. See also **Atelectasis**; **Bronchial Asthma**; **Bronchiectasis**; **Bronchitis**; **Common Cold**; **Cystic Fibrosis**; **Dyspnea**; **Emphysema**; **Influenza**; **Legionellosis**; **Pleurisy**; **Pneumokonioses**; and **Tuberculosis**.

RESPONSE (Instrument). With reference to industrial and scientific instruments and control systems, the Instrument Society of America includes the following definitions:

Dynamic Response. The behavior of the output of a device as a function of the input, both with respect to time.

Ramp Response. The total (transient plus steady-state) time response resulting from a sudden increase in the rate of change in the input from zero to some finite value.

Step Response. The time response of an instrument when subjected to an instantaneous change in input from one steady-state value to another.

Time Response. An output, expressed as a function of time, resulting from the application of a specified input under specified operating conditions.

RESTITUTION COEFFICIENT (or Collision Coefficient). In a two-body collision involving particles 1 and 2, moving in the same straight line, the coefficient of restitution is defined by

$$e = \frac{v_2 - v_1}{u_1 - u_2}$$

where $u_1 > u_2$ are the velocities with respect to a primary inertial system before collision and $v_2 > v_1$ are the corresponding velocities after collision. For a completely elastic collision $e = 1$. For an inelastic collision $e < 1$.

REST MASS. The mass m_0 of an entity in the system in which it appears to be at rest. It is the mass in the classical, or Newtonian sense; that is, it does not include the additional mass which, according to the relativity theory is acquired by a particle or body when set in motion.

RESULTANT WIND. See **Winds and Air Movement**.

RETAINING WALL. A retaining wall is a structure for supporting loose material at an angle greater than its natural angle of repose. Usually, a retaining wall is of concrete construction, and used to retain a bank of earth. Four types of retaining walls are illustrated in Fig. 1. They are the simple trapezoidal section with vertical loaded face, the section with earth pressure aiding masonry weight, and the cantilever retaining wall.

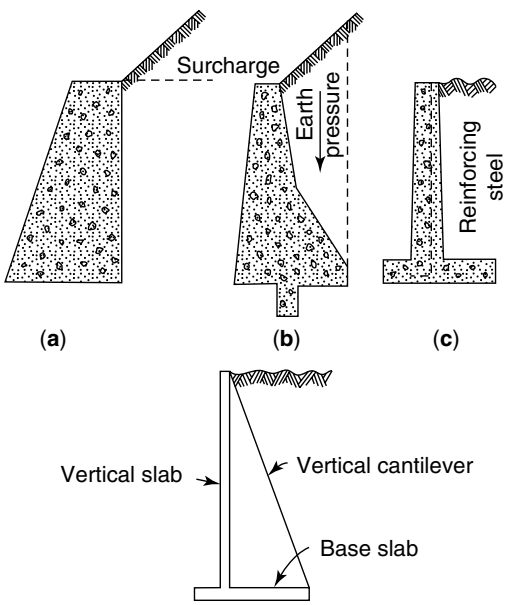

Fig. 1. Types of retaining walls.

The successful retaining wall must be built so that it will neither slide on its base under horizontal pressure, nor tip over. The pressure of the earth is, of course, variable, depending on its composition and moisture content. If the earth back of the wall is well drained, so that its moisture content is a minimum, it will possess more cohesion, and exert less overturning pressure against the wall. The retaining wall may, in some cases, have to be designed to withstand pressures of a surcharged embankment having a slope of at least the natural angle of repose. Quite often the retaining wall must be designed to withstand pressure due to a surcharge caused by highway or railway traffic. The stability of a solid masonry section, such as that in (a) may be determined in much the same way as that for gravity masonry dams, except that earth pressure is not so directly and definitely computable as water pressure. The section shown in (b) will need less masonry because its shape causes it to make use of some of the vertical weight of earth as a stabilizing earth pressure. Also, it is keyed into the ground so that the resistance to sliding is greatly increased. A cantilever retaining wall, shown in (c), is the one with a minimum of masonry, but, because its resistance to overturning is obtained by bending action, internal moments are developed which require that this type of wall be reinforced with steel. A counterfort retaining wall (d) is made up of a continuous vertical slab which is connected to a continuous horizontal base slab or footing and supported at intervals by reinforced buttresses, called counterforts, which rest on the base slab. The earth pressure is carried by the vertical slab, which transfers this load by beam action to the

counterforts. Since concrete is weak in tension, the sections of this type of wall must be properly reinforced with steel rods.

RETENTIVITY. That property (B_{rs}) of a magnetic material which is measured by the residual induction when a saturating magnetizing force is removed. See also **Hysteresis**.

RETICLE. A reticle is a set of two or more fine wires placed at the principal focus of a telescope lens. The reticle wires are usually sections of spider web or some equally fine fiber. In accordance with the fundamental principle of telescope construction this reticle must be in the principal focus of the eyepiece, and when the telescope is directed on an object both the image and the reticle will be in clear view in the eyepiece. Also called *reticule*.

RETICULUM (Constellation). A southern constellation located near Hydra.

RETIFICATION. The enrichment or purification of the vapor during the distillation process by contact and interaction with a countercurrent stream of liquid condensed from the vapor.

See also **Reflux**.

RETINA. The retina is the light-sensitive membrane that covers the inside of the back of the eye. It receives the images that come through the cornea and lens. The retina contains light-sensitive nerve cells, the rods and cones, which send nerve impulses along the optic nerve to the brain by way of a network of connecting and integrating cells, some of which have very long fibers.

The rods and cones are specialized for different purposes. The rods perceive light, while the cone cells perceive both light and color. The retina has 20 times more rod cells than cone cells. Because there are fewer cone cells and because they need more light to function, it is difficult to discern colors in dim light.

At the center of the retina is an area called the *fovea*, which has no blood vessels. Light-sensitive cells, primarily cones, are packed tightly in the fovea, so that it has the highest visual resolution.

When conducting an eye examination, the examiner uses the ophthalmoscope, a hand-held device with a bright light, to examine the retina. The eye care professional looks for such abnormal conditions as damage to the tiny blood vessels that can be caused by high blood pressure or diabetes, detachment of the retina from the back of the eyeball, or blank spots on surface of the eyeball.

Heavy drinking and cigarette smoking, along with poor nutrition, can also lead to retinal damage, as can vitamin deficiency and lead poisoning.

Congenital Disorders of the Retina

Color vision deficiency. Some disorders that affect the retina are inherited. Perhaps the best-known disorder is color vision deficiency. True color blindness, the inability to detect any color so that the world is seen in black and white, is rare.

Color vision deficiency, is caused by defect in or a reduced number of cone cells. Most cases are inherited, but some result from injury or certain diseases of the retina or optic nerve. The two common types of hereditary deficiency are a reduced ability to discriminate light wavelengths in the middle (green) and long (red) segments of the light spectrum. A blue deficiency is much less common.

The deficiency is gender-based, so that it is eight times more common in men of white European origin than in women. About 8% of men and 1% of women of that ethnic background have either green or red deficiency. The incidence is lower in Asians and Native Americans and lowest of all in the black population.

Color vision is tested with color plates. Most persons with color vision deficiency can function well in everyday life, but the condition can be dangerous for airline pilots or electricians, who work with color-coded wires.

Retinitis pigmentosa. This is a gradual degeneration of the rods and cones that can begin as early as adolescence, but most commonly occurs in middle age.

Tay-Sachs disease. Tay-Sachs affects not only the eye but also the brain, causing early death.

Other Retinal Diseases and Disorders

Age-related macular degeneration. An age-related retinal disorder is macular degeneration, gradual deterioration of the innermost part of the retina, the macula. There are two kinds of macular generation, wet and dry. In both kinds, there is a gradual breakdown of cells of the macula and the layer of cells below it, the retinal pigment epithelium.

The "dry" form is most common, accounting for about 90% of cases. Progressive breakdown of the cells causes a blind spot in the center of the eye. The "wet" form is caused by an overgrowth of blood cells in the area of the macula. Wet macular degeneration can be treated to some extent, but the dry form is currently untreatable.

Retinopathy. Retinopathy is a term used to describe a variety of disorders of the retina. One form is diabetic retinopathy, damage to the retina and the blood vessels that serve it when diabetes is not well controlled. The blood vessels can leak or burst, new vessels can grow on the surface of the retina, and there can be abnormal growth of fibrous tissue. Diabetic retinopathy is a major cause of loss of vision.

Hypertensive retinopathy results from high blood pressure, which causes the retinal blood vessels to become abnormally narrow.

Atherosclerosis of the retinal artery, the same kind of blood vessel blockage that leads to heart attack and stroke, can cause severe damage to the retina.

Retinal vein occlusion is a common cause of blindness. It happens when the central vein or artery of the retina is blocked.

Retinal tear and detachment. Retinal tear is a split in the retina that usually is caused by gradual degeneration. It is common in persons with severe nearsightedness, who have thinner-than-normal retinas. It can also be caused by a severe eye injury. A retinal tear often is followed by retinal detachment, in which the vitreous fluid of the eye collects between the delicate nerve membrane and the underlying layer of pigment.

Retinoblastoma. Retinoblastoma is a cancer that occurs early in childhood and has a genetic basis. It occurs in about one of every 20,000 births. It can be treated by radiation but most often requires surgical removal of the affected eye. If both eyes are affected, one may be removed, and the other may receive radiation therapy.

Retinal infections. The retina is also subject to infection.

One common infection is toxoplasmosis, caused by a parasite that is found in raw beef and cat feces. The infection often occurs before birth, and it causes progressive retinal damage over the years.

Other infections include toxocara canis, in which worm larvae lodge in the retina, causing severe damage, and onchocerciasis, another worm infestation.

Bacterial or viral infections elsewhere in the body may also be carried to the retina. They pose a special danger for persons with impaired immune systems. See also **Color Blindness**; **Macular**; **Ocular Hypertension**; **Retinal Detachment**; **Retinitis Pigmentosa**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

RETINAL BASCULAR THROMBOSIS. See **Thrombosis**.

RETINAL DETACHMENT. Retinal detachment occurs when the light-sensitive inner surface of the back of the eye becomes separated from the outer layers. Quick treatment is needed when this happens to prevent loss of vision in the affected eye. The risk of retinal detachment is higher for persons who are highly myopic (nearsighted), who have thin retinas, and those who have had cataract surgery.

There are three kinds of retinal detachment. Most often, retinal detachment occurs when a tear or hole develops in the retina. Fluid from the vitreous gel seeps into the opening, causing the inner surface of the retina to become detached. This kind of retinal detachment, called *rhegmatogenous*

or *mechanical detachment*, can occur in persons who have suffered injuries to the eye.

A less common form is *traditional retinal detachment*, in which there is fibrous tissue on the inner surface of the retina that contracts to pull the layers of the retina apart. Patients with diabetic retinopathy who have experienced a vitreous hemorrhage that produces scar tissue are vulnerable to this form of detachment. This can also occur after an eye injury or after surgery to repair the more common kind of detachment.

A third form is *exudative retinal detachment*, in which fluid oozes from the choroid, the layer of blood vessels between the retina and the sclera. This fluid then accumulates under the retina. An inflammation of the eye, uveitis or age-related macular degeneration can trigger this seepage.

The warning symptoms of retinal detachment include the occurrence, gradual or sudden, of flashes in one eye, usually at the edge of the field of vision and especially noticeable in the dark, lasting only a few seconds. Another symptom that may accompany these lightning-like flashes is a gradual or sudden appearance of floaters in one eye, which are spots or specks that can resemble insects, rings, or even hearts. The flashes occur when the light-sensitive cells of the retina are stimulated as the detachment begins, while the floaters result from the release of blood or pigment into the vitreous gel, the fluid that fills the eye. But sometimes the first symptom is the sudden occurrence of a dark drape, or curtain, that obscures part of the field of vision.

Quick action is needed to prevent detachment of the macula, the center of the retina, which causes loss of central vision. When the macula becomes detached, restoration of central vision may be impossible. If a drape or curtain has appeared, the position of the patient during treatment is important. If there is a descending drape, or lower detachment, the patient can remain upright, but if there is an upper detachment, the patient will be told to lie down to help prevent further detachment.

Retinal detachment is treated by specialized surgery. For mechanical detachment, the retinal surgeon will compress the sclera, which is the white of the eye, and use either a buckle or very small sponges to push the layers of the retina together again. Sometimes gas bubbles may be injected into the vitreous cavity to increase the push. Diathermy, which is heat treatment, may help reattach the retina. The patient may be told to stay in one position for several hours to facilitate the reattachment.

The tear or hole causing the detachment can be treated by bursts of laser light or cryotherapy, a freezing technique, to weld the retina together again. In some cases, retinal fluid that has accumulated beneath the detached segment of the retina will be drained surgically.

Complex microsurgical methods have been developed in recent years for treatment of the various kinds of retinal detachment. See also **Retina**.

Vision Rx, Inc., Elmsford, NY

RETINITIS PIGMENTOSA. Retinitis pigmentosa is a genetic condition that causes progressive loss of vision through the gradual deterioration of the rod and cone cells of the retina. It is one of the most common human inherited eye diseases, affecting between 50,000 and 100,000 persons in the United States and 1.5 million worldwide.

Retinitis pigmentosa encompasses a number of different conditions that are caused by mutations in many different diseases. As recently as the1990s, none of these genetic abnormalities were known. Now at least 6 different genes, and 100 different mutations, have been found to cause various forms of retinitis pigmentosa.

The first symptoms generally do not appear until adolescence, sometimes not until middle age, and the progression to blindness can take decades, with great variation from patient to patient. The first symptom usually is a loss of night vision, affecting visual ability in dim light. Testing of the field of vision shows a ring-shaped region of blindness that gradually extends over the visual field. The rods, which are found more in the periphery of the retina, are affected more than the cones. The cones are concentrated in the macula, the centermost part of the retina, so central vision usually is retained longer. An eye examination shows masses of branching black pigment in the areas of vision loss. That pigment gives the disease its name.

Until recently, there was no treatment for the condition. In 1993, however, a large-scale study sponsored by the National Eye Institute showed that daily doses of 15,000 units of vitamin A could slow the progression of the disease. An average person in the study who started taking the 15,000-unit dose daily retained some useful vision. The study also found that high doses of vitamin E had a negative effect. The disease progressed faster for patients taking 400 units of vitamin E each day. Normal dietary amounts of vitamin E had no effect.

The National Eye Institute recommends that persons with retinitis pigmentosa consult their eye professional about vitamin A supplementation, have blood levels of the vitamin measured before starting supplementation, and eat a balanced diet. In addition, retinitis pigmentosa patients should take vitamin A palmitate, the form used in the study. Vitamin A palmitate is better than beta-carotene, a natural precursor of vitamin A, because each person breaks down beta-carotene differently.

Identification of some of the genetic mutations has led to experiments on gene therapy, in which a virus is used to introduce a normal version of the affected gene. These experiments are in their early stage and are limited to work with laboratory animals. Some limited success has been reported, but human gene therapy for retinitis pigmentosa is at best a long-term prospect.

Vision Rx, Inc., Elmsford, NY

RETINOBLASTOMA. Retinoblastoma is the most common eye cancer of children, occurring in one of every 20,000 births. Some 300 cases are diagnosed every year in the United States, usually at about 18 months of age.

Retinoblastoma is often an inherited condition, although it can occur without a family history. It was the first cancer to be directly associated with a genetic abnormality, deletions, or mutations of one specific region of chromosome 14.

If genetic testing finds such a chromosomal abnormality in a family, there is a 45–50% chance that the parents will have another child with retinoblastoma. If there is no family history and no mutation is found, the risk is only 2–5%.

If retinoblastoma occurs in one child, young brothers and sisters should be observed for signs of the cancer. New retinoblastomas are rarely seen after the age of 7.

In about three-quarters of those cases, the first sign of retinoblastoma is an unusual whiteness of the pupil of the affected eye, which may lack vision. It can be accompanied by strabismus, an abnormal deviation of the line of sight of the eye. In some cases, both eyes are affected. Untreated, the cancer can spread from the eye to the orbit, the socket containing the eye, and then along the optic nerve to the brain.

Because other conditions such as congenital cataract and *Toxocara caris* can cause symptoms resembling retinoblastoma, the diagnosis usually is made by specialized blood tests, CAT scans, ultrasound evaluations, and an examination during which the young patient is anesthetized. In about one of every 20 cases, a biopsy may be needed for a definitive diagnosis.

Until recently, the standard treatment for retinoblastoma was enucleation, which is removal of the affected eye, or radiation therapy. If both eyes are affected, the one with the largest tumor can be removed and the other eye can receive radiation therapy. Enucleation successfully eliminates the cancer in 90% of the cases.

In recent years, the team of specialists treating retinoblastoma, an ophthalmic oncologist, pediatric oncologist, and radiation therapist, has favored radiation treatment, so the child can keep the eye. But evidence suggesting that radiation may increase the risk of other cancers has led to a number of studies focusing on a combination of chemotherapy and such modalities as laser therapy and freezing. The effectiveness of this treatment combination is being assessed.

RETORTING. 1. A process much used in the early years of chemistry for destructive distillation of heavy organic liquids and for laboratory separations. It involves the use of a cylindrical vessel made of glass (for laboratory work), fireclay, or metal, with a neck bent at a downward angle to facilitate distillation. For gas manufacture, the equipment is built on a heavier scale to handle destructive distillation of coal.

2. Processing shale oil.

3. Heating canned or pouched foods with steam to stop bacterial growth.

4. Volatilization of mercury from gold and silver amalgams.

RETRACTOR. A muscle which pulls an eversible or extensible part back to its normal resting position in the body. In the starfishes (see also **Asteroidea**) a pair of muscles in each ray, attached to the pouches of the stomach, serve as retractors for that organ, and in the mussels retractors draw the foot back into the mantle cavity when the animal closes its shell.

RETROGRADE MOTION. 1. Motion in an orbit opposite to the usual orbital direction of celestial bodies within a given system. Specifically, of a satellite, motion in a direction opposite to the direction of rotation of the primary. 2. The apparent motion of a planet westward among the stars. Also called *retrogression*. See also **Planet (Motions)**.

RETROREFLECTOR. Any instrument used to cause reflected rays to return along paths parallel to those of their corresponding incident rays. Also called *retroflector*. A type used for light is the retrodirective mirror. Another type of retroreflector, the corner reflector, is an efficient radar target.

RETROROCKET. A rocket fitted on or in a spacecraft, satellite, or the like to produce thrust opposed to forward motion. See also **Space Vehicle Guidance and Control**.

RETURN STROKE. See **Lightning**.

REUVEN RAMATY HIGH ENERGY SOLAR SPECTROSCOPE IMAGER.

REVEGETATION. Generally refers to the purposeful seeding and planting of an area that once was covered with grass, trees, shrubs, forbs, etc., but which was denuded of vegetation because of a natural disturbance, such as a lightning-caused fire, or because of an artificial disturbance, such as mining and construction projects. A great deal of attention has been given to seeding and planting programs in connection with large areas that have become barren as the result of unplanned strip mining of the coal fields, notably in Appalachia.

Extraction of coal by surface mining has disturbed about two million acres of land in 26 states of the United States, approximately 50% of this disturbance taking place between 1965 and 1975. Ninety percent is on land owned by mining companies, farmers, and other private interests. Even though there has been extensive damage, most of the mining was done under then existing state laws and regulations. Regulations are becoming more rigid. Land disturbed by surface mining is generally an undeveloped land resource. Evidence indicates, however, that all but a small percentage of such land is capable of producing some tangible or intangible societal benefit. Mined sites, appropriately reshaped, can be developed for many uses. In the Midwestern and Appalachian coal fields, they have been developed, in relatively few instances to date, into successful and profitable production of agricultural and horticultural crops. Conversion of such areas into recreational and wildlife developments is a popular target. Industrial and residential sites have been established on areas disturbed by surface mining. Sites planted to trees yield various forest products. As of the early 1980s, some progressive mining companies have identified opportunities and have developed areas that provide social and economic benefits. Such reclamation and revegetation programs, coupled with superior surface mining methods (See also **Coal**), can yield vitally needed coal without extensive spoiling of the land.

Spoil Evaluation. In evaluating old sites that were mined by conventional methods, prior to the use of such techniques as haulback methods, (valley fill or head-of-the-hollow method, mountaintop leveling, etc.), it is necessary to determine both chemical and physical characteristics of the spoil. Chemical factors include toxic ion concentrations and availability of nutrients. The important physical features include particle size, texture, and color of the spoil. Spoil evaluations are often complicated by changes that occur in weathering. Each rock stratum has distinct chemical and physical characteristics. Many of these properties change when fragments of rock are exposed to moisture, light, air, and temperature variations. Release of iron, sulfur, manganese, and aluminum compounds may result in off-site pollution and failure of vegetation. The release of essential nutrients, such as phosphorus, potassium, calcium, and magnesium may, on the other hand, improve the growth of vegetation, reduce acidity problems, and increase the possibilities of reclamation.

Physically, the spoil is a heterogeneous mass of rock fragments derived from the rock strata above the coal. The size of rock fragments after mining and reshaping depends on the size of the basic particles and the strength of the cementing materials, which naturally hold small mineral particles together. Fine-grained shales strongly bonded together may break into hard, platy fragments that resist weathering. Coarse-grained sandstones weakly cemented together may disintegrate rapidly into sand. Spoil may be a dynamic material, more reactive than natural soils that have been exposed to the process of soil genesis for centuries. The chemical and physical properties of a spoil may change rapidly for several years. The rate of change will gradually lessen as characteristics of natural soils develop. Needless to say, however, time required for natural reclamation processes is exceedingly long and provides no relief to the immediate problem.

Evaluations of the chemical properties of a soil could be perplexing if an attempt were made to include all components that affect plant growth. Methods in use today rely on indicators for judging the interaction of many factors at one time. Soil reaction or hydrogen ion concentration (expressed as pH) is the most widely used indicator. Acidity alone may or may not affect the establishment of plants. Changes in acidity determine the concentration of toxic ions and nutrients in the soil solution. At pH levels below 4.0, two chemical changes may occur: Toxic ions, such as manganese, aluminum, and iron, become more available to plants and some essential nutrients become less so. When the pH of a spoil is between 5.5 and 7.0, the concentration of toxic ions in the soil solution decreases and more essential nutrients become available. A soil classification system for acidic spoils is given in Table 1. No system has been proposed for the alkaline or sodic spoils in the western U.S. coal fields. The same principles can be applied, but the toxic ions or cations may differ.

TABLE 1. SYSTEM FOR CLASSIFYING SPOILS (ACIDIC)

Acidity			
Class Number	Description	pH Value	Extent on Area Sampled
1	Toxic	Less than 4.0	More than 75%
2	Marginal	Less than 4.0	50 to 75%
3	Acid[a]	4.0 to 6.9	50 to 75%
4	Calcareous	7.0 or more	More than 50%
5	Mixed	(Too varied to be classified as any above)	—

Texture	
Group	Description of Texture
A	Chiefly sand, sandstones, or sandy shales
B	Chiefly loamy materials and silty shales
C	Chiefly clay and clay shales

Combine acidity and textural classes to describe spoil type.

[a] Acid spoils may be subdivided into two classes: pH 4.1 to 5.4; and pH 5.5 to 6.9.

Source: Northeastern Forest Experiment Station, Forest Service, U.S. Department of Agriculture.

Other chemical analyses have been considered for identifying characteristics that result in specific nutrient deficiencies or toxicities. Phosphorus

is often deficient (0 to 7 parts per million) in spoil material. Several laboratory analyses provide estimates of plant-available phosphorus. Total soluble salts in the soil solution may be important for the very strongly acid or alkaline spoils. This does not necessarily mean high concentrations of sodium salts, but salts of all anions and cations in the soil solution. Some consideration has been given to laboratory analyses that give concentrations of exchangeable aluminum, manganese, and hydrogen. These analyses can identify specific toxicities and thus permit the selection of tolerant plant materials. Research has been initiated to determine whether the heavy metals, such as copper, zinc, nickel, mercury, and cobalt, occur in concentrations toxic to plants.

Texture and clay mineralogy influence the degree of compaction that results from heavy equipment passing over the surface during mining and reshaping. There is evidence that compaction may limit plant growth by reducing water infiltration and nutrient release. Texture may also determine the rate of release of toxic ions or nutrients from soil particles. Smaller particles expose a larger surface area per unit volume to the forces of weathering than coarse fragments. This results in a more rapid release of chemicals. Surface color is important because it influences heat exchange at the spoil surface. Dark materials absorb solar energy so the spoil may attain temperatures lethal to plants. The degree of risk depends on the season of the year, the slope of the exposed surface, and the exposure of the site. The highest risk may occur during summer months on steep slopes of black or dark gray material facing south or west.

Preparation of the Site. Treatments to prepare the site for seeding or planting are determined after evaluation of site data and establishment of the land-management options and objectives. Grass and legumes often require more surface preparation than trees and shrubs. Uncompacted fill slopes and freshly reshaped surfaces may make acceptable seedbeds. Hard crusts form on many spoils; fine clay-size particles are consolidated by the drying action of wind and sun. This crust may be broken by rainfall, frost, or mechanical scarification. In many cases, ground cover will be denser if it is seeded into fresh spoil or where spoil surfaces have been broken by natural or mechanical scarification.

Treatment to create special surface configurations may be required on toxic spoils, on steep slopes, or in geographical locations where precipitation is low or unfavorably distributed throughout the year. Rows or depressions, made by machinery, trap precipitation, moderate wind velocities, reduce evapotranspiration rates, and moderate spoil temperature extremes. The orientation of the furrows with respect to direction of slope, exposure to sun, or prevailing winds may determine the effectiveness of the treatment. Amendments to modify acidity should be applied weeks or months before seeding. Scarification will mix the ameliorating material into the top 6 to 8 inches of spoil and create a neutralized layer for root development. On extremely rocky spoils where scarification is not practical, frost action and infiltrating water may carry the neutralizing materials below the spoil surface. The rate of application of neutralizing material depends on the type of vegetation to be seeded, the present and predicted acidity of the surface spoil, and the neutralizing capacity of the material used. Agricultural limestone is preferred for most treatments, but it can be used only in areas accessible to application equipment. No practical system has been developed for applying large amounts of agricultural limestone to steeply sloping land. Small quantities of lime can be applied with a hydroseeder to steep slopes. Finely ground limestone or hydrated lime may be mixed with water to form a slurry. Repeated applications may be necessary to achieve high rates per acre. The cost of repeated treatments could make this procedure impractical. Alkaline power plant fly ash and bottom ash are neutralizing materials, but they are usually not as effective as limestone. Fly ash contains various quantities of essential plant nutrients, such as phosphorus, zinc, molybdenum, and boron. However symptoms of boron toxicity have been observed on plants growing on sites treated with large amounts of fly ash. Rock phosphate provides a slowly available source of phosphorus and helps to neutralize acidity. Spoil acidity may react with rock phosphate to slowly release plant-available phosphorus.

Fertilization is generally recommended for grass and legume crops. Nitrogen and phosphorus have been used to accelerate the growth of trees on spoils. Tests show that most spoils are deficient in nitrogen. Phosphorus occurs in various concentrations, but deficiencies often limit plant growth. Potassium is usually adequate. There is little information about the concentrations of other nutrients. For most land-management objectives, the formulation of the fertilizer makes little difference when equivalent rates are applied. High-analysis fertilizers, ammonium nitrate, triple superphosphate, and ammonium phosphate are often preferred. Using low-analysis fertilizers on sites that require high rates of application may increase the total soluble-salt concentration to levels toxic to some plants.

Rates of fertilization vary with the seeded crop, the inherent fertility of the spoil, and the land-management objective. Nitrogen and phosphorus at 50 and 22 pounds per acre (56 and 246 kilograms per hectare) respectively, are sufficient to establish grass on many spoils. Higher rates of phosphate are important for legumes. More consideration is being given to retreatment at regular intervals. Multiple treatments are attractive because they reduce the chance of unacceptable cover and increase the probability of achieving land use objectives within the shortest time.

Much research on fertilizer application remains to be done. Research results thus far show that placing selected fertilizers in or near the planting hole increases the growth of black locust. This leguminous species responded to additions of nitrogen and phosphorus placed near seedlings on extremely acid spoil. In other trials, direct-seeded black locust made more rapid growth after surface applications of nitrogen and phosphorus. Five tons of lime per acre per foot of soil increased the growth of loblolly, shortleaf, Virginia, and a hybrid (pitch/loblolly) pine planted in extremely acid spoil. Pitch pine did not respond to the liming treatments. Ten tons of lime per acre-foot reduced the growth of the pines.

Municipal waste products have been considered for surface-mine reclamation. Waste applications could improve soil texture, add essential plant nutrients, and provide mulch for seed and seedlings. Shredded or composted waste could be applied to the surface, and mechanical methods could be used to incorporate it into the spoil. Sewage sludge can be applied in water slurry or in dried form. Mixtures of shredded or composted waste and sewage sludge offer another possibility. Thus far, use of these materials has been restricted to relatively small demonstration areas for public health reasons.

Seeding and Planting. For each of the major coal-producing regions in the United States, there is a group of preferred plant species. These may be grouped under four major categories: (1) grasses; (2) forbs; (3) trees; and (4) shrubs. The grasses and forbs may be further classified as (a) temporary; (b) semipermanent; and (c) permanent, depending on life expectancy of the plant. Temporary species give prompt and effective site protection by reason of quick growth, fibrous roots, and ability to endure unfavorable site conditions. Semipermanent species are perennials that will be ultimately replaced by permanent vegetation. Under favorable conditions, permanent species will persist for many years.

The grasses are a varied group of plant species well suited to surface-mine restoration. Experience has shown that many grasses are adapted to wide ranges of climate, spoil texture, nutrient regimes, and toxic ion concentrations. Germination is usually rapid, and growth often produces a crop, or at least site protection, during the first growing season. Annual grasses often grown as agricultural crops may be used to provide quick site protection. These temporary quick-cover crops also may serve as nurse crops for slower-developing perennials. Some species are better adapted to summer seeding; others should be seeded in the fall.

Leguminous forbs are considered by many to be essential components of ground-cover mixtures. The fixation of atmospheric nitrogen by the legumes benefits associated plants. This assists in maintaining a vigorous ground cover and may reduce the need for retreatment. The leguminous forbs generally are less tolerant of toxic ion concentrations and require more phosphorus than the grasses.

Forbs not classified as legumes are being evaluated in the western United States. The emphasis is on species that are components of natural vegetative cover and are common invaders of disturbed areas. Initial evaluations indicate that some species may be useful for surface-mine revegetation.

Inoculation with specific strains of rhizobium bacteria stimulates nodulation on leguminous forbs. Commercial inoculants are available for the important legume species. Rhizobium bacteria may not survive or produce effective nodules in acidic spoils with pH below 5.0.

Grass and legume ground covers reduce tree growth, but this is often unavoidable because some state laws and regulations require a herbaceous

cover. Manipulation of the species composition and reduction of groundcover density may minimize the adverse effects.

Trees are often planted by hand, using one of several planting tools. On selected spoils, machine planting is possible. Most planting stock is small, 1 to 2 years old, and bare-rooted. Spacing between trees varies by species, site characteristics, and end-objectives. Plantings may be mixtures of several species, or pure plantings of one species. The arrangement may be random or designed to protect seedlings from environmental extremes. There is increasing interest in the establishment of trees by direct seeding. Success has been achieved with several pine species in Alabama. Black locust is used in West Virginia and Kentucky, The planting of shrub species has not been emphasized in surface-mine revegetation. Shrubs have little tangible value; benefits accrue from site protection, wildlife food and cover, and aesthetics.

Costs of Refuse Disposal and Land Reclamation. A predominant advantage of so-called strip mining over underground mining over the years and particularly with reference to smaller, previously unestablished mining operations, has been one of economics. Obviously, as costs of reclamation of stripped areas and of improved surface mining techniques are added to strip mining costs, the differential becomes much less. Past despoilage of the land thus has resulted from comparative economics. While some progressive operators have reduced their profits in order to lessen the damage to the land, such voluntary action is simply more than can be expected on a massive scale. Concerns with land spoilage prevention and reclamation of spoiled lands, unfortunately, are coincident timewise with a growing demand for coal. This, in the early 1980s, hardly felt the impact of the numerous coal conversion programs most of which were still under test and development for the gasification and liquefaction of coal in terms of the new coal technology for supplanting waning supplies of natural gas and petroleum energy sources. The practical, interim solution to the energy/environment problem must be one of compromise.

REVELLE, ROGER R. (1909–1991). Once described by the New York Times as "one of the world's most articulate spokesmen for science" and "an early predictor of global warming," Roger Revelle was a giant in American science who accomplished enough during his eighty-two years to distinguish several lifetimes.

Revelle first made his mark in oceanography as a scientist, explorer, and administrator, and went on to become a senior spokesman for science, giving counsel in areas ranging from the environment and education to agriculture and world population. He was one of the first scientists to recognize the effects of rising levels of atmospheric carbon dioxide on the Earth's surface temperature.

Born in Seattle, Washington, Revelle was raised in Pasadena, California, and was identified as a gifted student early in his academic career. In 1925, Revelle entered Pomona College with an interest in journalism, but later turned to geology as his major field of study.

After receiving his bachelor's degree from Pomona in 1929, Revelle entered the University of California-Berkley to continue his studies in geology. In 1931, at the recommendation of his major professor, George Davis Louderback, he received a research assistantship in oceanography at the Scripps Institute of Oceanography in La Jolla, CA. While at Scripps, Revelle was awarded his Ph.D. and immediately appointed oceanography instructor at Scripps.

Revelle served in the U.S. Navy during World War II as the commander of the oceanographic section of the Bureau of Ships and became head of their geophysics branch in 1946. He returned to Scripps in 1948 and served as its director from 1951 to 1964.

In 1957, Revelle and Hans Suess, one of the founders of radiocarbon dating, demonstrated that carbon dioxide had increased in the air as a result of the use of fossil fuels in a famous article published in Tellus, a European meteorology and oceanography journal. Revelle's interest in atmospheric carbon dioxide engaged his attention for the remainder of his life. He brought the subject to the attention of the public as a member of the President's Science Advisory Committee Panel on Environmental Pollution in 1965. Under Revelle's leadership, the committee published the first authoritative U.S. government report in which carbon dioxide from fossil fuels was officially recognized as a potential global problem.

Revelle chaired the National Academy of Sciences Energy and Climate Panel in 1977, which found that about forty percent of the anthropogenic carbon dioxide has remained in the atmosphere, two-thirds of that from fossil fuel, and one-third from the clearing of forests.

Revelle influenced public opinion on the carbon dioxide issue through a widely read article published in *Scientific American* in August 1982. His research addressed issues such as the rise in global sea level and the relative role played by the melting of glaciers and ice sheets versus the thermal expansion of the warming surface waters. Revelle's international scientific contacts did a great deal to disseminate research findings and to foster discussion about the data, environmental and social effects of increased atmospheric carbon dioxide, and governmental policy and action. Revelle considered this work very important, once estimating that he spent twenty percent of his time keeping current with the issue.

In 1963, Revelle took a leave of absence from Scripps and formally switched fields from oceanography to public policy. He founded the Center for Population Studies at Harvard University, and spent more than a decade as director. His primary interests were applications of science and technology to world hunger. In 1976, Revelle returned to the University of California-San Diego where he received the title of Professor of Science and Public Policy and joined the Department of Political Science.

Revelle served on scores of academic, scientific, and government committees advising on a wide spectrum of topics. He was science adviser to the Secretary of the Interior, president of the American Association for the Advancement of Science, and a member of the NASA Advisory Council. In November 1990, Roger Revelle received the National Medal of Science from President George Bush. He remarked to a reporter: "I got it for being the grandfather of the greenhouse effect."

REVERBERATION. 1. The persistence of sound in an enclosed space, as a result of multiple reflections after the sound source has stopped.

2. The sound that persists in an enclosed space, as a result of repeated reflection or scattering after the source of the sound has stopped.

REVERBERATORY FURNACE. A metallurgical furnace in which the charge, lying in a shallow hearth, is heated by flame passing over its surface and by radiation from a low roof.

REVERSE ACTING CONTROLLER. A controller in which the absolute value of the output signal decreases as the absolute value of the input (measured variable) increases.

REVERSE OSMOSIS. A method for separating inorganic salts and simple organic compounds under pressure. The size of the species usually is considered in terms of molecular weight. Solvent transport through reverse-osmosis membranes is substantially diffusive in nature. The membranes used are anisotropic (thin-skinned, overlaying a porous substructure). In

all probability, the skin contains no pores. If water is the solvent phase, the water passes through the membrane by true diffusion. At some point in its passage through the membrane, the solvent water actually becomes a part of the membrane water structure. As low-molecular-weight solutes exhibit osmotic pressure when concentrated, system pressure in excess of the osmotic pressure of the concentrated solutes must be applied to create a pressure driving force. Depending upon materials being separated and membrane used, reverse osmosis system pressures may range from 200 to nearly 1500 pounds per square inch (13.6 to 102 atmospheres), but the lower values are most frequently encountered.

It has been well appreciated for many years that reverse osmosis concentration has considerable potential in the chemical and food processing field. Reverse osmosis is used for processing whey. A new approach to the production of protein isolates and concentrates from oilseed flour combines ultrafiltration and reverse osmosis. See also **Ultrafiltration**. In 1977, this process was optimized for use with soy flour. The process uses semipermeable membranes to directly process protein extracts from defatted soy flour. Some researchers have found that essentially all the solubilized protein is recovered and the generation of whey like products is avoided. Other desirable features of the combined ultrafiltration/reverse osmosis process include its shorter time span, increased yield of isolate (since whey proteins are harvested along with proteins normally precipitated), and the enhanced nitrogen solubility of the products. For the ultrafiltration part of the system, second-generation, noncellulosic membranes have been used. The membranes used in reverse osmosis are cellulose-based because noncellulosic reverse osmosis membranes have not been fully developed. Cellulose acetate membranes are generally restricted to operating temperatures below about 50 °C and a pH of less than 9.

Japanese researchers have developed a method for washing membranes and overcoming the adhesive effects of mandarin orange juice fouling on reverse osmosis membranes. The importance of keeping fluxes high by controlling concentration polarization and membrane fouling has been observed by several researchers. Other observers have noted that high axial velocities and turbulence promoters minimize the flux decrease caused by concentration polarization and fouling. Considerable research has been undertaken as regards the energy requirements for reverse-osmosis process and these are reviewed in some of the references listed.

Molecular diffusion in reverse osmosis is represented schematically in the Fig. 1 .

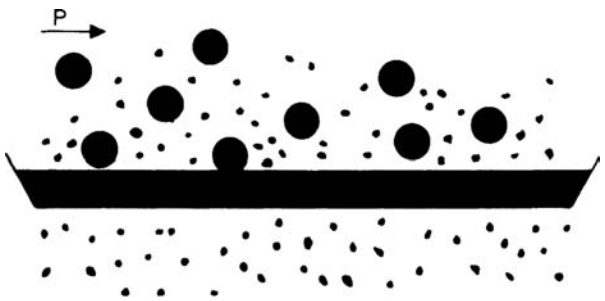

Fig. 1. Schematic representation of molecular diffusion in reverse osmosis.

REVERSIBILITY (Principle of). If all parts of a beam of light are reflected directly back on themselves, no matter how many reflections or refractions it has undergone, the light will travel back over the identical path (or paths) it followed before reversal.

REVERSIBLE AND IRREVERSIBLE PROCESSES. Consider a system which undergoes the transformation *ABC*. See Fig. 1. The change is said to be *reversible* if there exists a change *CBA* such that:

1. The variables characterizing the state of the system return through the same values, but in the inverse order;
2. Exchanges of heat, matter and work with the surroundings are of the reverse sign and take place in the reverse order. Thus, for example, if in the trajectory *ABC* the system receives a quantity of heat Q, it must give up the same quantity in the inverse trajectory *CBA*.

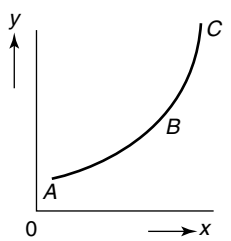

Fig. 1. Depiction of reversible and irreversible processes.

All changes that do not satisfy those two conditions are termed *irreversible*. No changes that take place in nature are reversible. All are irreversible. But in many cases real processes can be derived approaching as nearly as we wish to reversible processes.

Thus let us consider a wide U-tube containing water in which initially the water level is higher in one arm than in the other. The level in this arm falls, passes through the equilibrium position, and rises again. If we could reduce friction and viscosity to zero, we should obtain on the limit a reversible change.

A reversible change may always be considered as a succession of equilibrium states. However, there are processes in nature that cannot be considered as reversible without suppressing them completely. For example, the equalization of temperatures, chemical reactions, and diffusion are processes of this kind.

REVERSIBLE MOIST-ADIABATIC PROCESS. A moist-adiabatic process in which the air is maintained at saturation by the evaporation or condensation of water substance, the enthalpy of water vapor formed or removed being supplied by or to the air, respectively.

In contrast to a pseudoadiabatic expansion, the liquid water that condenses in an air parcel expanding through a reversible moist-adiabatic process is carried with the parcel, so that subsequent compression occurs with moist-adiabatic warming, leading to the original state. This can only happen if the condensed water drops are small enough to have negligible fallout velocities. The moist-adiabatic lapse rate for the reversible process is given by

$$\Gamma_{rm} = g\frac{(1+r_t)\left(1+\dfrac{L_v r_v}{RT}\right)}{c_{pd}+r_v c_{pv}+r_l c+\dfrac{L_v^2 r_v(\varepsilon+r_v)}{RT^2}},$$

where Γ_{rm} is the reversible moist-adiabatic lapse rate; g is gravity; r_v, r_l, and r_t are the mixing of water vapor, liquid water, and total water; c_{pd}, c_{pv}, and c are the specific heats at constant pressure of dry air, water vapor, and liquid water; L_v is the heat of vaporization; R is the dry air gas constant; ε is the ratio of the gas constants of dry air and water vapor ($\approx$0.622); and T is temperature.

See also **Moist-Adiabatic Lapse Rate**; and **Pseudoadiabatic Expansion**.

AMS

REVERSION OF SERIES. A given power series

$$y = a_0 + a_1x + a_2x^2 + \cdots$$

may be reverted to give an explicit representation of x as a function of y. The result is

$$x = z + c_1z^2 + c_2z^3 + \cdots$$
$$z = (y - a_0)/a_1;\ c_1 = -a_2/a_1;\ c_2 = -a_3/a_1 + 2(a_2/a_1)^2$$
$$c_3 = a_4/a_1 + 5a_2a_3/a_1^2 - 5(a_2/a_1)^3; \ldots\ldots$$

The method of undetermined coefficients can be used to obtain further coefficients in the series but the labor becomes great. A series can be reverted more elegantly by means of the theory of residues. Inversion is also used for this procedure, instead of reversion.

REVOLUTION. 1. Motion of a celestial body in its orbit; circular motion about an axis usually external to the body. In some contexts, the terms revolution and rotation are used interchangeably but, with reference to the motions of a celestial body, revolution refers to motion in an orbit or about an axis external to the body, whereas rotation refers to motion about an axis within the body. Thus, the Earth revolves about the Sun annually and rotates about its axis daily.

2. One complete cycle of the movement of a celestial body in its orbit, or of a body about an external axis, as a revolution of the Earth about the Sun.

REYE'S SYNDROME. Sometimes fatal, Reye's syndrome is an encephalopathy usually accompanied by fatty infiltration of the liver. Statistics indicate that the disease is frequently found in persons under the age of 16 years who have had prior infections with influenza or other viruses. Less frequently, the disease is noted among a small percentage of middle-age adults.

The onset is sudden, with intractable vomiting a few days after viral illness. Sensorial impairment appears soon afterward and may progress to coma. Seizures may occur. The liver is usually enlarged. Reye's syndrome is sometimes a complication of chickenpox (varicella), depending upon the patient's immunologic competency.

During the 1978–1979 period, peak reporting of cases of Reye's syndrome occurred between December and March. Using data collected through nearly sixty World Health Organization laboratories as a measure of influenza activity, a temporal association was observed between the occurrence of Reye's syndrome and the reporting of isolates of the H1N1 influenza virus. Concurrent widespread influenza activity was reported in all regions where the incidence of Reye's syndrome was high. In the United States, Reye's syndrome outbreaks followed the occurrence of outbreaks of influenza A in each region, with the first cases of Reye's syndrome occurring in the western United States, followed by cases in the Southeast and Midwest. While influenza B has been epidemiologically associated with outbreaks of Reye's syndrome, statistics showed for the first time that influenza A outbreaks have been associated with temporal and geographic clustering of cases of Reye's syndrome in the United States. See also **Influenza**; and **Liver**.

Specific therapy is not available. Supportive measures include lactulose to control hyperammonemia, fresh frozen plasma to replenish clotting factors, mannitol or dexamethasone to lower increased intercranial pressure, and mechanical ventilation. Fatality rates as high as 23% of cases have been reported in some epidemics.

Although convincing causative evidence has not been uncovered, physicians strongly suggest that salicylates (such as aspirin) may be implicated and thus avoidance of these medicants in patients, especially children, with influenza or chicken pox, is indicated as a precautionary measure.

REYNOLDS NUMBER. A dimensionless number that establishes the proportionality between fluid inertia and the sheer stress due to viscosity. The work of Osborne Reynolds has shown that the flow profile of fluid in a closed conduit depends upon the conduit diameter, the density and viscosity of the flowing fluid, and the flow velocity.

Pipe Reynolds number, R_D, is the dimensionless ratio, $VD\gamma/g\mu_e$, where

V = Velocity in any units consistent with the rest of the equation
D = Inside diameter of the conduit (pipe)
γ = Specific weight in any units consistent with the rest of the equation
g = Acceleration of gravity, feet/second^2
μ_e = Absolute viscosity, pound-second/feet^2

The foregoing equation is inconvenient for commercial use because commonly used units of measurement are rarely consistent. Two alternative equation forms are:

$$(1)\quad R_D = \frac{6.32 \times \text{Rate of Flow (pounds/hour)}}{\text{Pipe Diameter (inches)} \times \text{Absolute Viscosity (centipoise)}}$$

$$(2)\quad R_D = \frac{52.77 \times \text{Rate of Flow (gallons/hour at flowing temperature)}}{\text{Pipe Diameter (inches)} \times \text{Kinetic Viscosity (centistokes)}}$$

Flow generally is considered to be fully laminar at Reynolds numbers below 1500; in transition between 1500 and 4000; and turbulent above 4000. Thus, the Reynolds number is a most useful tool in constructing piping system designs and in sizing flowmeters. Orifice or throat Reynolds number, $R_d = R_D/d/D$, where d = diameter of orifice bore (inches); D = inside diameter of conduit or pipe (inches).

Another general way of expressing Reynolds number is by the ratio

$$\frac{\text{Scale Velocity} \times \text{Scale length}}{\text{Kinematic Viscosity}}$$

This also is referred to as the Reynolds criterion. Reynolds numbers are only comparable when they refer to geometrically similar flows; and, provided that all the boundary conditions can be described by the scale velocity and scale length, flows of the same Reynolds number are dynamically similar. For an airfoil, it is

$$\frac{\text{Air Velocity} \times \text{Chord of the Airfoil}}{\text{Kinematic Viscosity of the Air}}$$

Reynolds numbers are of value in the various fields because tests of models are directly comparable to full-scale results of geometrically similar shapes if the Reynolds ratio for the model equals that of the actual or full-scale project. This has its practical applications in the field of hydrodynamics, in the study of water resistance of hulls or floats, and in the study of water velocities, levee problems, etc., of large rivers. It is used also to establish the best proportions of hydraulic turbines through the use of models. Much of the science of aeronautics rests upon experimental data obtained in wind tunnels. Dangerous inaccuracies might exist in drawing conclusions for actual construction from model tests, unless either the model were tested at a Reynolds number equal to that of the completed project, or due corrections and allowances were made for the Reynolds number. See also **Aerodynamics and Aerostatics**; and **Heat Transfer**.

RHEA *(Aves, Rheiformes).* Large flightless birds of South America, which weigh considerably less and are much smaller than ostriches.

Standing upright they reach 1.70 meters ($5\frac{1}{2}$ feet) and may weigh up to 25 kilograms (55 pounds). The head, neck, rump and thighs are feathered, and their plumage is soft and loose. There are 3 front toes, and the hind toe is absent. The tarsus has horizontal plates in front. The gut and particularly the caeca are very long. They are grass and leaf eaters.

There are 2 genera, each with 1 species and 7 subspecies. (a) The Common Rhea (*Rhea americana*) and (b) Darwin's Rhea (*Pterocnemia pennata*).

The Common Rhea reaches heights up to 170 centimeters (70 inches); the height of the back is 100 centimeters (39 inches), the wingspan reaches 250 centimeters (98 inches), the tarsal length is 30–37 centimeters (12–15 inches), and the beak length is 9–12 centimeters ($3\frac{1}{2}$–5 inches). The tarsus has about 22 horizontal plates in front. Albinos occur in this species. The eggs measure 135 × 95 millimeters (5.3 × 3.7 inches) and weigh 530–680 grams (19–24 ounces). They are elliptical with a shiny surface and are ivory or golden-yellow with black stripe-shaped pores; the color pales with time. The young at first are yellow with black longitudinal stripes on the back; after 2 years they resemble the parents.

Darwin's Rhea is smaller with a height at the back of 90 centimeters (35 inches). The tarsus is 28–30 centimeters (11–12 inches) and has about 18 horizontal plates. The eggs are 125 × 85 millimeters (4.9 × 3.3 inches) and weigh 500–550 grams (18–19 ounces). They are yellowish-green when laid and later become a pale yellow.

The home of the rheas is the grass steppes of South America. See Fig. 1. They avoid forests and mountains. Generally they live in groups of one cock and several hens within a distinct territory. After the breeding season, loose flocks of 50 or more may form. Good eyes and acute hearing allow them to detect enemies from far away; their fast legs, which can take strides of up to 1.5 meters (5 feet), carry them quickly out of danger. In an emergency they can escape by suddenly dodging aside. This maneuver is facilitated by the use of the wings, which, for a flightless bird, are remarkably long. While running, they raise one wing and lower the other; this has a steering effect, like the rudders of an airplane, and makes such sudden changes of direction possible.

The rheas' food consists of grasses and herbs (alfalfa, clover, serradella) and insects and other small animals. Because they prefer the same food plants as sheep, they are food competitors. However, their consumption of the burrlike seeds that tangle the wool of sheep also makes them useful. If they find enough juicy plants, they require very little water.

In the breeding season between September and December, earlier in the north than in the south, the cock expels all rivals from his territory. He only tolerates hens. The courtship display consists of his running around with his plumage erected, dodging sideways and swinging the neck from side to side. At this time he gives his deep call, which can be heard far away, "nan-du," which is responsible for one of its names, "nandu." The cock builds the nest, a simple depression lined with a few pieces of plants; only the cock incubates. Each hen lays her eggs outside the nest at two day intervals. Usually there are 15 to 20 eggs in a clutch; since each hen lays 10 to 15 eggs and several hens lay for their cock, it hardly matters if many eggs are lost. Nests containing up to 80 eggs have been found. But the cock, during incubation, cannot cover so many and hence he cannot hatch them all. The young hatch after about 40 days of incubation. After half a year, they reach adult size, and at 2 to 3 years they are capable of reproduction. See also **Ratites**.

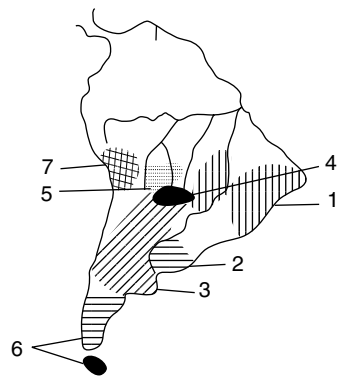

Fig. 1. Areas inhabited by the Rheas, including subspecies. Rhea (*Rhea americana*); (1) *Rhea americana americana*; (2) *Rhea americana intermedia*; (3) *Rhea americana albescens*; (4, 5) *Rhea americana araneiceps*; Darwin's Rhea (*Pterocnemia pennata*); (6) *Pterocnemia pennata pennata*; (7) *Pterocnemia pennata garleppi*.

RHEIFORMES. See **Rhea**.

RHENIUM. [CAS: 7440-15-5]. Chemical element, symbol Re, at. no. 75, at. wt. 186.2, periodic table group 7, mp 3,186 °C (5,767 °F), bp 5,596 °C (10,105 °F), density 21.04 g/cm^3 (20 °C (68 °F). Elemental rhenium has a close-packed hexagonal crystal structure.

Rhenium is a platinum-white, very hard metal; stable in air below 600 °C (1,112 °F) (at this temperature, the metal begins to generate a white, nonpoisonous, vaporous oxide, Re_2O_7 [CAS: 1314-68-7]); practically insoluble in hydrochloric acid HCl [CAS: 7647-01-0] or hydrofluoric acid [CAS: 7664-39-3], but soluble in nitric acid HNO_3 [CAS: 7697-37-2] with the formation of perrhenic acid [CAS: 13768-11-1]; forms sodium rhenate [CAS: 12051-88-6] when fused with sodium hydroxide NaOH [CAS: 1310-73-2] and nitrate. Discovered by Walter Noddack, Ida Tacke and Otto Berg (Berlin, Germany) in 1925 in tantalite, wolframite, and columbite by the Moseley X-ray spectrographic method of analysis, and later found present in molybdenite, from which rhenium is obtained. Predicted by Mendeleev, in 1871, as an element to be discovered with properties resembling manganese, and named by him dvi-manganese. See also **Chemical Elements: History of the Origin**.

There are two natural isotopes, ^{185}Re and ^{187}Re, of which the latter is radioactive with respect to beta decay, having a half-life of 5×10^{10} years reverting to ^{187}Os. Other radioactive isotopes include ^{177}Re, ^{178}Re, ^{180}Re, ^{183}Re, ^{184}Re, ^{186}Re, ^{188}Re, and ^{189}Re. The latter isotope has a long half-life, something less than 10^3 years; the half-lives of the remaining isotopes are comparatively short, measured in minutes, hours, or days.

Because Re and Os are highly refractory and siderophilic elements, the Re-Os isotope system is important in studies concerned with metal phases and high-temperature inclusions of meteorites. R.J. Walker (Carnegie Institute of Washington) and J.W. Morgan (U.S. Geological Survey) observe, "Potential applications of the system include dating meteorites, especially with respect to the chronology of the assembly and subsequent metamorphism of genetically disparate components, and providing estimates of the initial Os isotopic composition and Re/Os ratio of the early earth. This ratio is an important chemical tracer for understanding the formation of the earth's core and the chemical evolution of the mantle and crust."

In terms of abundance, rhenium ranks 75th among the elements, based upon estimated contents of the universe. Rhenium is not plentiful in the earth's crust, being essentially confined to association with the mineral molybdenite. First ionization potential, 7.87 eV. Oxidation potentials $Re + 4H_2O \rightarrow ReO_4^- + 8H^+ + 7e^-$, −0.15V; $Re + 8OH^- \rightarrow ReO_4^- + 4H_2O + 7e^-$, 0.81V. Other important physical properties of rhenium are given under **Chemical Elements**.

Rhenium is a minor constituent (100 ppb) of molybdenite-bearing porphyry copper ores, of which there is extensive mining in the United States and South America. Commercial rhenium is recovered from by-product molybdenum. As the result of roasting molybdenum (IV) sulphide MoS_2 [CAS: 1317-33-5] and molybdenum (III) sulphide MoO_3 [CAS: 12033-33-9], the rhenium is concentrated to levels of 300–1,000 ppm. At the high process temperatures, the rhenium is oxidized and volatilized as rhenium heptoxide, Re_2O_7 [CAS: 1314-68-7]. This compound is recovered from flue gases by way of wet scrubbing and chemical separation techniques as the relatively crude ammonium perrhenate [CAS: 13598-65-7]. The latter compound is reduced with hydrogen to produce rhenium metal.

Uses

Rhenium finds rather wide use as a catalyst in selective hydrogenation and other chemical reactions. It sometimes is used in conjunction with platinum in reforming operations. Additional processes for which rhenium has been tested and used as a catalyst include alkylation, de-alkylation,

dehydrochlorination, dehydrogenation, dehydroisomerization, enrichment of water, hydrocracking, and oxidation. The outstanding feature of rhenium catalysts is their high selectivity, very important in hydrogenation reactions. Rhenium catalysts also resist such catalyst poisons as nitrogen, sulfur, and phosphorus. In terms of activity, rhenium commonly surpasses cobalt [CAS: 7440-48-4], molybdenum [CAS: 7439-98-7], and tungsten [CAS: 7440-33-7] type catalysts and approximates palladium [CAS: 7440-05-3], nickel [CAS: 7440-02-0], and platinum [CAS: 7440-06-4] catalysts.

Because of the very heavy ionic weight (250) of the perrhenate ion, it is one of the heaviest simple anions obtainable in readily soluble salts. It has found use as a precipitant for potassium and some other heavy univalent ions; also as a precipitant for such complex ions as $Co(NH_3)_6^{2+}$, and for the separation of alkaloids and organic bases. Perrhenate also is used in the fractional crystallization of the rare-earth elements.

When rhenium is added to other refractory metals, such as molybdenum and tungsten, ductility and tensile strength are improved. These improvements persist even after heating above the recrystallization temperature. An excellent example is the complete ductility shown by a molybdenum-rhenium fusion weld. Rhenium and rhenium alloys have gained some acceptance in semiconductor, thermocouple, and nuclear reactor applications. The alloys also are used in gyroscopes, miniature rockets, electrical contacts, electronic-tube components, and thermionic converters.

Because rhenium is very difficult to machine with carbide tools and other conventional methods, electrical-discharge machining (EDM), electrochemical machining (ECM), abrasive cutting, or grinding is recommended.

Rhenium can be consolidated by powder metallurgy techniques, inert-atmosphere arc melting, and thermal decomposition of volatile halides. In the powder metallurgy process, bars are pressed at 200 MPa, and this is followed by vacuum sintering at 1,200 °C (2,192 °F) and hydrogen sintering at 2,700 °C (4,892 °F). Rhenium is usually fabricated from sintered bar by cold working, following by annealing. Reductions of 10–20% can be taken with intermediate anneals for one to two hours at 1,700 °C (3,092 °F). Primary working is by rolling, swaging, or forging. Wire drawing is possible down to 2 mils for strip and wire. Because of its excellent ductility at room temperature, rhenium is suitable for forming of complex shapes (Knipple, 1979).

The cost and scarcity of pure rhenium preclude its extensive use for large structural components. Typical applications include wear-resistant electrical contacts and mass spectrometer cathodes. Rhenium also is being studied for use in the reactor core of space nuclear power systems as, for example, fuel-pin liners that prevent interaction with the fuel and also provide high neutron capture under some operating conditions. Rhenium coatings are used to enhance the heat resistance of carbon and graphite parts in low-oxygen environments. Tungsten and molybdenum alloys containing rhenium have been used for heating elements, compact electromagnetic coils, high-temperature thermocouples, anti-friction and wear parts, and high-temperature elastic elements. Rhenium and rhenium-containing alloys are principally produced by powder metallurgy. The use of vacuum or inert-gas atmosphere melting or chemical vapor deposition processes tend to be cost prohibitive.

As observed by B.D. Bryskin (Sandvik Rhenium Alloys Inc., Elyria, Ohio), "Rhenium has poor oxidation resistance, but is chemically inert in most oxygen-free atmospheres. When it oxidizes in air, Re_2O_7 is emitted as a white smoke. When hot worked in air, rhenium is embrittled by grain boundary penetration of liquid-phase oxide. Consequently, hot deformation of Re is practical only in a nonoxidizing protective atmosphere (hydrogen or vacuum), or if the workpiece is encapsulated by an oxidation-resistant material. Rhenium is unique among refractory metals in that it does not form a stable carbide. The solubility for carbon is rather high, resulting in a eutectic melting point at about 2773 K (2500 °C; 4530 °F) and 0.085% (wt) carbon." Further excellent application information is given in the Bryskin reference listed.

Chemistry and Compounds

Rhenium has a $5d^5 6s^2$ electron configuration and all oxidation states from 0 to 7+ are known, although the heptavalent is the most stable state.

The supposed compounds of Re(–I), formulated as $M^I\ Re(H_2O)_4$, have been shown actually to be tetrahydrorhenates(III), e.g., potassium tetrahydrorhenate, $KReH_4$. These compounds are obtained by reducing potassium perrhenate, in a solution of water and ethanolamine, with the alkali metal. In addition to these compounds, however, rhenium differs from its congener manganese in that it forms more compounds that are in the higher valence group. Instead of the larger number of divalent compounds formed by manganese, the stable compounds of rhenium begin with the trivalent ones. The oxides include Re_2O_3 [CAS: 12060-05-8], ReO_2 [CAS: 12036-09-8], ReO_3 [CAS: 1314-28-9], and Re_2O_7 [CAS: 1314-68-7]. The heptoxide differs from the corresponding manganese compound in its stability, as does the acid obtained by its reaction with water, perrhenic acid, $HReO_4$. Perrhenic acid is a strong acid ($pK_A = 1.25$), but not as strong an oxidizing agent as the permanganic acid. Rhenium dioxide is obtained by reduction of perrhenic acid or rhenium heptoxide, and thermal decomposition of the dioxan addition product of the latter yields rhenium trioxide, ReO_3.

Rhenium forms a number of halides and oxyhalides. Direct reaction by heating with chlorine yields $ReCl_5$ [CAS: 13596-35-5], but heating that compound in a nitrogen atmosphere yields $ReCl_3$ [CAS: 13569-63-6]. $ReCl_4$ [CAS: 13569-71-6] and $ReCl_6$ [CAS: 31234-26-1] are also known. Direct reaction by heating with fluorine carries the halogenation further, to ReF_6 [CAS: 10049-17-9] and ReF_7 [CAS: 17029-21-9], which may be reduced to ReF_4 [CAS: 15192-42-4]. Direct reaction by heating with bromine yields $ReBr_3$ [CAS: 13569-49-8]. Reaction of the halides with oxygen, or the oxides or oxyacid salts with halogen-containing substances yields a considerable number of oxyhalogen compounds, e.g., $ReOF_4$, ReO_2F_2, ReO_2Cl_2, ReO_2Br_2, ReO_3F and ReO_3Cl. ReO_3F may also be prepared by the action of liquid HF on $KReO_4$ and ReO_3Cl may be prepared by reaction of ReO_3 and Cl_2.

The complexes of rhenium have not been studied as extensively as those of manganese. Among the known complex ions are $Re(NH_3)_6^{3+}$, $Re(CN)_6^{3-}$, $Re(CN)_8^{4-}$, $Re(CN)_8^{3-}$, $ReO_2(CN)_4^{2-}$, $ReCl_4^-$, ReF_6^{2-}, $ReCl_6^{2-}$, $ReBr_6^{2-}$ and ReI_6^{2-}.

The sulfides include ReS_2 [CAS: 12038-63-0] and Re_2S_7 [CAS: 12038-67-4].

The iodides include ReI_4 [CAS: 59301-47-1] and $[ReI_3]_3$ [CAS: 15622-42-1].

The tellurides include $ReTe_2$ [CAS: 12067-00-4].

Unlike manganese, rhenium is reported to form an alkyl compound, trimethyl rhenium, $Re(CH_3)_3$. Like manganese, it forms a dirhenium compound with carbon monoxide, $(CO)_5ReRe(CO)_5$ [CAS: 14285-68-8], as well as hydrogen-halogen and alkyl-carbonyl compounds. It also forms a dicyclopentadienyl compound, $(C_5H_5)ReH$.

RHEOLOGY. The study of the response of materials to an applied force. Rheology deals with the deformation and flow of matter.

Heraclitus, a pre-Socratic metaphysician, recognized in the fifth century B.C. that $\pi\acute{\alpha}\nu\tau\alpha\rho\epsilon\acute{\iota}$, or "everything flows." Long before Heraclitus, the prophetess Deborah, fourth judge of the Israelites, had sung that "the mountains flowed before the Lord" in celebrating the victory of Barak over the Canaanites (*Judges* 5:5). Reiner (1964) proposed the dimensionless quantity D (for *Deborah*), where:

$$D = \frac{\text{time of relaxation}}{\text{time of observation}} = \frac{\tau}{t} \tag{1}$$

The difference between solids and liquids is found in the magnitude of D. Liquids, which relax in small fractions of a second, have small D. Solids have a large D. A sufficient time span can reduce the Deborah number of a solid to unity, and impact loading can increase D of a liquid. Viscoelastic materials are best characterized under conditions in which D lies within a few decades of unity.

Force Balance Equation. When a force f is applied to a body, four things may happen. The body may be accelerated, strained, made to flow, or slide along another body. If these four responses are added, one can write an expression for motion in one direction:

$$f = m\ddot{x} + r\dot{x} + sx - f_0 \tag{2}$$

where m is the mass, r is a damping parameter related to viscosity, s to elasticity, and f_0 to the yield value. Evaluation of the coefficients m, r, and s involves the measurement of displacements x and their time derivatives in a manner which links these kinematic variables via an equation of state, such as given in Eq. (2), to stress σ (force per unit area) and its time derivatives.

Scope of Rheology. In contrast to the discipline of mechanics, wherein the responses of bodies to unbalanced forces are of concern, rheology concerns balanced forces which do not change the center of gravity of the body. Since rheology involves deformation and flow, it is concerned primarily with the evaluation of the coefficients r and s of Eq. (2). The coefficients account for most of the energy dissipated and stored, respectively, during the process of distorting a body. Most rheological systems lie between the two extremes of ideality — the Hookean solid and the Newtonian liquid.

Measurements of Viscosity and Elasticity in Shear (Simple Shear). Shear viscosity η and shear elasticity G are determined by evaluating the coefficients of the variables $\dot{x}$ and x, respectively, which result when the geometry of the system has been taken into account. The resulting equation of state balances stress against shear rate $\dot{\gamma}$ (reciprocal seconds) and shear γ (dimensionless) as the kinematic variables. For a purely elastic, or Hookean, response:

$$\sigma = G\dot{\gamma} \tag{3}$$

and for a purely viscous, or Newtonian response:

$$\sigma = \eta\dot{\gamma} \tag{4}$$

As a consequence, G can be measured from stress-strain measurements, and η from stress-shear rate measurements.

Elasticoviscous behavior is described in terms of the additivity of shear rates:

$$\dot{\gamma} = \frac{\sigma}{\eta} + \frac{\dot{\sigma}}{G} \tag{5}$$

whereas viscoelastic behavior is characterized by the additivity of stress, according to Eq. (2);

$$\sigma = G\gamma + \eta\dot{\gamma} \tag{6}$$

Relaxation. Numerous attempts have been made to fit simplified mechanical models to the two behavior patterns described by Eqs and (6). One can picture the elastic element as a spring-arrayed network parallel with the viscous element to give essentially a (Kelvin) solid with retarded elastic behavior, wherein:

$$\frac{\eta_k}{G_k} = \text{retardation time (sec)} \tag{7}$$

or as a (Maxwellian) series network which flows when stressed or relaxes, under constant strain:

$$\frac{\eta_m}{G_m} = \text{relaxation time (sec)} \tag{8}$$

and transient experiments may be designed to measure these parameters singly. In real systems, a single relaxation (or retardation) time fails to account for experimental results. A distribution of relaxation time exists.

Dynamic Studies. When Eq. (2) is written in the form:

$$\ddot{x} + 2k\dot{x} + \omega_1^2 x = 0 \tag{2b}$$

the equation suggests that the variation in stress should be cyclic. Rheometers are designed so that the system may oscillate in free vibration of natural resonant frequency ω_1, or else so that a cyclic shearing stress of the form $f_0 \cos \omega t$ is impressed on the sample over a frequency range which spans ω_1. In neither case is the material strained beyond its range of linearity. Equation (2b) represents a damped harmonic oscillator, providing that the coefficients are constant (i.e., providing that they do not depend on the strain magnitude). Not all systems meet this requirement in the strict sense, with the result that one of the first checks the experimenter makes is for linearity. Doubling the amplitude of oscillation should double the stress and should not change the phase relationships between the cyclic stress and the deformation.

Time-Temperature Equivalence (Steady-State Phenomena). The creep of a viscoelastic body or the stress relaxation of an elasticoviscous one is employed in the evaluation of η and G. In such studies, the long-time behavior of a material at low temperatures resembles the short-time response at high temperatures. A means of superimposing data over a wide range of temperatures has resulted which permits the mechanical behavior of viscoelastic materials to be expressed as a master curve over a reduced time scale covering as much as twenty decades (powers of ten).

Polymeric materials generally display large G values (10^{10} dynes/cm^2 or greater) at low temperatures or at short times of measurement. As either of these variables is increased, the modulus drops slowly at first, then attains a steady rate of roughly one decade drop per decade increase in time. If the material possesses a yield value, this steady drop is arrested at a level of G which ranges from 10^7 downward.

Dynamic Behavior. The application of sinusoidal stress to a body leads inevitably to the complex modulus G^*, where

$$G^* = G' + iG'' = G' + i\omega\eta' \tag{9}$$

where G' is the in-phase modulus $(\sigma/\dot{\gamma})$ which represents the stored energy, and G'' is the out-of-phase modulus $(\sigma/\dot{\gamma})$ representing dissipated energy (as its relation to η suggests); the variable against which G' and η' are determined is the circular frequency ω. Superposition of variable temperature data or variable frequency data provides a master curve of the type previously described for steady-state parameters.

Problems in Three Dimensions (State of Stress). The forces and stresses applied to a body may be resolved in three vectors, one normal to an arbitrarily selected element of area and two tangential. For the yz plane, the stress vectors are σ_{xx} and σ_{xy}, σ_{xz}, respectively. Six analogous stresses exist for the other orthogonal orientations, giving a total of nine quantities, of which three exist as commutative pairs ($\sigma_{rs} = \sigma_{sr}$). The state of stress, therefore, is defined by three tensile or normal components ($\sigma_{xx}, \sigma_{yy}, \sigma_{zz}$) and three shear or tangential components ($\sigma_{xy}, \sigma_{xz}, \sigma_{yz}$). The shear components are most readily applicable to the determination of η and G.

Strain Components. For each stress component σ there exists a corresponding strain component γ. Even for an ideally elastic body, however, a pure tension does not produce a pure γ_{xx} strain; γ components exist which constrict the body in the y and z directions.

The complete stress-strain relation requires the six σs to be written in terms of the six γ components. The result is a 6×6 matrix with 36 coefficients k_{rs} in place of the single constant. Twenty-one of these coefficients (the diagonal elements and half of the cross elements) are needed to express the deformation of a completely anisotropic material. Only three are necessary for a cubic crystal, and two for an amorphous

TABLE 1. EXAMPLES OF NON-NEWTONIAN FLUIDS EXHIBITING DIVERSE RHEOLOGIC PROPERTIES

Pseudoplastic	Plastic	Trixotropic*	Rheopectic	Dilatant*

		Lard		
		Fruit juice concentrates		
		Asphalts		

*Some liquids may change from thixotropic to dilatannt or vice versa as the temperature or concentration changes.

isotropic body. Similar considerations prevail for viscous flow, in which the kinematic variable is $\dot{\gamma}$.

Applications. The study of rheology is important to many sciences and technologies. Numerous instruments have been constructed to make manual, semiautomatic, and automatic measurements (and control) of such variables as viscosity, and consistency (flowability). These variables are particularly important in the food processing, chemical, and plastics industries, where many of the products and intermediates lie between Hookean solids and Newtonian liquids. Consistency measurement is of large importance in the paper manufacturing industry. See also **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

Some terms commonly used in industry include:

Newtonian Substance — Fundamentally, liquids or suspensions in liquids when subjected to a shear stress behave in two ways: (1) A Newtonian substance undergoes deformation, the ratio of shear rate (flow) to shear stress (force) is constant. See Fig. 1.

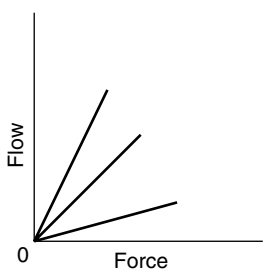

Fig. 1. Behavior of Newtonian substances.

Non-Newtonian Substance — (2) In a non-Newtonian substance, the ratio of shear rate to flow is not constant. See Fig. 2.

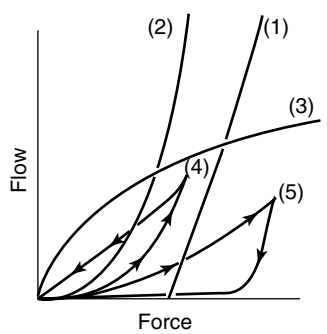

Fig. 2. Behavior of non-New-tonian substances: (1) true plastic (sometimes called a Bingham body); (2) pseudoplastic; (3) dilatant; (4) thixotropic; and (5) rheopectic.

Dilatant — The initial flow of a dilatant substance under a low shear stress is at a high rate; further increases in shear stress result in a lower flow rate. A dilatant substance is sometimes called an inverted plastic or inverted pseudoplastic.

Pseudoplastic — A material of this type appears to have a yield stress beyond which flow commences and increases sharply with increase in stress. In practice, such substances are found to exhibit flow at all shear stresses, although the ratio of flow to force increases negligibly until the force exceeds the apparent yield stress.

Thixotropic — The flow rate of a thixotropic substance increases with increasing duration of agitation, as well as with increased shear stress. When agitation is stopped, internal shear stress exhibits hysteresis. Upon reagitation, generally less force is required to create a given flow than is required for first agitation.

Rheopectic — If certain thixotropic suspensions are rhythmically shaken or tapped, they will "set" or build up very rapidly, a phenomenon termed rheopexy. Apparent viscosity of a rheopectic substance increases with time (duration of agitation) at any constant shear rate.

See Table 1. See also **Colloid System**; **Fluid**; **Stokes Flow**; **Stokes Law for Viscosity**; **Viscoelasticity**; and **Viscosity**.

RHEOPECTIC SUBSTANCE. See **Colloid System**.

RHEOSTAT. A variable resistance used for operation or control of electrical equipment. Rheostats might be classified as metallic, carbon, and electrolytic types. The most common form is the metallic type, in which the resistance is in the form of a metal wire or ribbon, or cast grid, these being made of a metal having poor conductivity, and little deterioration from heating. The variable resistance of metallic rheostats is obtained by bringing out taps from different points of the resistance wire to the points of a multi-pointed switch which can be used to short-circuit different sections of the resistance. Laboratory rheostats are frequently coils of resistance wire wound closely on an insulating cylinder and provided with a sliding contact finger which will bear on the wires themselves, and which can be employed to short-circuit any desired number of turns of the resistance wire.

RHEUMATIC DISEASES. Characteristically, and essentially by definition, the rheumatic diseases involve the joints. The functional characteristics of the various connective tissues that make up a joint are manifestations of the chemical structure of these elements. In a healthy,

well-functioning (*diathroidal*) joint, there are essentially perfect biochemical processes going on to maintain ideal functionality. Connective tissue consists of large and complex molecules, such as collagen. See also **Bone**. In processes as complex and intricate as these, there are many potential opportunities for "natural" errors. Some genetic disorders of collagen have been identified. These reflect errors in the biosynthesis processes. In the makeup of a joint, there are other equally complex substances. The other major component of connective tissue matrix is the ground substance, composed of complex proteoglycans. Synovial membrane and synovial fluid are also complex biochemically. These varied substances, each characterized by its own biochemistry, explain in a very general way why there are so many kinds and degrees of rheumatic diseases.

The etiology of only a few rheumatic diseases is reasonably well understood. Much progress has been made in this area in recent years, with some fundamental findings dating back to the 1930s. Thus, over the years, the science of the rheumatic diseases has been revised considerably. In 1964, the American Rheumatism Association proposed a reclassification of the rheumatic diseases and has since been revising the classification as new information warrants. This classification is given in Table 1.

TABLE 1. CLASSIFICATION OF RHEUMATIC DISEASES[1]

1. *Polyarthritis of unknown etiology*, as exemplified by rheumatoid arthritis, ankylosing spondylitis, and Reiter's syndrome.
2. *Acquired connective tissue disorders*, as exemplified by systemic lupus erythematosus, scleroderma, polymyositis, and dermatomyositis.
3. *Rheumatic fever*.
4. *Degenerative joint disease*, where the primary form is of unknown cause, and where the secondary form may be associated with mechanical or metabolic disorders. Exemplified by osteoarthritis and osteoarthrosis.
5. *Nonarticular rheumatism*, exemplified by fibrositis, intervertebral disk and low back syndrome, myositis and myalgia, tendinitis and bursitis.
6. *Diseases frequently associated with arthritis*, such as sarcoidosis, relapsing polychondritis, ulcerative colitis, regional enteritis, Sjögren's syndrome, and familial Mediterranean fever.
7. *Infectious arthritis*, such as bacterial arthritis involving *Gonococcus, Meringococcus, Pneumococcus, Streptococcus, Staphylococcus, Salmonella, Brucella, Streptobacilus moniliformis*; or involving mycobacteria, such as *M. tuberculosis*; or involving fungi, parasites, and viruses.
8. *Traumatic and neurogenic disorders*, as exemplified by traumatic arthritis resulting from direct trauma, neuropathic arthropathy, and diabetic neuropathy, among others.
9. *Biochemical or endocrine disorders*, as exemplified by gout, Gaucher's disease, and Fabry's disease, among others.
10. *Neoplasms*, as found in synovioma, primary juxta-articular bone tumors, multiple myeloma, and others.
11. *Allergic and reactive disorders*, such as serum sickness and drug reactions.
12. *Inherited and congenital disorders*.
13. *Miscellaneous disorders*.

[1]Essentially as proposed by American Rheumatism Association (in abridged format).

The concept that immunologic alterations may play a role in rheumatoid arthritis was first suggested a number of years ago. In the 1930s, the abnormal agglutinating properties of the serum of several rheumatoid arthritis patients led to the discovery of the *rheumatoid factor*. See also **Immune System and Immunology**. Later, the abnormality of the humoral immune mechanisms was indicated by noting increased circulatory levels of the immunoglobulins, IgM, IgA, and IgG, in a high percentage of affected individuals.

Several articles in this encyclopedia relate to rheumatic diseases. Check alphabetical index for such key words as arthritis, bone, bursa and bursitis, gout, osteoarthritis, rheumatic fever, rheumatoid arthritis, scleroderma, spondylarthropathies, and systemic lupus erythematosus.

RHEUMATIC FEVER. An inflammatory disease precipitated by a Group A streptococcal infection. The preceding infection, which may occur almost anywhere in the body, is key to diagnosis. It is important to affirm the infection because the disease can be mediated by early treatment of the infection. Rheumatic fever is predominantly found in persons between the ages of 5 and 15 years. Much remains to be learned concerning the manner by which Group A streptococci damage various tissues in the body, but it has been reasonably well established that antibodies directed against streptococcal antigens play an important role. It is also believed that a genetically determined aberration in the immune response is of major importance.

Principal manifestations of rheumatic fever are: inflammation of the heart (carditis), which occurs in 50–60% of cases; inflammation of joints (polyarthritis), which occurs in 70% of cases, subcutaneous nodules, which occur in most severe cases; erythema marginatum (characteristic skin rash), which occurs in about 5% of cases; and chorea, in about 5% of cases.

The lesions of rheumatic fever tend to favor connective tissue. Such lesions (Aschoff nodules) may be seen throughout the heart in some cases and can cause severe permanent damage. Ultimately the lesions regress and cause an area of fibrosis. Valvular lesions tend to undergo fibrous thickening as they heal, sometimes resulting in permanent valvular dysfunction.

The course of the disease ranges from a few weeks to three months (in 90% of cases) to six months (less than 5% of cases) or longer. Rheumatic fever is prone to recur, but such recurrences have been greatly reduced through antibiotic therapy. In moderate cases, heart valvular lesions will heal, but in some cases this condition may worsen. Recurrence retards the healing process. Patients who escape carditis in the initial attack usually also escape this involvement during recurrent attacks.

Four stages are recognized in the progressive development of rheumatic fever: (1) acute streptococcus infection; (2) a period of apparent recovery lasting from a few days to about 3 weeks; (3) appearance of the major symptoms of the disease as previously described; and (4) chronic manifestations of the disease in the form of damage, such as occurs in valvular stenosis. The disease usually runs a milder course in adults than in children. See also **Bacterial Diseases**.

RHEUMATOID ARTHRITIS. A chronic, inflammatory, systemic disorder that principally affects the joints and tendon sheaths. The disease is of varied characteristics, ranging from one of relatively minor aches and pains of one or more joints to a severely debilitating condition involving mutilative structural changes. Onset of the disease usually occurs during the third or fourth decade of life, but can appear at any age. About 1% of the population is affected in some way by rheumatoid arthritis. The disease appears in women at three times the rate of men. The etiology of the disease is difficult to determine — either generally for rheumatoid arthritis or for specific cases. There are no apparent biological markers for the disease and thus the usual routine laboratory tests are of little, if any value, to the physician in making a definite diagnosis of rheumatoid arthritis. The joints of the extremities are particularly prone to involvement and symmetry is often present. The joints most commonly affected, in general order of rate of occurrence, are the hands and wrists, elbows, shoulders, hips, knees, ankles and feet, and spine (cervical spine disease). Systemic involvement of the disease appears in a

number of organs of the body, with each case having its own particular profile. Other systemic manifestations may include *Sjögren's syndrome* (eye involvement). This condition involves a sensation of grittiness of the eye, an accumulation of dried mucoid material, and frequently a lessening of eye fluid (tear) production. Other systemic manifestations include *lung involvement* (pleurisy with effusion); *heart* (pericardial effusion); *blood* (mild anemia); *neuromuscular* (muscle weakness); and *vasculature* (vasculitis).

Although some linkages of a genetic nature have been demonstrated in rheumatoid arthritis, there is a lack of convincing evidence particularly as regards the adult form of the disease. It also has long been suspected that bacteria and/or viruses may be causative agents, but research to date has not revealed well-documented evidence of such connections. The absence of a strong biological marker for the disease makes such connections very difficult to prove. Although *rheumatoid factors* are found in 80% of cases of adult rheumatoid arthritis, these factors are not specific to the disease. See entry on **Rheumatic Diseases**. Thus diagnosis of the disease in its early phases is essentially a matter of the physician's experience with numbers of cases of the disease and relating early physical evidence to the patient's history and description of complaints. X-rays taken in the early stages are not always helpful because, during the early period, the disease is essentially confined to the synovium and alterations that do not show up on X-ray films. Some months after the onset of the disease, x-rays may then indicate some loss of bone mass (*osteoporosis*), particularly of finger joints. X-ray examinations generally are most helpful in connection with the larger joints, such as the knee and hip, after the disease has progressed for a number of months or longer.

Because of the various profiles of the disease, generalization is difficult. Keeping this in mind, the most common form of rheumatoid arthritis is that which is only marginally noticeable during the early phases and that slowly progresses to more serious phases over a period of many months, even years. One qualitative confirmation of the disease is the nature of joint stiffness. For example, in most older people, there will be a certain amount of stiffness of joints experienced upon rising in the morning. This may persist for several minutes to close to an hour before the person feels "limbered up" for the day. No swelling follows such stiffness. If rheumatoid arthritis is present, certain joints will swell after brief periods of exercise.

Rheumatoid arthritis is frequently of a rather cyclic nature, i.e., alternating periods of remission and exacerbation — where the symptoms may essentially disappear or decrease to minimal proportions, but with periods of increasingly severe symptoms occurring between remissions. This is highly variable with patients and difficult, if not impossible, to forecast in advance. Usually patients who experience a relatively favorable course of the disease, that is, with long remissions, are usually less than 40 years of age and with involvement of just a few of the larger joints. The less favorable course of the disease is most frequently experienced by persons over 40 years of age and where the disease has commenced slowly, but where, after the initial phase of the disease, rheumatoid nodules have appeared at a rather rapid rate. Such patients also will usually be found to have high titers of rheumatoid factor and to have experienced weight loss, these factors indicating more serious systemic involvement.

After rheumatoid arthritis has progressed for a period, increased numbers of lining cells (most often found in recesses of the joint) will be found. It is believed that these cells may be due to proliferation of the cells per se or represent the presence of cells that have migrated to the joint from the blood. The surface of the cartilage will be covered with fibrin (an insoluble protein), and there may be edema of the sublining cells. The diseased synovial fluid contains various forms of debris, with consequent alteration of the fluid volume (increase) and of various physical characteristics (decrease of viscosity; increase in protein content, notably of large protein molecules). There is alteration of hyaluronic acid brought about by reactions between hyaluronic acid and proteins. There is demineralization of bone collagen, which may result from local decreases in pH and possibly chelation by organic acids. Other changes have been confirmed or postulated, the end result of which processes are bone loss or degeneration. Nodules (from a few millimeters to two centimeters in diameter and often occurring in clusters) will appear under the skin on the forearm, the tibia, the Achilles tendon, and other sites, varying with the particular course of the disease in a given patient. It is interesting to note that these nodules may be noted elsewhere (not confined to joints) in the body — the lungs, intestinal tract, heart, and dura, among others. Similar nodules are also seen in systemic lupus erythematosus and rheumatic fever and thus are not specific to rheumatoid arthritis.

In the treatment of rheumatoid arthritis, the regimen includes the administration of analgesics (for pain), anti-inflammatory agents, considerable dependence on physical therapy, sometimes in a hospital environment, and, less frequently, surgery.

Aspirin has been a mainstay for arthritis therapy for a number of years. Aspirin serves the dual function as an analgesic and anti-inflammatory agent. The drug, properly administered, assists in reducing swelling, relieving stiffness, and generally makes most patients, particularly in the initial phase of the disease, feel much better. Levels just below those that cause *tinnitus* (ringing in ears) and loss of hearing may be prescribed by some physicians. In some patients, gastrointestinal side effects usually can be alleviated by taking aspirin with milk or by using specially buffered or enteric-coated preparations. Some complications, such as interference with platelet formation, may rule out aspirin in some patients.

Nonsteroidal anti-inflammatory drugs, such as indomethacin and phenylbutazone, are prescribed in some cases. Although not fully free of gastric side effects in some patients, ibuprofen (Motrin®), fenoprofen, naproxen, tolmetin, and sulindac, among others, are sometimes used as substitutes for aspirin.

Although sometimes used, antimalarial drugs, such as chloroquine and hydroxychloroquine, are regarded by some authorities as of limited usefulness in rheumatoid arthritis and may cause retinopathy and irreversible decrease in vision. They are usually only used in patients who do not respond well to any of the drugs previously mentioned.

In highly persistent rheumatoid arthritis, soluble gold salts may be indicated. These compounds have been demonstrated in controlled tests to be effective in decreasing inflammation and contributing to improved frequency of remissions. However, tests also show that not all patients have a positive response to these compounds. The salts, such as gold sodium thiomalate or gold thioglucose, are usually administered intramuscularly. Several months may be required to determine the nature of response. Some patients develop a skin outbreak or stomatitis (inflammation of mouth) of a relatively minor and transient nature. Where such symptoms are serious and persist, another gold salt or a lower dosage may be attempted after a short period, or gold salt therapy may be ruled out altogether. This therapy requires the careful monitoring of a physician because, although they are uncommon, serious side effects may occur in some patients.

Released relatively recently for use in the United States and some other countries, D-penicillamine is now used for some severe cases of rheumatoid arthritis. The drug produces toxic reactions in some patients not unlike the reactions from gold salts as previously mentioned. The physician will usually start the patient on a low dosage, gradually increasing the dosage until the patient develops a tolerance for the drug.

Glucocorticoids, such as prednisone, are powerful anti-inflammatory agents. In some patients, suppression of the major symptoms of rheumatoid arthritis is quite marked. However, when prescribed in dosages sufficient to achieve such dramatic effects, there are long-term side effects of a serious nature, including increased susceptibility to infection, osteoporosis, osteonecrosis, cataracts, and gastrointestinal bleeding. Convincing evidence has not been forthcoming to the effect that the glucocorticoids actually alter the course of the disease, which leads to joint and other structural damage. Thus, these drugs are used with discretion, often confining their use to local injections, which usually lower the risk of side effects considerably.

In extreme cases of rheumatoid arthritis, where there are life-threatening implications and very serious crippling, cytotoxic agents, such as cyclophosphamide and azathioprine, may be used. These drugs are used infrequently because of serious side effects, including the induction of neoplasias and chromosomal abnormalities.

Physical therapy is an important adjunct in the overall management of prolonged cases of rheumatoid arthritis. Surgery to repair or replace affected joints and structures is used where there is a serious degree of crippling or debilitation. Complete joint replacement, including total hip replacement, is sometimes effected. In some patients, replacement of the hip joint with an alloy steel articulating ball mounted on a stem within a high-density polyethylene socket has proved quite successful, providing

a joint that is stable, that allows satisfactory motion, and that is free from pain.

Fig. 1. (Top) Former and present distribution of the black rhinocerous (*Diceros bicornis*). This is the only species of rhinoceros that still occurs with some, but diminishing frequency in areas indicated by black triangles. (Bottom) The fights of the rhinoceros, after study, have been shown to be fair duels, which are performed according to specific rules. Serious injuries rarely occur, and often these fights are mere play.

RHINITIS. Inflammation or infection of the mucous membrane of the nose. The common head cold is primarily a rhinitis. Chronic rhinitis, also termed dry rhinitis, usually is associated with some form of chronic debilitating disease, notably persistent kidney problems and diabetes. The principal complaint is dryness of the nose and accompanying encrustation. There is no atrophication of nasal bone and lining in the case of *rhinitis sicca*, but in *atrophic rhinitis* such alterations occur. The primary treatment of any rhinitis is directed to the general health and other causative disease factors, coupled with local medication for the stimulation of nasal mucosa to alleviate dryness. Rhinoviruses are described under **Virus**. See also **Common Cold**.

Increased secretion by nasal and bronchial mucous glands, in some cases, is believed to result from some of the mediators of immediate hypersensitivity as part of a complex of reactions occurring in the immune system. See also **Immune System and Immunology**.

RHINOCEROS *(Mammalia, Perissodactyla).* A large animal, *Rhinoceros*, of the Oriental region and Africa, with rather short legs and a long muzzle bearing one or two conical horns behind the nostrils. There are four species in the Oriental region and two in Africa. The common African species stands over 6 feet (1.8 meters) high at the shoulders and has an anterior horn over 3 feet (0.9 meter) long. Because of its thick skin, it is difficult to kill. These animals are described as generally dull and timid, but when brought to bay they can be very aggressive. Because of their great size, they can be dangerous when provoked. See Figs. 1 and 2.

The true rhinoceros of the Rhinocerotidae family during the Tertiary period was a widely distributed group of many species. During the Eocene, a hornless, small form with slender feet, probably not too different from the other odd-toed ungulates of the era, first appeared. The skull was low and flat, without any indication of horns. The molar teeth consisted of premolars and molars with low crowns and ridges across and on the sides. This basic structure, in spite of some variations, is the same as found in the later rhinoceros. Fossils of members of the subfamily Caenopodinae (*Eotrigonias, Caenopus*, etc.), which belong to the most primitive, oldest rhinoceros, and fossils of several such forms have been found in the Early Tertiary stratum of North America and Europe. These slender-footed, hornless, primitive rhinoceros still had a complete set of front teeth and molars.

Of the contemporary rhinoceros, the *Asiatic two-horned rhinoceros (Dicerorhiniae)* may be traced back approximately forty million years into the Oligocene. At first they occurred as small animals (*Dicerorhinus*

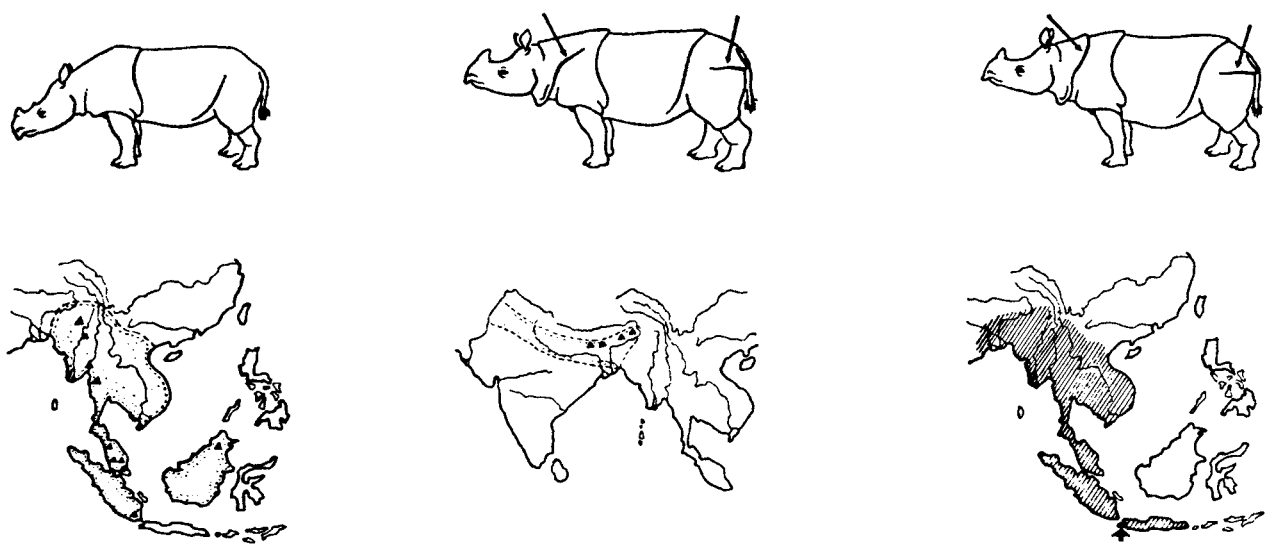

Fig. 2. Asiatic species of rhinoceros: (Left) Former and present distribution of the Sumatran rhino. This species now exists only in those few places marked by triangles on map. (Middle) Former and present distribution of the great Indian rhino. Presently, it is found only in a few protected areas, marked by triangles. (Right) Former and present distribution of the Javan rhino. Only a few animals exist today in the Udjong-Kulon Preserve in Java, noted by arrow. Skin folds at shoulder and base of tail are indicated by arrows in cases of the great Indian and Javan rhinos.

tagius), which were less than the size of a tapir and soon split up into different lines. One line led to the well known, early glacial *Wooly Rhinoceros (Coelodonta antiquitatis)*. This was a cold-resistant species with a long-haired, thick coat. Knowledge of this is gained not only from bones, but also from complete bodies with skin and fur discovered in the Siberian permafrost soil. In addition, the people of the Early Stone Age have portrayed the animal on their cave drawings. The species was extinct by the end of the glacial period.

The contemporary *square-lipped rhinoceros* is a grass-eating animal of the steppe, which traces back to the earlier and middle glacial period of Europe. The larger *Merck rhinoceros (Dicerorhinus kirchbergensis)* from the same glacial period was a forest type. The only contemporary species of this group, the *Sumatran rhinoceros (Dicerohinus sumatrensis)* is much closer to the phylogenetically older forms than its glacial relatives, a fact which is frequently found in the inhabitants of the tropical prime forests. However, since the species still has front teeth and molars with low crowns, which are not suitable for crushing hard steppe grass, authorities consider the species as a slightly modified survivor from the Tertiary Period. The *great Indian rhinoceros*, which lives in South Asia today, can be traced back to the Tertiary (Miocene, approximately 25 to 10 million years ago). The *African rhinoceros* forms a separate branch which includes the *black rhinoceros*, an animal that originally fed on foliage. Another African species, the *square-lipped rhinoceros*, is a more highly evolved grass-eater.

A History of Extinction

Compared with the multitude of species that existed in earlier times, the surviving genera (great Indian, Javan, Sumatran, square-lipped, and black) appear rather stunted despite their size. They all live in remote habitats, seemingly because they have not been able to compete any longer with the other ungulates, especially the ruminants. Above all, however, human influence has basically changed wide areas of Africa and Asia, thus making them uninhabitable for the rhinoceros. Since humans first pursued animals, the rhinoceros has been hunted. The pictures found in the Early Stone Age caves of Pech-Merle, Rouffignac, Colombiàre, and Les Trois Freres tell an obvious story. They show that these animals have had mystical significance since early times.

The Rhino Horn — Fascination and Superstition. It is commonly held that rhinoceros horns consist of matted hair, a view that is not quite correct. The horns consist throughout of *keratin*, and they do not have a bony pith like the horns of cattle. Under a microscope, however, one can see that the individual rods are not coated with an individual protective layer as is real hair. They adhere densely together in layers and thus resemble neither the hair nor the horn of a ruminant, but rather the material of the hoof. This construction gives the nose horn a stiffness and quality similar to a ruminant's horn with a pith. The nose horn sits on a bony dome formed by the nasal bone; it may unravel in places, causing it to look like a growth of hair. If it is torn by accident, only a lightly bleeding area remains on the nose. Soon a new horn begins to grow. In young animals, a horn may be replaced completely.

Except for the elephants, we find the largest terrestrial mammals among the rhinoceros. However, these handsome mammals provide a classical example of the extent to which humans are responsible for the decrease and extinction of large mammals. *Superstition* played a dominant and especially destructive part in the disappearance of many rhinoceros species. The Chinese, as well as other Asiatic people, have believed that powdered rhinoceros horns make an aphrodisiac. Many centuries ago, the powder made from these horns was sold in East Asiatic pharmacies at a high price. Since the rhinoceros is easy to kill, it has been poached ever since. Poaching has essentially made Asiatic species extinct, and African rhinos are rapidly facing extinction. A number of scientists have carefully tested the potions made from rhino horns and no evidence whatever has been produced to back up the superstitious claims.

Protection of the rhinoceros by raising them in captivity has had some success. The first rhinoceros ever to be born in captivity was a Sumatran rhino, born in 1889 at the Calcutta, India zoo. At that time the Sumatran rhino was not as rare as it is now. Success in raising rhinos in a zoo atmosphere is difficult to achieve for many reasons. Although the females reach sexual maturity at three years, the bulls do not become sexually mature until they are seven to nine years old. The average gestation period in captivity is between 462 and 489 days. The birth starts with episodes of labor lasting about an hour; the actual birth requires only 15–30 minutes. A neonate great Indian rhinoceros has an average weight of 143 pounds (65 kg). It has folded skin like an adult, with all the "rivets" and protuberances. The plum-shaped head is especially conspicuous in the newborn. There is a flat, smooth, oval plate where the nose horn will grow later. The young rhino grows at a fairly rapid rate, gaining as much as $4\frac{1}{2}$ to $6\frac{1}{2}$ pounds (2–3 kg) per day. Thus, the weight at birth is multiplied tenfold within one year. Shortly after birth, the shoulder height is about 25 inches (63 cm) and, in the second year, this approximately doubles. At the age of $3\frac{1}{2}$ to 4 years, the female is fully grown, while the bull may continue growing for up to five years.

Unlike roaming elephants, rhinos rarely return to areas where they once were exterminated. To reintroduce them, they must be caught in other places, transported, and set free. Since we obtain our information on the rhino no longer from big game hunters, but rather from scientists and game wardens, much has been learned about their life. Studies on their behavior really began only in 1960.

RHINOSPORIDIOSIS. A disease due to a yeastlike organism (*Rhinosporidium seeberi*), which infects the mucous membrane of the nose producing nasal polyps and, in other locations, tumors on the cheek, conjunctivae, lacrima, uvula, penis, and skin. It is found most often in India and Sri Lanka, but has also been reported from Indonesia, Malaysia, the Philippines, Iran, South Africa, Italy, the United Kingdom, the southern United States, and South and Central America. The disease is most often seen in children and young adults, in men more than women, but it can occur at any age and there is no racial differentiation. Infection is most often seen in laborers who are frequently exposed to water in streams or pools and cases have occurred in men who dive to recover sand. This suggests that *R. seeberi* has a natural habitat in the water, growing as a parasite of either fish or water insects. The most striking feature in the stroma of the polyps is the appearance of sharply defined globular cysts, varying in size from 10 to 200 micrometers (diameter). There is a chronic inflammatory reaction and occasionally micro-abscesses occur.

Friable, highly vascular, sessile and pedunculated polyps may be disseminated hematogeneously to the urine, palate, lungs, liver, spleen and other organs.

Treatment is essentially, surgical.

A. C. V.

RHINOVIRUSES. See **Virus**.

RHIZOIDS. Filamentous outgrowths from the surface, or from epidermal cells, formed of one or many cells, which serve to hold the plants of mosses and hepatics or the prothallia of ferns to the substratum. Similar structures occur in the thallophytes.

RHIZOME (or Rootstock). A horizontal stem growing beneath the surface of the ground or at times, at the surface. Rhizome has all the characteristics of a stem, such as nodes, and internodes, leaves and branches. Often it is very much enlarged and contains much reserve food material. See also **Stem (Plant)**; and **Asexual Reproduction**.

RHODIUM. [CAS: 7440-16-6]. Chemical element, symbol Rh, at. no. 45, at. wt. 102.906, periodic table group 9, mp. 1,963 to 1,969 °C, bp. 3,627 to 3,827 °C, density 12.44 g/cm^3 for solid (20 °C). Elemental rhodium has

a face-centered cubic crystal structure. The one stable isotope is ^{103}Rh. The seven unstable isotopes are ^{99}Rh through ^{101}Rh and ^{104}Rh through ^{107}Rh. In terms of earthly abundance, rhodium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for rhodium at 0.0067. No notable presence of rhodium in seawater has been found.

Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^8 5s^1$. Ionic radii Rh^{3+} 0.75 Å, Rh^{4+} 0.65 Å. Metallic radius 1.345 Å. First ionization potential 7.7 eV. Other physical properties of rhodium will be found under **Platinum and Platinum Group**. See also **Chemical Elements**.

Rhodium was discovered by Wollaston (England) in 1803. Compact Rh is almost insoluble in all acids at 100 °C, including aqua regia. Hot concentrated H_2SO_4 will slowly dissolve the finely divided metal. When alloyed with 90% or more of Pt, it is soluble in aqua regia. The metal is attacked by fused bisulfates. Rh is soluble in molten Pb. This is the basis of the classic separation of Rh and Ir.

Rh compounds exhibit valences of 2, 3, 4, and 6. The trivalent form is by far the most stable. When Rh is heated in air, it becomes coated with a film of oxide. Rhodium(III) oxide [CAS: 12036-35-0], Rh_2O_3, can be prepared by heating the finely divided metal or its nitrate in air or O_2. The rhodium(IV) oxide is also known. Rhodium trihydroxide may be precipitated as a yellow compound by adding the stoichiometric amount of KOH to a solution of $RhCl_3$. The hydroxide is soluble in acids and excess base. When the freshly precipitated $Rh(OH)_3$ is dissolved in HCl at a controlled pH, a yellow solution is first obtained in which the aquochloro complex of Rh behaves as a cation. The hexachlororhodate(III) anion is formed when the solution is boiled for 1 hour with excess HCl. The solution chemistry of $RhCl_3$ is often very complex. Two trichlorides of Rh are known. The trichloride formed by high-temperature combination of the elements is a red, crystalline, nonvolatile compound, insoluble in all acids. When Rh is heated in molten NaCl and treated with Cl_2, Na_3RhCl_6 is formed, a soluble salt that forms a hydrate in solution. Rhodium(III) iodide is formed by the addition of KI to a hot solution of trivalent Rh.

Rhodium(III) sulfate exists in yellow and red forms. If $Rh(OH)_3$ is dissolved in cold H_2SO_4, the product is the yellow form, in which the sulfate is ionic. If this solution is evaporated in hot H_2SO_4, the product is a red, nonionic sulfate. When Rh is treated with F_2 at 500–600 °C, RhF_3 is slowly formed. This compound is practically insoluble in water, concentrated HCl, HNO_3, H_2SO_4, HF, or NaOH.

If a solution of $RhCl_3$ is treated with $NaNO_2$, the very soluble sodium hexanitritorhodate(III), $Na_3Rh(NO_2)_6$, is formed. The solubility of this compound in alkaline solution makes it useful for refining, as many base metals are precipitated as their hydroxides under these conditions. The analogous ammonium and potassium salts are relatively insoluble.

When H_2S is passed into a solution of a trivalent Rh salt at 100 °C, the hydrosulfide, $Rh(SH)_3$, is formed. This black precipitate is insoluble in $(NH_4)_2S$. Rh forms many complexes with NH_3, amines, cyanide, chloride, bromide, and numerous polynitrogen and polyoxygen chelating agents.

EDITOR'S NOTE: In 1982, J. Halpern (University of Chicago) reported that rhodium complexes containing chiral phosphine ligands catalyze the hydrogenation of olefinic substrates such as alpha-aminoacrylic acid derivatives, producing chiral products with very high optical yields. Elucidation of the mechanisms of such reactions leads to the conclusion that the stereoselection is dictated not by the preferred initial binding of the substrate to the chiral catalyst, but rather by the much higher reactivity of the minor diastereomer of the catalyst-substrate adduct corresponding to the less favored binding mode. In the Halpern 1982 reference listed, a relatively restricted class of asymmetric catalytic reactions, namely, the hydrogenation of alpha-acylaminoacrylic acid derivatives and related substrates, catalyzed by rhodium complexes containing chiral phosphine ligands, is discussed.

RHODOCHROSITE. Rhodochrosite, manganese carbonate [CAS: 598-62-9], $MnCO_3$, is a rose-pink to red hexagonal mineral, occurring as small crystals, in cleavable masses, granular or compact. It is a brittle mineral; hardness, 3.5–4; specific gravity, 3.7 (pure $MnCO_3$, usually 3.4–3.6); luster, vitreous to pearly; color, various shades of pink, red and reddish-brown; transparent to opaque; streak, white. Rhodochrosite has a perfect rhombohedral cleavage. Rhodochrosite is a product of high-temperature metamorphic deposits; as a gangue mineral in ore veins of hydrothermal origin, and as secondary residual deposits from bodies of manganese or iron oxides, and in sedimentary deposits precipitated like siderite by organic matter acting, in the absence of oxygen, upon bicarbonates.

Spectacular, gemmy red rhombohedrons, up to 3 inches (7.5 centimeters) on an edge occur at the Sweet Home Mine, Alma, Colorado, and the John Reed Mine, Alicante, Colorado. Exceptionally fine stalactitic formations are found in Catamarca Province, Argentina. Recently the most beautiful, large transparent gem red scalenohedron crystals ever found have come from Hotazel and the Kalahari manganese field in northern Cape Province, South Africa. This region encompasses one of the largest and richest known manganese deposits in the world. Other localities for this mineral are in Rumania, Saxony, Westphalia, and Cornwall, England. In the United States rhodochrosite is found at Franklin, New Jersey; Butte Montana; and in various localities in Colorado and Nevada. The name rhodochrosite is derived from the Greek meaning rose, and color.

RHODODENDRONS. See **Heather Shrubs and Trees**.

RHODONITE. The mineral rhodonite, manganese metasilicate, (Mn,Fe, Mg)SiO_3, crystallizes in the triclinic system forming large, irregular tabular crystals but usually occurring massive. Prismatic and basal cleavages excellent; fracture conchoidal to uneven; hardness, 5.5–5.6; specific gravity, 3.57–3.76; luster, vitreous to pearly on cleavage faces; color, red to brownish-red; rarely yellow to gray; streak, white; transparent to translucent. A variety containing much calcium is called bustamite. Zinc may replace the manganese in rhodonite; it is then known as fowlerite. Rhodonite is found in the Harz Mountains, Germany; in the Urals of the former U.S.S.R.; in Hungary, Italy, and Sweden. Bustamite from Mexico, Franklin and Sterling Hill, New Jersey, occurs with fowlerite.

Rhodonite has been occasionally used for an ornamental stone. Its name is derived from the Greek meaning a rose, because of the color.

RHOMBIC ANTENNA. See **Antenna**.

RHO-THETA SYSTEM. 1. Any electronic navigation system in which position is defined in terms of distance, or radius ρ and bearing θ with respect to a transmitting station. Also called an *R-theta system*. 2. Specifically, a polar-coordinate navigation system providing data with sufficient accuracy to permit the use of a computer which will provide arbitrary course lines anywhere within the coverage area of the system. See also **Navigation**.

RHUBARB *(Rheum rhaponticum; Polygonaceae).* The rhubarb plant is perennial from thick, short rhizomes. The large, somewhat triangular leaf

blades are elevated on long fleshy petioles. The flowers are small, greenish-white and borne in large compound leafy inflorescences. The plant is principally grown for its fleshy petioles. These are stewed to yield a tart sauce used as filling for pies and tarts. The plant is indigenous to Asia.

RHUMB LINE. Unless a ship is tacking or executing some other maneuver its course is generally constant for several hours at least. In such a case the ship is said to be following a rhumb line. The rhumb line, or loxodromic curve, may be defined as any curve on the surface of the earth such that the tangent of the curve at any point cuts the meridian through that point at a constant angle. In case this angle has any value other than 0° or 90°; it may be proved that the rhumb line is a spiral approaching one of the poles of the earth as a limit.

Obviously, the rhumb line course between any two points is the simplest course to follow, for once having set the course it will not have to be changed until the destination is reached. However, except in the particular cases where the two points are either on the same meridian or are both on the equator, the rhumb line will not be the shortest distance between the two points. The mercator chart was designed for the purpose of facilitating the laying down of rhumb-line courses. On a mercator chart, and only on this chart, the rhumb line appears as a straight line.

See also **Course**; and **Navigation**.

RHYOLITE. The general term for a group of acidic igneous rocks, the effusive equivalent of the granites. It occurs as lava flows, breccias, and in volcanic necks and dikes. In the porphyritic varieties the phenocrysts are frequently quartz or othoclase feldspar imbedded in a highly felsitic or glassy ground mass. Rhyolites, including obsidian, frequently show flow, spherulitic, nodular, and lithophysal structures.

RIBBON LIGHTNING. See **Lightning**.

RIBBON PARACHUTE. A type of parachute having a canopy consisting of an arrangement of closely spaced tapes. This parachute has high porosity with attendant stability and slight opening shock.

RIBONUCLEASE. An enzyme that causes splitting of ribonucleic acid. Pancreatic ribonuclease for example, cleaves only phosphodiester bonds that are linked to pyrimidine-3′-phosphates. It is a critical regulator of life processes in the cell. The first enzyme to be synthesized (1969), is composed of 124 amino acid residues. It is one of the proteins for which the sequence of amino acids has been elucidated (the order of sequence of amino acids is of critical importance in the functioning of enzymes, genes, and nucleotides).

See also **Genetic Code**; and **Genetics and Gene Science (Classical)**.

RIBOSE. See **Nucleic Acids and Nucleoproteins**.

RIBOSOME. A ribonucleoprotein, the smallest organized structure in the cell. Ribosomes occur in all cells including bacteria, fungi, algae, and protozoa. They are the central point of protein synthesis. They contain from 45 to 60% of ribonucleic acid (RNA), the balance being proteins. Ribsome crystals have been produced; in the electron microscope these appear as sheets of black dots, each sheet (one ribosome thick) containing hundreds of ribosomes in recurring groups of four.

See also **Genetics and Gene Science (Classical)**.

RIBS. In humans, the ribs number twenty-four, twelve on either side. They are attached to the vertebral column behind, and the first seven pairs are connected with the sternum in front and are called true ribs. The remaining five are called false ribs. The eighth, ninth and tenth are attached in front to the cartilaginous portion of the next rib above. The lower two, that is the eleventh and twelfth, are not attached in front at all and are called floating ribs. The spaces between the ribs are called intercostal spaces; they contain the intercostal muscles, nerves and arteries. The ribs form the greater part of the bony cage of the thorax; they preserve its outline and allow for easy motion in breathing, due to their elasticity.

RICE *(Oryza sativa; Gramineae).* An annual grass, which grows wild in tropical Asia and Africa. Cultivated rice is probably derived from an Asiatic species, and is especially adapted to grow in swampy or very wet lowlands. It is a shallow rooted plant, the stems of which tiller abundantly and grow from 2–6 feet (0.6–1.8 meters) or more in height. The leaves are long and smooth. The inflorescence is a panicle the branches of which may occur singly or in pairs. See Fig. 1. The laterally compressed spikelets are one-flowered, and have a pair of small bristlelike glumes; the lemma is tough, parchment-like and sometimes awned; the palea resembles the lemma, but is somewhat smaller. A distinctive character of the flower is the presence of six functional stamens. Commonly, rice is self-pollinated. The grain or karyopsis is enwrapped in the palea, and frequently also in the lemma. In this condition, rice grain is known as paddy, or rough rice. The grain itself is smooth and shining, has a pair of longitudinal grooves on its surface, and a glassy endosperm. In structure it is very similar to wheat grain.

Fig. 1. Rice panicle in bloom showing the anthers that have just dehisced and shed pollen on the stigma. (*USDA photo*.)

The milling of rice involves several processes. First, the outer coverings are removed by revolving stones and fans. After this, the outer seed-coats and embryo are largely removed by rubbing; the remaining grain is scoured and polished by rubbing on leather surfaces. Finally, the polished grain is given a coat of glucose and talc, and is ready for market.

Varieties. There are two major eco-geographic races of *O. sativa*: (1) indica and (2) japonica. The latter sometimes also is known as *sinica* or *keng*.

Indica is the major group grown throughout southeastern Asia and in most areas of the People's Republic of China. The majority of indica varieties raised in the monsoon tropics have evolved from combined natural and human selection processes. They are well adapted to conditions of low-soil fertility, uncertain weather, and poor water control. Most indicas have resistance to endemic diseases and insects, and they also compete well with weeds. They also have the dry cooking characteristics preferred by consumers in tropical and subtropical areas. But the features that enable the tropical types of indica to survive (i.e., tall and high tillering plants, late maturity, long and drooping leaves) also provide the basis for their weakness under modern agricultural practices. Improved fertilization, for example, will lead mainly to vegetative growth and lodging (tendency of a crop to bend over and avoid being cut by a machine) rather than significantly increased yield.

Japonica varieties are distributed widely in several areas of the Temperate Zone, such as the Yangtze valley of China, Korea, Japan, Europe, part of Australia, and the United States. The japonica varieties evolved in China more recently than the indicas and are the result of an intensive human selection process. In comparison with the indicas, the japonicas have darker and more upright leaves, a shorter and stiffer stalk, earlier maturity, and more thrifty vegetative growth. Japonicas respond well to improved cultural practices, especially the application of fertilizer, and are more resistant to lodging. See Fig. 2.

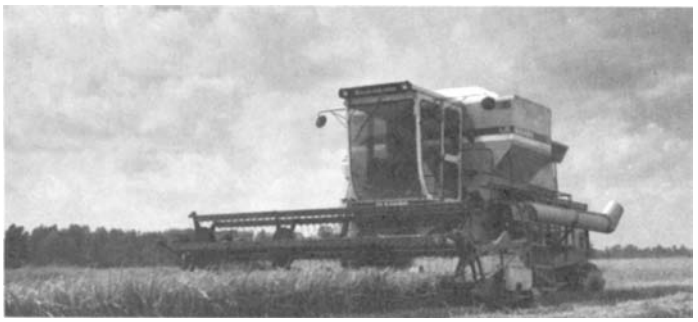

Fig. 2. Rice field in the United States showing a large, specially designed harvesting machine. (Allis-Chalmers.)

Japonicas, however, are not well adapted for the traditional cultural practices in tropical Asia because:

1. They require precise amounts of water.
2. They need weed and insect control.
3. Most are susceptible to virus diseases of the tropics.
4. Some react to high temperatures during early growth stages by flowering too early.
5. They lack the grain dormancy needed in the monsoon season.
6. The grains have a sticky cooking quality not desirable in the Orient.

Wild rice is found and harvested in some regions of the world. The variety *Zizania acquatica* grows in lakes and small streams in the upper midwestern United States and southern Canada. Wild rice is an annual grass that also can be grown in flooded soils similar to white rice. The grain of wild rice was a staple food for the American Indians in such regions and now is considered a favorite of the gourmet chef. Much of the wild rice grown in the United States comes from the Minnesota and Wisconsin lakes.

High-yielding types of rice tend to be raised under irrigated conditions. Both the quality of irrigation systems and the need for irrigation vary widely in the developing nations. Irrigation systems range from virtually complete, year-round supplies to occasional supplementations of rainfall. Most commonly, the systems supplement rainfall during the wet season and service only a limited area during the dry season.

Extensive research into the genetics of rice and toward breeding improved varieties has occurred, mainly since the early 1960s. The activities of the International Rice Research Institute (IRRI, Los Banos, Philippines) and the Indian Council of Agricultural Research are particularly well known. The use of high-yielding varieties of rice (along with wheat) formed the basis for what became known as the "green revolution." See also **Green Revolution**.

Culture. As previously mentioned, most rice is grown in tropical and subtropical regions of the world (between 30° North and 30° South latitude). Notable exceptions are Italy, Japan, Korea, Spain, and the United States. The growing season for rice ranges from 4 to 6 months, during which time the mean temperature should be no lower than 70 °F (21.1 °C). Without irrigation, rainfall in excess of 40 inches (102 cm) per year is required. But the crop does very well in irrigated and flooded areas where the weather may be hot and dry. Situations like this prevail in the Po valley of Italy, the Nile valley of Egypt, and the Sacramento valley of California, where rice is grown on flooded land. See Fig. 3. In many areas, such as California, the soil is submerged with 4 to 8 inches (10–20 cm) of water from seeding or shortly thereafter until a short time before the grain

(**a**)

(**b**)

Fig. 3. Rice fields in the United States. (**a**) Submerged field of young rice; (**b**) 6 to 8 weeks after submerging the land. (*USDA photo*.)

is mature. Water may be drained off once or twice for a few days for applications of fertilizer and chemicals to aid the control of algae, rice water weevils, and aquatic weeds. The chemistry of flooded soils differs markedly from dry soils:

1. Decrease in exchange of air (gases) between soil and the atmosphere, leading to low oxygen levels and high levels of hydrogen, methane, and various oxides of nitrogen in the soil;
2. An increase in soil pH from 0.7 to 1.5 units; and
3. An increased salt content of the soil.

Soil microorganisms under flooded conditions tend to be active forms of anaerobes. These forms require less energy, and thus soil organic matter decomposition takes place at a slower rate. A significant factor is that flooding makes the use of nitrate forms of nitrogen less efficient because of potential denitrification and loss of nitrogen. Nitrogen deficiency as well as those of phosphorus and potassium can be applied preplant, at planting, or within 2 to 3 weeks after planting.

In summary, of the cereal crops, rice ranks second in world tonnage and sixth in tonnage of cereal crops produced in the United States.

In terms of major rice-producing countries, China accounts for about 30%, followed by India (about 20%) and the southeastern Asian countries (about 50%). The United States accounts for less than 2% of world production.

RICHARDSON NUMBER. This number is a ratio used in meteorological evaluation of the degree to which atmospheric flow (winds) will be turbulent or nonturbulent. The ratio is formed by dividing the square of the shear of the horizontal wind in the vertical direction into the thermal stability of the atmosphere. The general form of the number is

$$R_i = \frac{\frac{g}{\theta}\frac{d\theta}{dh}}{\left[\frac{dV}{dh}\right]^2}$$

where g = gravitational acceleration
i = the meteorological potential temperature
V = the horizontal wind vector
h = height

Liberally interpreted, the denominator represents the turbulent generating forces and the numerator the turbulent damping forces. The expectancy would be that the borderline value would be unity. However, in actual cases, the breakover from laminal to onset of turbulent flow is in the general region of $R_i = 0.25$. See also **Atmospheric Turbulence**.

RICHARDS, THEODORE W. (1868–1928). An American chemist born in Germantown, PA. He was the first American to receive the Nobel Prize in chemistry (in recognition of his accurate determinations of the atomic weight of a large number of chemical elements). He studied chemistry at Haverford and Harvard, with a doctorate in chemistry from Harvard where he later became Erving Professor of Chemistry. An outstanding ezperimental chemist, his major interests were atomic weights, thermochemistry, and thermodynamics. He was also a brilliant teacher. He was president of the ACS in 1914, and the recipient of many honorary awards, including the Davy, Faraday, and Gibbs medals.

RICHET, CHARLES (1850–1935). The eldest son of one of the most prominent surgeons in Paris, Richet reluctantly followed his father's wishes and entered medical school in 1868. He was bored by his medical studies, especially by clinical practice, and soon decided to devote himself to physiological experimentation. During the 1870s, Richet spent several research periods in the laboratories of many leading French physiologists of the day, including Paul Bert, Jules Marey and Charles Robin. In 1881 he was appointed a member, and in 1887 Professor of Physiology, in the Medical Faculty in Paris, where he stayed until the end of his academic life. See also **Immunology (The History)**; and **Physiology (The History)**.

Richet began his scientific career when physiology was just entering its modern, experimental period. At the time, physiology and pathology were rapidly adapting to the new aetiological stance, propagated mainly by German scientists like the physiologist Carl Ludwig and the bacteriologist Robert Koch. Their aim was to make sense of all life processes in terms of specific agents (e.g. cells, or microorganisms) bringing about specific processes (e.g. digestion, or a specific disease). Richet, on the other hand, largely adhered to a (mostly French) tradition of attempting to comprehend physiological phenomena in their totality. Instead of identifying causal agents, Richet wished to understand the reactivity patterns of organisms when confronted with environmental changes. Thus, rather than attempting to specify, for example, the typical pathologies of particular toxins, Richet focused on the general physiological reactions underlying intoxication. This interest in the ability of the individual to respond to external challenges, and specifically in the regulative functions of the body, became one of Richet's main areas of research after 1880. It was while investigating the dynamics of heat regulation that, in 1886, he discovered the cooling function of rapid breathing in dogs. In many ways, Richet's work between 1880 and 1900 was a forerunner of Walter Cannon's researches on homeostasis some thirty years later. See also **Koch, Heinrich Hermann Robert (1843–1910)**; and **Ludwig, Carl Wilhelm Friedrich (1816–1895)**.

Richet's discovery of anaphylaxis was a direct derivative of his general research program. In July 1901 Richet was invited by Prince Albert of Monaco to join him on a research cruise on his yacht. Richet collaborated with another French biologist, Paul Portier, in investigating the toxic properties of the *Physalia* found in the South Seas (Portuguese man-of-war). One of the reasons Richet became so interested in the extracted toxin was its peculiar effect. In small doses, not sufficient to kill the animals available on board, the toxin had an effect that Richet considered reminiscent of hypnosis — he thus named it "hypnotoxin." Back in France, Richet and Portier carried on their investigation, attempting to understand the patterns of immunization or sensitization to the toxin. They soon realized that repeated injections of very small doses of the substance to dogs often brought about an unexpected adverse reaction, usually fatal to the animal.

The mere fact that some individuals react adversely to repeated immunization was known at least since the introduction of mass immunization against diphtheria in the early 1890s, but little systematic study had been done on the phenomenon. Emil von Behring reported several such cases and even coined the term "hypersensitivity." However, interested only in specific bacteria and their specific "antibodies," Behring and his colleague Paul Ehrlich largely dismissed "hypersensitivity" as a mere anomaly. Richet, on the other hand, and in contrast to most of his contemporaries, was attentive to the mechanism behind this idiosyncratic reaction. He hypothesized that it was yet another protective and regulatory reactivity pattern of the organism — a "defense reflex." Consequently, as with other reflexes he had studied, Richet hypothesized the reflex associated with hypersensitivity to be dependent on a specific frequency of excitement. In a series of experiments between 1901 and 1908 Richet had shown that various substances, when injected into laboratory animals in extremely small doses (too small to provoke any observable reaction), become highly harmful when injected again, in the same minimal dose, after an interval of several weeks. This secondary intoxication (*anaphylactic shock*) is acute but short — either the animal dies or it rapidly and fully recovers. See also **Ehrlich, Paul (1854–1915)**.

Richet's discovery was followed, most notably, by the work of Maurice Arthus on the "Arthus reaction" and Clemens von Pirquet's explanation of "serum sickness." Within a few years, a new field of research emerged, dealing with the adverse reaction of the body to foreign substances to which it is exposed — the science of hypersensitivity and allergy. For his work on anaphylaxis Richet was awarded the 1913 Nobel Prize for Physiology or Medicine.

Richet was an enthusiastic admirer of technology. He employed many new experimental technologies in his work, including photography and graphic recordings. In the second phase of his career he became increasingly interested in the practical applications of science. In the 1890s he took part in the first attempt to build a manned airplane in France. Shortly afterwards he claimed to have developed a new nutrient supplement, termed "Zomine," made of raw meat extracts and allegedly helping to cure a series of human diseases. During World War I he received official permission to use sick soldiers as "guinea-pigs" to test this substance. As he reported, "it seemed to work." Similarly, during the war he experimented on blood transfusions with wounded soldiers — an endeavor that, in the absence of awareness of blood groups, had fatal results. See also **Nutritional Science (The History)**.

Richet's fields of interest went far beyond experimental physiology. His writings include historical, political and literary works. Most notable is his life-long interest in hypnosis and parapsychology. Richet rejected unsubstantiated spiritualist claims, but at the same time believed humans

may possess faculties and capabilities science had not yet recognized. He maintained that strict experimental procedures could lead to the understanding of phenomena like telepathy and telekinesis.

RICHTER, CHARLES FRANCIS (1900–1985). Richter was an American scientist who was a pioneer in seismology. He was born in Ohio, but moved to California when he was nine years old. He loved the outdoors and hiked and backpacked throughout California. He earned an A.B. degree in physics from Stanford University. Although he started graduate work at Caltech, he changed directions and took a job at the Carnegie Institution of Washington's seismological laboratory. Here, working with Beno Gutenberg, Richter in 1935, devised a scale to measure the magnitude of earthquakes. Richter's scale measured a quake's magnitude at its epicenter.

Richter and Gutenberg went to Caltech in 1937 and continued to work on earthquake research documenting that several hundred thousand earthquakes occur each year around the world. They mapped earthquake-prone areas. Richter is credited with convincing Los Angeles City to update its building codes and do retro-fit work to lessen damage from earthquakes.

RICKETTSIAL DISEASES. This group of diseases is caused by very small ($1-2 \times 0.3$ micrometer) Gram-negative bacilli which are distinguished from other bacteria because of their obligate intracellular parasitism. The mode of entry into, and growth in, eukaryotic cells is variable and in this the symptoms manifested by their presence are influenced. As a whole, the group of diseases has been divided into three groups: (1) the *typhus group*, including endemic (murine) typhus, epidemic (louse-borne) typhus, and Brill-Zinsser disease; (2) the *spotted-fever group*, including Rocky Mountain spotted fever and rickettsial pox; and (3) a miscellaneous group, of which the main disease is Q fever. With the exception of Q fever, rickettsia enter the body by way of the bite of an insect, such as tick and louse. In Q fever, the microorganisms are inhaled as components of infected dust.

Typhus (Murine Endemic). In the United States, the disease is endemic in the southeastern and Gulf states. The reservoir of *Rickettsia typhi*, the causative agent, is the rat, in which the disease is a natural infection. Murine typhus occurs worldwide. The disease is transmitted from rat to human by a rat flea. When infected, the rat flea excretes rickettsias in its feces. In the absence of their normal host, the rat flea will attack humans and while feeding will drop rickettsia-containing feces. If the latter are rubbed into the bite site or other breaks in the skin, human infection commences. The incidence of murine typhus in the United States dropped to a low point of about 40 cases in 1969, rose to nearly 70 cases in 1977 and, in recent years, has cycled between 50 and 60 cases per year. As in past years, most cases are reported from Texas, although Maryland, Florida, Tennessee, Louisiana, California, and Hawaii also have reported occurrences. Statistics show that the highest incidence occurs during the summer and fall, with a majority of cases found in persons who work in various food depositories, which are, of course, attractive to rats. Effective rodent and flea control can reduce the incidence of the disease.

After an incubation period of 6–14 days, clinical features include headache, malaise, backache, and chills — to be followed later by shaking chills, fever, severe headache, vomiting, and nausea. The fever ranges between 102–103 °F (38.9–39.4 °C). In the untreated individual, there is a pattern of remittent fever, sometimes accompanied by tachycardia (fast heartbeat). On about the fifth day of fever, a rash consisting of irregular, discrete, pink macules occurs in the axilla and inner surface of the upper arms. Later, the lesions will appear on the trunk, thighs, and lower arms. Rarely are they found on the face, hands, or feet. The rash usually disappears in about one week. During the second week of infection. a dry cough may develop. In elderly people and persons of marginal health, more severe symptoms may be manifested. These include a greater severity of headache, stiff neck, aggravating backache, and, sometimes, mental confusion. These symptoms may be confused with those of meningitis.

Murine typhus is sometimes difficult to differentiate from Rocky Mountain spotted fever, particularly since the two diseases are frequently present in the same geographical region. Compared with other rickettsial diseases, murine typhus is relatively mild. The mortality rate of murine typhus is low, even in untreated cases. Therapy usually consists of oral doses of tetracycline.

Typhus (Louse-Borne Epidemic). Unlike murine typhus, this form of typhus, of which the causative agent is *R. prowazekii*, is very serious and has caused millions of deaths, particularly in eastern Europe and the Balkan countries after World Wars I and II. The body louse is the vector of transmission. The incubation period approximates one week. Clinical features include an abrupt commencement of headache, chills, prostration, and high fever, which may rise to 103–104 °F (39.4–40.0 °C). These symptoms, including fever, may persist for several days. As with murine typhus, a pink rash occurs on about the fifth day. Conjunctivitis frequently occurs. There may be a dry cough. In severe infections, renal failure and mental confusion may be present. The fever lowers in about two weeks in untreated patients.

As with murine typhus, louse-borne typhus is sometimes difficult to differentiate from Rocky Mountain spotted fever. In making the diagnosis, the physician will carefully note the differences in the evolution and character of the rash, as well as considering the epidemiologic setting.

Drugs of choice for the treatment of epidemic typhus include chloramphenicol and tetracycline. Doxycycline is also sometimes used. If treatment is commenced within a day or two of onset of symptoms, fever is usually reduced within 48 hours. The severity of epidemic typhus is age-related. The disease is mild and with few fatalities in children. The mortality in untreated adults ranges between 10 and 50%, even higher among adults over 60 years of age. With the availability of antibiotic therapy, the mortality rate has been reduced to a few percent of cases.

Prior vaccination against typhus reduces the severity and duration of the disease. This is a killed rickettsial vaccine derived from infected yolk sac tissue. In the United States, the rate of typhoid fever occurrence has remained relatively steady for the past decade. Underreporting does not appear to be a major problem affecting the statistics. In recent years, more than half of the cases have been acquired during travel to other countries. During World War II years, there were just over 4 cases per 100,000 population reported. Current incidence is about 0.2 case per 100,000 population.

Even at some risk, an effective way to prevent epidemic typhus is the mass delousing of the population with an insecticide, such as DDT or lindane powder, which have been banned by many countries except in emergency situations.

Brill-Zinsser Disease (Recrudescent Epidemic Typhus). This disease occurs after a prior infection with louse-born typhus and results from reactivation and multiplication of *R. prowazekii*, which have been dormant for a long period. The delayed mechanism for this activation is poorly understood. The disease is usually a mild form of the prior infection and is to be suspected in patients who present with fever and headache and who, upon interviewing, had epidemic typhus, particularly during the epidemic of World War II. The frequency of Brill-Zinsser disease is greatest in Eastern Europe, Poland, and the former U.S.S.R.

Rocky Mountain Spotted Fever. Caused by *R. rickettsii*, this disease is transmitted by tick vectors. In the eastern United States, the dog tick is usually responsible; the wood tick in the western states; and the Lone Star tick in the southwestern states. Ticks are infected by feeding on infected rodents and other small wild animals. The infection is non-lethal to the tick and is carried throughout the life of the tick. Although the disease was first identified in the Rocky Mountain area, this region now accounts for less than 5% of cases. The majority of cases in the United States are now found in the southeastern states, notably in the Piedmont region. About 90% of patients have onset of illness from early April to early September. A large number of cases occur in children. Mortality rates have fallen, but still remain above the overall mortality rate of 3.2%. In 1979, the incidence was 0.5 case per 100,000 population. Although not fully understood, it is now known that pet dogs can be accidental hosts to the rickettsiae.

The incubation period of the disease is approximately 2 to 7 days. Onset is usually abrupt and the clinical features are severe headache, nausea, rigor, and high fever. Severe abdominal pain may be present. Within one or two days, the fever rises to 103–105 °F (39.4–40.6 °C). A rash appears, usually in the regions of the wrists and ankles, but gradually spreads to include the trunk and face. Unlike the rickettsial diseases previously described, in Rocky Mountain spotted fever, lesions do appear on palms and soles, these serving as useful diagnostic indicators. A tenderness of the muscles is noted upon compression of limbs. In some cases, a dry cough may be present. Heartbeat increases with fever. Prior to appearance of the rash, the symptoms tend to parallel those of several acute bacterial or viral infections. The physician, during this period, will question the patient as regards possible recent exposure to areas where ticks may be found. Antimicrobial therapy should be commenced at the time the rash appears. Drugs of choice are chloramphenicol or tetracycline. Sulfonamides have not proved effective in the treatment of this disease. Commencement of therapy prior to the sixth day of illness usually results in excellent prognosis.

Q Fever. This is an influenzalike disease first reported from Queensland (Australia) in 1935 and since then from Montana and other parts of the United States as well as North Africa, Switzerland, and Great Britain. Q fever is caused by the rickettsia *Coxiella burnetii*, which has its major effect on the lungs. The infection is nearly always airborne. The disease is particularly found in regions where cattle, sheep, and goats are produced. Livestock usually are infected by breathing dust containing the microorganism, but may be infected by ticks. Notably prone to infection are workers in dairies, abattoirs, and laboratory workers engaged in research on the rickettsiae. The incubation period ranges from 18 to 20 days. Clinical features include headache, chills, fever, myalgias, anorexia, and malaise. There is no rash. Fever may reach 104 °F (40 °C). Chest x-rays almost always indicate focal areas of pneumonitis. Complications include granulomatous hepatitis, jaundice, and abnormal liver function. In several instances, infective endocarditis has been reported. Early diagnosis is often difficult because the symptoms resemble those of numerous other acute febrile illnesses, such as salmonellosis, infectious hepatitis, brucellosis, leptospirosis, and infectious mononucleosis. In the early stages, indication by the patient of recent contact with livestock is an excellent clue.

The drugs of choice for treatment include tetracycline or chloramphenicol. Recovery with treatment is normally rapid. Some protection to persons of high risk to infection can be provided by killed vaccines made from *C. burnetti* grown in chick embryo culture. In rare instances, Q fever can be transmitted by infected milk.

Other Rickettsial Diseases. Boutonneuse fever is found along the coasts of the Mediterranean and Black Seas, as well as in the interior of Africa, where it is called *South African tick bite fever*. *Siberian tick typhus* is found in Mongolia and Siberia. *Queensland tick typhus* occurs in Australia. Caused by *R. tsutsugamushi* with a mite as vector, scrub typhus occurs in southeastern Asia, India, northern Australia, and the western Pacific Islands. *Trench fever* or *Volhynia fever* is transmitted by a louse and occurs in Mexico, northern Africa, Poland, and the former U.S.S.R. This disease is caused by *Rochalimaea quintana*. These rickettsial diseases essentially have symptoms that parallel those of the diseases previously described in this entry. Chloramphenicol or tetracycline are usually the drugs of choice in their treatment.

RIDGE. 1. In meteorology, an elongated area of relatively high atmospheric pressure, almost always associated with and most clearly identified as an area of maximum anticyclonic curvature of wind flow. The locus of this maximum curvature is called the ridge line. Sometimes, particularly in discussions of atmospheric waves embedded in the westerlies, a ridge line is considered to be a line drawn through all points at which the anticyclonically curved isobars or contour lines are tangent to a latitude circle. The most common use of this term is to distinguish it from the closed circulation of a high (or anticyclone); but a ridge may include a high (and an upper-air ridge may be associated with a surface high) and a high may have one or more distinct ridges radiating from its center. The opposite of a ridge is a trough.

2. Also used as reference to other meteorological quantities such as equivalent potential temperature, temperature, and mixing ratio. That is, an elongated area of relatively high values of any particular field emanating from a maximum.

3. In oceanography, a linear accumulation of broken ice blocks projecting upward, formed by ice deformation, often at the edge of a floe. A ridge is distinguished from a hummock by being much longer than it is wide. The term ridge is often used to describe an entire ridged ice feature, in which case the portion above the water line is termed the sail and the portion below the water line is termed the keel.

RIEBECKITE. The mineral riebeckite, essentially sodium iron silicate, $Na_2(Fe_3^{2+}, Fe_2^{3+})_5Si_8O_{22}(OH)_2$, is a monoclinic member of the amphibole group, usually in prismatic crystals. It has a prismatic cleavage; hardness, 5; specific gravity, 3.32–3.382; vitreous luster; color dark bluish to black. It occurs in granites and syenites chiefly. It is found in Greenland, Portugal, Madagascar, and South Africa (crocidolite), and in the United States at Quincy, Massachusetts; near Pikes Peak, Colorado, and the San Francisco Mountains, Arizona.

RIEKE DIAGRAM. A polar-coordinate load diagram for microwave oscillators, particularly klystrons and magnetrons. Constant-power and constant-frequency contours are plotted against the polar plot of load admittance, commonly called the Smith chart.

RIEMANN, (GEORG FRIEDRICH) BERNHARD (1826–1866). Riemann was a German mathematician whose early work was on the theory of functions of a complex variable and on the potential theory. He was a brilliant thinker and is remembered for a new non-Euclidean system of

geometry that is important in modern physics. Riemann is credited with introducing the idea of finite but unbounded space.

RIEMANN HYPOTHESIS. See **Number Theory**.

RIEMANNIAN GEOMETRY. See **Geometry**.

RIEMANN-PAPPERITZ EQUATION. A second-order linear differential equation, as studied in the Fuchs theorem, with three regular singular points in the finite plane at $x = a, b, c$. It may be symbolized by the Riemann P-function

$$y = P \left\{ \begin{matrix} a & b & c & \\ a' & b' & c' ; & x \\ a'' & b'' & c'' & \end{matrix} \right\}$$

where a', a'', b', b'', c', c'' are the exponents at the singularities, y is the dependent variable and x, the independent variable.

The Riemann problem in the theory of linear differential equations consisted of the search for a function to satisfy a given P-function. It is shown that the transformation of variable

$$u = \left(\frac{x-a}{x-b}\right)^k \left(\frac{x-c}{x-b}\right)^l y$$

will shift the exponents of the differential equation to $a' + k$, $a'' + k$, $b' - k - l$, $b'' - k - l$, $c' + l$, $c'' + l$, without affecting the singular points. On the other hand, the general linear transformation

$$x = (Az + B)/(Cz + D); \quad (AD - BC) \neq 0$$

will shift the singular points to three new positions, say a_1, b_1, c_1, as determined by the transformation but the exponents will not be altered. Combination of these two transformations will thus result in a standard form of the linear differential equation of Fuchsian type. The standard form is usually taken as the Gauss hypergeometric equation. The solution of any given linear differential equation of second order with three or fewer singular points will therefore be a special case of solutions to the Gauss equation, for the given differential equation can always be converted into the latter by suitable transformation of variables as described.

See also **Gauss Hypergeometric Equation**.

RIEMANN SURFACE. A surface used in representing multivalued functions of the complex variable. One sheet is assigned to each branch of the function, each sheet is cut at the branch line, and all are joined together so that a closed contour may be traced by passing continuously along the sheets of the surface.

See also **Geometry**.

RIEMANN ZETA FUNCTION. An infinite series in the complex variable $z = x + iy$, with n an integer:

The function is analytic with a simple pole at $z = 1$. It is a higher transcendental

$$\zeta(z) = \sum_{n=1}^{\infty} n^{-z}$$

function, that is, one not defined as the solution of a differential equation.

RIESZ, FRIGYES (1880–1956). Riesz was born in Hungary. He studied at Budapest and did his doctoral dissertation on geometry. He is best remembered for being the founder of functional analysis. He provided a link between Lebesgue's work on real functions and the area of integral equations developed by Hilbert. The Riesz-Fischer theorem is fundamental in the Fourier analysis of Hilbert space. His findings in functional analysis had fundamental importance in early quantum theory.

Riesz was chair of mathematics in the University of Budapest, he was elected to the Hungarian Academy of Science and was awarded the 1949 Kossuth Prize.

See also **Functional Analysis**.

J. M. I.

RIFT VALLEY FEVER. Rift Valley fever (RVF) is an acute, fever-causing viral disease that affects domestic animals (such as cattle, buffalo, sheep, goats, and camels) and humans. The RVF is most commonly associated with mosquito-borne epidemics during years of heavy rainfall.

The disease is caused by the RVF virus, a member of the genus *Phlebovirus* in the family Bunyaviridae. This disease was first reported among livestock by veterinary officers in Kenya in the early 1900s. RVF is generally found in regions of eastern and southern Africa where sheep and cattle are raised. However, RVF virus also exists in most countries of sub-Saharan Africa and Madagascar.

The RVF virus primarily affects livestock and can cause disease in a large number of domestic animals (this situation is referred to as an "epizootic"). The presence of an RVF epizootic can lead to an epidemic among humans who are exposed to diseased animals. The most notable epizootic of RVF, which occurred in Kenya in 1950–1951, resulted in the death of an estimated 100,000 sheep. In 1977, the virus was detected in Egypt (probably exported there in infected domestic animals from Sudan) and caused a large outbreak of RVF among animals and humans. The first epidemic of RVF in West Africa was reported in 1987 and was linked to construction of the Senegal River Project. The project caused flooding in the lower Senegal River area and altered interactions between animals and humans resulting in transmission of the RVF virus to humans.

An epizootic of RVF is generally observed during years in which heavy rainfall and localized flooding occur. The excessive rainfall allows mosquito eggs, usually of the genus *Aedes*, to hatch. The mosquito eggs are naturally infected with the RVF virus, and the resulting mosquitoes transfer the virus to the livestock on which they feed. Once the livestock is infected, other species of mosquitoes can become infected from the animals and can spread the disease. In addition, it is possible that the virus can be transmitted by other biting insects.

Humans can get RVF as a result of bites from mosquitoes and possibly other blood-sucking insects that serve as vectors. Humans can also get the disease if they are exposed to either the blood or other body fluids of infected animals. This exposure can result from the slaughtering or handling of infected animals or by touching contaminated meat during the preparation of food. Infection through aerosol transmission of RVF virus has resulted from contact with laboratory specimens containing the virus.

The RVF virus can cause several different disease syndromes. People with RVF typically have either no symptoms or a mild illness associated with fever and liver abnormalities. However, in some patients the illness can progress to hemorrhagic fever (which can lead to shock or hemorrhage), encephalitis (inflammation of the brain, which can lead to headaches, coma, or seizures), or ocular disease (diseases affecting the eye). Patients who become ill usually experience fever, generalized weakness, back pain, dizziness, and extreme weight loss at the onset of the illness. Typically, patients recover within two days to one week after onset of illness.

The most common complication associated with RVF is inflammation of the retina (a structure connecting the nerves of the eye to the brain). As a result, approximately 1–10% of affected patients may have some permanent vision loss.

Approximately 1% of humans that become infected with RVF die of the disease. Case fatality proportions are significantly higher for infected animals. The most severe impact is observed in pregnant livestock infected with RVF, which results in abortion of virtually 100% of fetuses.

There is no established course of treatment for patients infected with RVF virus. However, studies in monkeys and other animals have shown promise for ribavirin, an antiviral drug, for use in humans. Additional studies suggest that interferon, immune modulators, and convalescent-phase plasma may also help in the treatment of patients with RVF.

Studies have shown that sleeping outdoors at night, in geographical regions where outbreaks occur, could be a risk factor for exposure to mosquito and other insect vectors. Animal herdsmen, abattoir workers, and other individuals who work with animals in RVF-endemic areas (areas where the virus is present) have an increased risk for infection. Persons in high-risk professions, such as veterinarians and slaughterhouse workers, have an increased chance of contracting the virus from an infected animal. International travelers increase their chances of getting the disease when

they visit RVF-endemic locations during periods when sporadic cases or epidemics are occurring.

A person's chances of becoming infected can be reduced by taking measures to decrease contact with mosquitoes and other blood-sucking insects through the use of mosquito repellents and bed nets. Avoiding exposure to blood or tissues of animals that may potentially be infected is an important protective measure for persons working with animals in RVF-endemic areas.

A number of challenges remain for the control and prevention of RVF. Knowledge regarding how the virus is transmitted among mosquitoes and the role of vertebrates in propagating the virus must be answered to predict and control future outbreaks of RVF. Vaccines for veterinary use are available, but they can cause birth defects and abortions in sheep and induce only low-level protection in cattle. The human live attenuated vaccine, MP-12, has demonstrated promising results in laboratory trials in domestic animals, but more research will be needed before the vaccine can be used in the field. In addition, surveillance (close monitoring for RVF infection in animal and human populations) is essential to learning more about how RVF virus infection is transmitted and to formulate effective measures for reducing the number of infections. See also **Viral Hemorrhagic Fevers**.

RIFT VOLCANO. See Volcano.

RIGEL (β Orionis). Ranking seventh in apparent brightness among the stars, Rigel has a true brightness value of 40,000 as compared with unity for the sun. Rigel is a blue-white, spectral type B star and is located in the constellation Orion. Rigel is known as a blue supergiant star, with a total mass in the range of 36 times that of the sun. Although the estimated distance of this star from the earth is 800 light years, its brightness signifies its enormity. See also **Constellations**; and **Star**.

RIGHI-LEDUC EFFECT. If heat is flowing through a strip of metal and the strip is placed in a magnetic field perpendicular to its plane, a temperature difference develops across the strip. This effect, discovered in 1887 independently by Righi and by Leduc, bears the same relation to the Nernst effect that the Ettingshausen effect bears to the Hall effect. It may indeed be regarded as analogous to the Hall effect, but with a longitudinal flow of heat replacing the electric current and a transverse temperature difference replacing the potential difference. If, to one looking along the strip in the direction of the heat flow, and with the magnetic field downward, the decrease of temperature is toward the right, the effect is said to be positive. It is positive in iron and negative in bismuth.

RIGHT ASCENSION. Angular distance east of the vernal equinox; the arc of the celestial equator, or the angle at the celestial pole, between the hour circle of a point on the celestial sphere, measured eastward from the hour circle of the vernal equinox through 24 hours. Angular distance west of the vernal equinox, through 360 degrees, is sidereal hour angle.

RIGID BODY. An aggregate of material particles in which the interaction forces of the particles are such that the distance between any two particles remains constant with time.

RIGID FRAME (or Continuous Frame). An indeterminate structure in which continuity of action between the intersecting or adjacent members is obtained by means of moment-resisting joints (joints capable of resisting bending moment).

Rigid frames are usually constructed of structural steel or reinforced concrete, although some frames are built of wood and of prestressed concrete. In the steel structures, the joints are either riveted or welded whereas in the concrete structures continuity is obtained by running the main reinforcing rods through the joint.

Rigid frames are used as bridges, and as bents in mill and multiple-story buildings. The Vierendeel girder bridge is a rigid frame which is similar in outline to the usual bridge truss. However, the diagonals are omitted since the chords are designed for flexure. This truss is very useful for special cases of building framing. Rigid frame action is also utilized in the design of reinforced concrete culverts and sewers. See Fig. 1.

See also **Indeterminate Structure**.

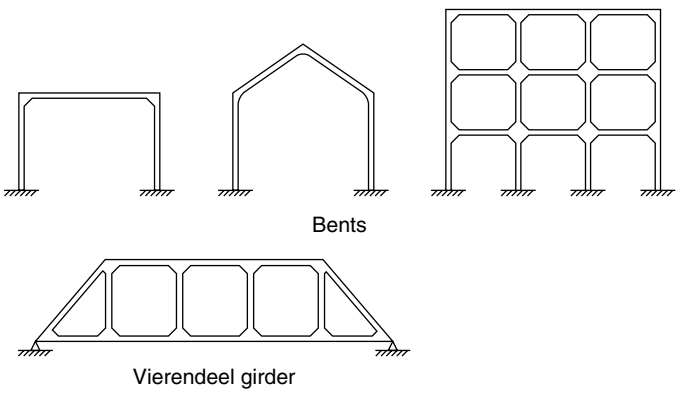

Fig. 1. Types of rigid frames.

RILL. A deep, narrow depression on the lunar surface that cuts across all other types of lunar topographic features. (from German *rille*, meaning groove).

RIME. A white or milky and opaque granular deposit of ice formed by the rapid freezing of supercooled water drops as they impinge upon an exposed object. It is denser and harder than hoarfrost, but lighter, softer, and less transparent than glaze. Rime is composed essentially of discrete ice granules and has densities as low as 0.2–0.3 g cm^{-3}. Glaze is generally continuous but with some air pockets and has much higher densities. Factors that favor rime formation are small drop size, slow accretion, a high degree of supercooling, and rapid dissipation of latent heat of fusion. The opposite effects favor glaze formation. Both rime and glaze occur when supercooled water drops strike an object at a temperature below freezing. Such formation on terrestrial objects constitutes an ice storm; on aircraft, it is called aircraft icing (where rime is known as rime ice). Either rime or glaze may form on snow crystals, droxtals, or other ice particles in the atmosphere. When such a deposit is wholly or chiefly of rime, snow pellets result; when most or all of the deposit is glaze, ordinary hail or ice pellets result. The alternating clear and opaque layers of some hailstones represent glaze and rime, deposited under varying conditions around the growing hailstone. See also **Rime Icing**.

RIME ICING. Rime aircraft icing is opaque, brittle, and granular. It is formed by the rapid freezing of small supercooled water droplets, allowing air to be trapped in. It is generally less hazardous than glaze icing, because it usually forms more slowly and is more conformal to the existing aerodynamic surface. It is the most frequent type, composing about 75% of icing reports.

RING AROUND. Self-interrogation of a beacon due to insufficient isolation between receiver and transmitter, i.e., the beacon transmitter pulse passes through the receiver and retriggers the transmitter.

RINGED SNAKES. See **Snakes**.

RING GALAXY. See **Galaxy**.

RING (Mathematics). A mathematical system for which two binary operations are defined, call them addition and multiplication, such that both operations are commutative and associative (these conditions are sometimes relaxed for multiplication) and multiplication is distributive over addition; also subtraction is always possible (cf. **Field (Mathematics)**). For example, the even integers $\ldots -4, -2, 0, 2, 4, \ldots$ form a ring.

RING OF FIRE. See **Earth Tectonics and Earthquakes**; and **Volcano**.

RINGWORM. See **Dermatitis and Dermatosis**.

RIOMETER. An acronym for a relative ionospheric (sound) opacity meter, an instrument designed to determine the degree of absorption of high-frequency radio waves during the period of ionospheric storms. At times of sudden noise absorption in the ionosphere, this automatically operating device registers a drop in received noise power, which may be used to determine certain properties of the ionosphere.

RIP CURRENT. A narrow current in the surf zone flowing seaward from the shore. It usually appears as a visible band of agitated water and is the return movement of water piled up on the shore by incoming waves and winds. It is often mistakenly called a "rip tide" or "riptide", though the occurrence is not related to the tides. Colloquially a rip current is known simply as a *rip*. Although rip currents would exist even without the tides, they can make an existing rip much more dangerous (especially low tide). Typical flow is at 0.5 meters per second (1-2 feet per second), and can be as fast as 2.5 meters per second (8 feet per second). Rip currents can move to different locations on a beach break, up to a few hundred feet a day. They can occur at any beach with breaking waves, including the world's oceans, seas, and large lakes such as the Great Lakes in the United States and Canada.

Such currents can all be extremely dangerous, dragging swimmers away from the beach and leading to death by drowning when they attempt to fight the current and become exhausted. Although rare, rip currents can be deadly for non-swimmers as well: a person standing waist deep in water can be dragged out into deeper waters, where they can drown if they are unable to swim and are not wearing a flotation device.

Rip currents cause approximately 100 deaths annually in the United States, more than all other natural hazards except heat. Over 80% of rescues by surf beach lifeguards are due to rip currents. A common misconception is that a rip occurring under the water, instead of on top — an undertow — is strong enough to drag people under the surface of the water; this is not true.

Causes and Occurrence

While the precise conditions leading to a rip current are not known, the general picture is as follows. When wind and waves push water towards the shore, the previous backwash is often pushed sideways by the oncoming waves. This water streams along the shoreline until it finds an exit back to the sea. The resulting rip current is usually narrow and located in a trench between sandbars, under piers or along jetties. The current is strongest at the surface, and can dampen incoming waves, leading to the illusion of a particularly calm area, luring some swimmers in.

Rip currents are stronger when the surf is rough (such as during high onshore winds, or when a strong hurricane is far offshore) or when the tide is low.

When caught in a rip current, one should not fight it, but rather swim parallel to the shoreline in order to leave it. Floating until the current disperses into deeper waters is another method of surviving such a dangerous incident, but it may leave the swimmer farther out from shore.

RIPPLE. Ripples are surface waves on a liquid whose wavelength is so short that the motion is effectively controlled by surface tension forces. This requires that the wavelength should be less than

$$\lambda_c = 2\pi\sqrt{\frac{\gamma}{\rho g}}$$

where γ is surface tension, and ρ, liquid density. For water, $\lambda_c = 1.7$ centimeters.

In electricity, ripple is the alternating-current component from a direct-current power supply, arising from sources within the power supply. Unless otherwise specified, percent ripple is the ratio of the root-mean-square value of the ripple voltage to the absolute value of the total voltage, expressed in percent.

RIPPLE MARK. Corrugations developed in sands and muds by currents in the water which covers them. Ripple marks may be classified as due either to oscillation or translation. The former are the result of oscillation currents set up in the water by the wind; the result of ordinary water waves. The latter are the result of progressive, directional water currents, and the resulting ripple mark is essentially a subaqueous dune. Ripple mark is helpful in determining the conditions under which aqueous, clastic sediments are deposited. Ripple mark has also been used to help determine the depth of water in which the rippled sediments have been deposited. Ripple mark is also helpful in determining the original position of formations that have been subsequently deformed or overturned.

RIPPLE VOLTAGE. When an ac is rectified, the resultant current or voltage consists of pulsating dc. In the case of simple half-wave rectifiers, this output is a series of half-sine waves spaced by equal intervals of no output while for full wave, single-phase rectifiers it consists of half-sine waves with no appreciable space between them. Poly-phase rectifiers give outputs which, while they do not vary as markedly as this, consist of a series of adjacent portions of sine waves. In every case the output may be considered as made up of a smooth dc component and an ac or ripple component. The first is the value read by a dc instrument in the circuit and the latter is the component which will produce objectionable hum in communication equipment supplied by the voltage. To reduce this ripple component various filter systems are used, the amount of filtering depending upon the equipment being supplied by the rectifier-filter combination. In many industrial applications the output of the rectifier alone is satisfactory, in communications the output must contain an extremely small amount of ac. This is measured in terms of percent ripple, which is the A.C. component of voltage divided by the D.C. component of voltage and multiplied by 100.

RISE TIME. The time required for the output of a system (other than the first order) to make the change from a small specified percentage (often 5 or 10) of the steady-state increment to a large specified percentage (often 90 to 95), either before or in the absence of overshoot. See figure that accompanies entry on **Response (Instrument)**. If the term is unqualified, response to a unit step stimulus is understood; otherwise the pattern and magnitude of the stimulus should be specified.

RISK/BENEFIT ANALYSIS. A nonstandard, rather poorly defined procedure for weighing the pros and cons of materials, machines, and devices in terms of their impact upon society. The concept can be applied to a wide range of consumer products, ranging from food additives to drugs, cosmetics, transportation safety devices, fireproof materials, insulation, aerosol packages — items of commerce that in some way have been identified with a threat to human life, health, or more generally, to the environment and ecology of various regions. Risk/benefit analysis usually is not brought into play until some chemical or physical quality of a product is *found to be* or is *believed to be* a serious threat. Frequently both sides of an advocacy contest will apply risk/benefit analysis, quite understandably sometimes with built-in biases in one direction or the other. Although scientific findings are often introduced as parts of such analyses, the procedure is essentially a judgmental art and not a science.

RITCHEY-CHRETIEN TELESCOPE. A two-mirror telescope combining an oblate spheroidal primary and an ellipsoidal secondary, and resulting in a large field free of coma. See also **Telescope (Astronomical-Optical)**.

RIVER BASINS. A river basin (also called drainage basin, watershed, or catchment) is the area that provides runoff to a given section of a stream and is separated from adjacent basins by a divide. All surface

runoff produced by precipitation that falls within the area is discharged through the lowest point in the divide.

Basins are delineated on topographical maps, integrated if necessary with aerial photographs or field survey; a line is drawn that encloses all drainage lines and depressions in the basin and passes through the highest points. It is assumed that the movement of groundwater follows the surface divides, but in areas characterized by a particular geologic structure, it is possible that the phreatic divide does coincide with the topographic divide; large amounts of water could be transported below the surface from one basin to another. In this case, the groundwater divide needs to be determined by hydrogeologic prospection.

A river basin is generally considered the fundamental unit for geomorphologic and hydrological studies; it can be treated as an open system that receives energy from the climate (input) and loses energy by evapotranspiration to the atmosphere and by stream flow and sediment yield through the basin mouth (output) that determine storage changes in groundwater and soil moisture (Fig. 1).

A river basin may be described by a Geographic Information System (GIS) combined with a digital elevation model (DEM). A GIS is an electronic system of maps connected to tables of data that describe the features on the maps; a DEM represents a spatial distribution of elevations. The DEM can be structured by a square-grid network, a contour-based network, or a triangulated irregular network (TIN). In a raster-based GIS, the basin is subdivided into uniform grid cells; to each of these cells, numerous attributes relative to basin characteristics can be attached. The GIS system is a useful tool for automating much of the geometric data acquisition necessary for hydrologic analyses. A raster-based GIS is well suited to the application of hydrologic rainfall–runoff models based on distributed parameters. Alternatively, the GIS procedure allows computing average basin parameters for the entire watershed that are necessary as input in lumped parameter hydrologic models.

Basin Characteristics

A river basin is composed of several subsystems: the drainage basin itself in its areal extent, and the channel system, in which by a further subdivision, we can distinguish the channel cross section, the channel reach, and the channel network. It is important to describe the river basin in quantitative terms to understand the processes and to analyze the interrelationships existing among these characteristics.

Drainage Basin. A river basin's characteristics can be subdivided into topographic, rock and soil, vegetative and land use, and climatic characteristics.

Topographic Characteristics. Topographic characteristics directly influence the transport of water and sediment within a basin. Topographic attributes may be described by index of area, length, shape, and relief.

Basin Area. The area of a drainage basin is the area enclosed by the curve obtained by projecting the basin divide on a horizontal plane. This represents its most important physical parameter because it is correlated with almost every other characteristic, but for this reason it is not always easy to interpret its significance.

Empirical relations between stream discharge Q and basin area A assume the form,

$$Q = aA^b, \tag{1}$$

where Q represents some index of stream flow such as the mean annual flood. The value of exponent b generally varies from 0.5 to 1.0. Stream flow per unit area is inversely proportional to area because intense precipitation tends to occur on a restricted area. Sediment yield per unit area in many regions, it has been found, is inversely proportional to basin area. Erosion is predominant in small basins, whereas in large basins, there are, in proportion, more locations for temporary sediment storage.

Basin Length. Basin length is usually defined as the length of the mainstream measured along the main channel from the outlet to the basin divide. Length is closely related to area, and a large number of rivers seem to satisfy the relation expressed by Hack:

$$L = 1.4A^{0.6}, \tag{2}$$

where L is the stream length in miles and A is the area in square miles. The exponent 0.6 suggests that geometric similarity is not preserved as a river basin increases in area because A/L^2 decreases and the basin tends to elongate, becoming longer and narrower.

Basin Shape. The basin shape normally tends to a pear-shaped ovoid, but many substantial deviations from this shape due to geologic constraints have been observed. Several parameters have been proposed to describe basin shape. The form factor F is defined as what is F?

$$R_f = \frac{A}{L^2}, \tag{3}$$

where A is the drainage basin area and L the basin length.

The basin circularity compares the basin area with the area of a circle that has the same perimeter p:

$$R_c = \frac{4\pi A}{p^2}. \tag{4}$$

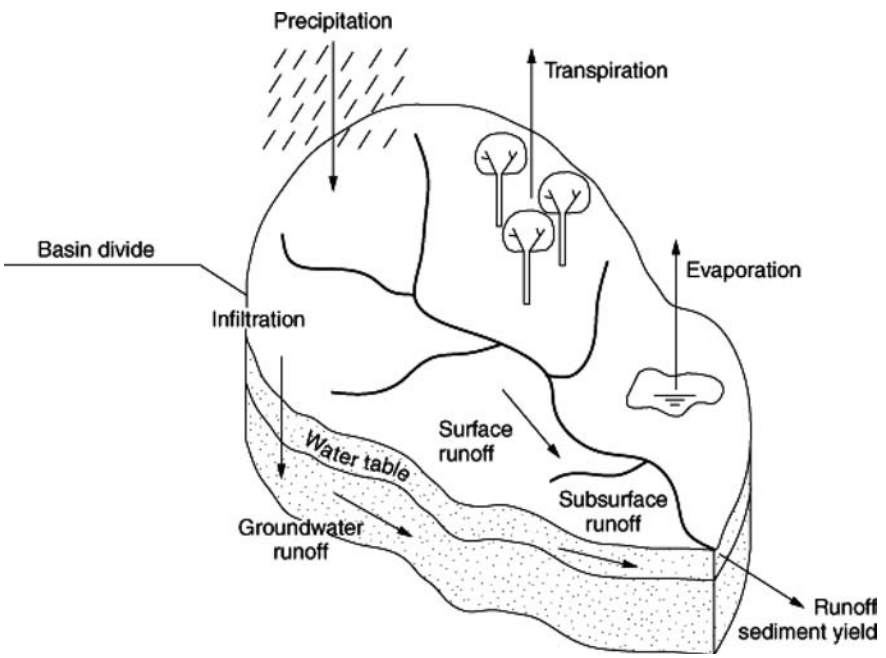

Fig. 1. River basin.

The basin elongation is defined as the ratio of the diameter of a circle that has the same area as the basin to the basin length:

$$R_e = \frac{2\sqrt{A}}{L\sqrt{\pi}}. \quad (5)$$

R_e assumes values from 0.6 to 0.8 in regions of high relief, and in areas of low relief, values near one have been observed. The usefulness of these shape factors has been analyzed, and the elongation ratio has proved to be the parameter best correlated with hydrology. The basin shape affects the stream-flow hydrograph, in particular, the lag time and the time of rise.

Relief. The hypsometric area–altitude analysis expresses the relation between basin area and elevation. It is obtained by plotting the area above a certain elevation versus the elevation itself. The shape of the *hypsometric curve* gives an indication of the basin's geologic evolution any stage in the erosion cycle. The hypsometric curve is useful if hydrologic variables such as precipitation or evaporation, which vary with altitude, are studied.

The *mean basin elevation* can be obtained by integrating of the area–elevation curve and dividing the result by the drainage area; the median elevation is defined as the elevation that corresponds to 50% of the drainage area.

The *maximum basin relief* is the elevation difference between the highest point on the basin perimeter and the basin outlet.

The *basin slope* is a major factor in the overland flow process, and several methods have been developed for determining its average value because of the variation in land–surface slope throughout the basin. In the grid-square method, a grid of uniformly spaced lines is established over a map of the basin, and the slope of a short segment of line normal to the contours is determined at each grid intersection. The basin slope is then calculated as the mean of the resulting local slopes. In the random-coordinate method, the procedure is the same except that the points where the local slope is evaluated are randomly located over the basin. Basin slope can also be determined by measuring the total length L_{tot} along contours at contour intervals $Deltaz$ and calculating the average value:

$$i = \frac{\Delta z L_{\text{tot}}}{A}. \quad (6)$$

Computations by this formula are time-consuming, but by introducing a DEM, they become more feasible. However, using a DEM, it is also possible to calculate the slope of each individual square or triangle in a raster or TIN model, respectively, and to use these values to compute the average basin slope.

The peak discharge per unit of basin area is strongly correlated with the mean basin slope. In basins that have a high relief ratio, the lag time and time of hydrograph rise are shorter, and the peak discharge rate is higher (Fig. 2**a**). Sediment erosion that takes place mainly during peak stream flow is also correlated with basin relief.

Rock and Soil Characteristics. Rock and soil characteristics determine the rate of rainfall infiltration into the soil and thus affect runoff. The character of the rock beneath the basin with regard to these processes can be expressed by porosity and permeability. *Porosity* is the percentage volume of voids in a material and is a measure of the amount of water that can be retained by a deposit; *permeability* provides an index of the ability of a material to transmit water and is a function of soil texture, grain size, density of grains, and particle shape. The Soil Conservation Service has classified most soils into four hydrologic soil groups A, B, C, and D, dependent on their infiltration rate:

— group A: deep, well-drained sand;
— group B: sandy loam;
— group C: clay loam;
— group D: clay soils of a high swelling potential.

The geology of a basin affects the type and the amount of material available for erosion and transport. The extent of removal and transport of sediment is influenced by the physical and chemical properties of the rock. The vulnerability of soils to weathering can be evaluated by several indexes of soil erodibility which depend upon particle size, moisture content, permeability, dispersion properties of the soil and shear resistance.

Vegetation and Land Use Characteristics. Vegetative cover is a significant factor influencing drainage basin dynamics because it affects the amount of net precipitation that reaches the ground surface through interception, evapotranspiration, and infiltration, and also the water and sediment rate produced by the basin.

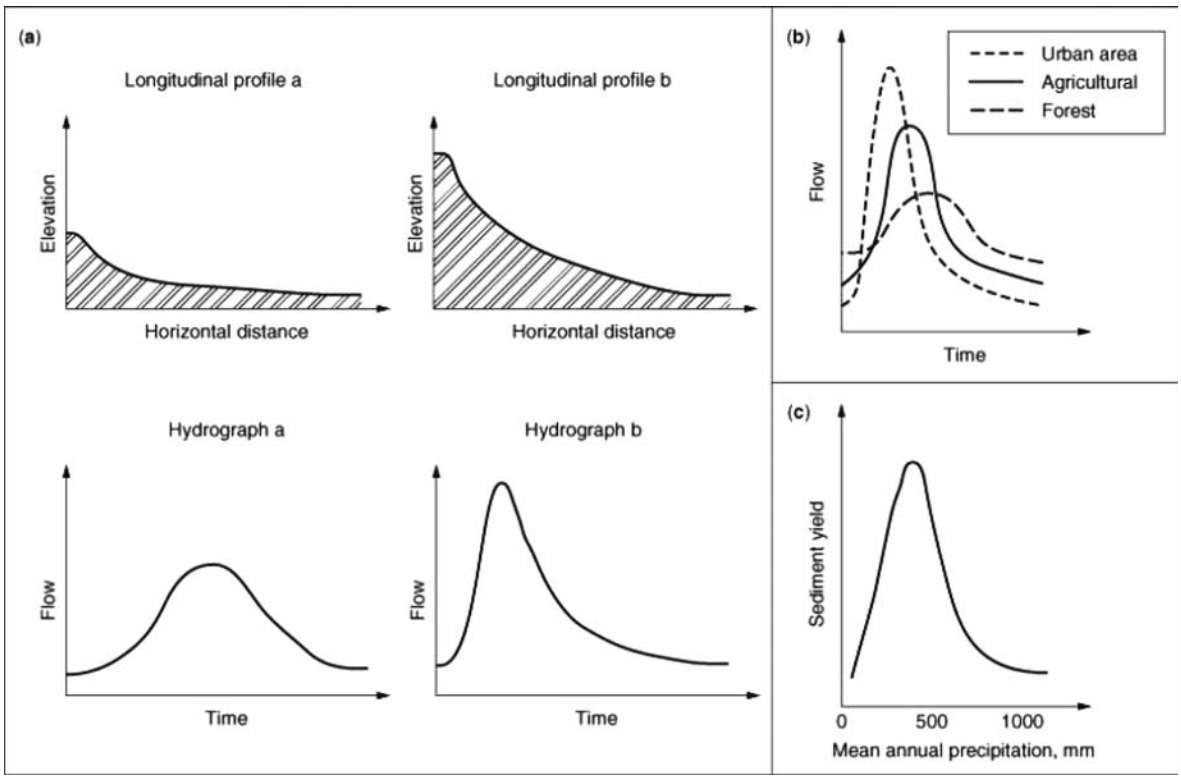

Fig. 2. Influence of relief (**a**) and vegetative cover (**b**) on runoff and influence of climatic characteristics (**c**) on sediment yield.

Interception losses are given by the sum of precipitation retained on vegetative surfaces such as leaves, stems, and tree trunks. The amount of water captured by vegetation depends on the amount of leaf cover; the type, age and density of vegetative cover; seasonal variations; the amount, duration, and intensity of precipitation; and antecedent moisture conditions.

Vegetative cover also determines losses by evapotranspiration, which is the combination of evaporation from plant surfaces and transpiration of water from plants. Evapotranspiration is related to plant characteristics and environmental conditions, such as atmospheric pressure and moisture, air temperature, wind speed, soil moisture, and light intensity.

The effect of vegetative cover is also displayed by an increase in soil infiltration capacity due to the resistance afforded by vegetation, which slows down overland flow and thus allows the water to have more time to enter the soil surface and flow to the plant roots which make the soil more pervious to infiltrating water. The type and density of vegetation, the presence of plant litter on the soil surface, and the depth and density of roots may influence infiltration dynamics.

The vegetative cover influences stream-flow runoff in a basin. As the vegetation extent decreases, passing from forested areas to agricultural land and further to urban areas, the range of flows between peak and low flows becomes wider, and the peak discharge is amplified and occurs earlier (Fig. 2b).

Sediment production by erosion depends on land use character, especially cover density. Vegetal cover has a protective influence against erosion processes. A dense cover such as grass reduces the flow velocity and operates simultaneously as a protection covering the underlying soil. Sediment production is maximum from cultivated land, decreases in pasture land, and is minimum in forest and wild land.

Climatic Characteristics. Climatic characteristics govern the amount of water received at the surface. Sediment yield is broadly correlated with mean annual precipitation. Maximum values occur in semiarid areas, where the proportion of precipitation available for surface runoff and therefore for erosion is greater. In more arid and more humid areas, sediment production decreases because of the reduced runoff potential and the increase in vegetative cover, respectively (Fig. 2c).

Channel System

Channel Cross Section. The shape and size of alluvial channel cross sections are strongly correlated with stream discharge. Numerous relationships that express the variation in channel characteristics, such as top width, mean depth, mean velocity, slope, with discharge at a particular section and between cross sections have been developed (9). As discharge increases downstream, surface width and mean depth tends to increase, whereas slope decreases. Downstream variations in channel form are influenced by local factors such as type and quantity of sediment load, rock type, superficial deposits, and vegetative cover. Thus, quantitative relationships between hydraulic geometry and discharge may be applied only locally in the same region where the data from which the equations are derived have been obtained, for example, to estimate stream flow from channel measurements in a site where no stream-flow records are available.

Channel Slope. The slope of the principal drainage channel can be estimated by several methods (Fig. 3). The simplest method consists of dividing the difference in elevation between the source and the mouth by the length of the channel (Definition 1). The slope can also be determined by calculating the slope of a line drawn on the channel profile through the lowest point such that the area under it equals the area under the profile curve (Definition 2). Channel slope affects flow velocity, travel time, and sediment transport capacity, so it influences water and sediment routing through the basin.

Channel Patterns. River channel patterns have been classified into meandering, braided, and straight (Fig. 3).

A channel is meandering where it assumes the form of a number of loops or bends. The *sinuosity* is the ratio of channel length to valley length and has an average value of 1.5. Meander wavelength and amplitude range from 7 to 10 and from 3 to 20 times the channel width, respectively. Meander wavelength has proved to be strongly correlated with discharge. A channel is braided where the stream bifurcates into two or more intertwined channels separated by islands or bars. Braided channels are characterized by wide, shallow beds of coarse material. The factors that contribute to the development of braided channels are essentially bed-load availability, irregularity of stream flow, intense precipitation which causes high peak

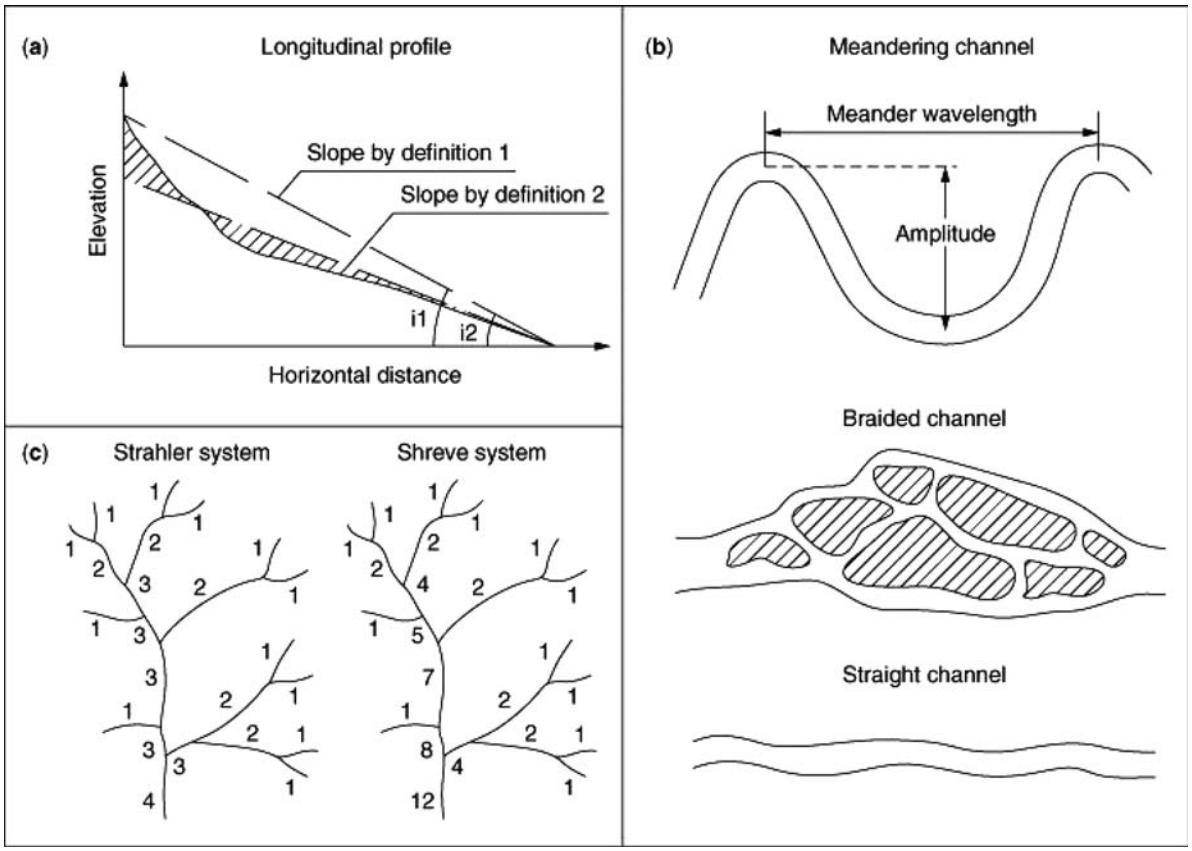

Fig. 3. Channel system: (**a**) Channel slope definition; (**b**) channel pattern description; (**c**) stream order designation.

discharges, and high slopes. Perfectly straight channels are seldom found in nature, so the definition of straight channel has been extended to a channel whose sinuosity is less than 1.25.

Drainage Density. The density of a channel network is the total length of channels per unit area. Values of drainage density observed range from 1 to 248 km/km^2. High density is observed in basins that have weak and impermeable rocks, sparse vegetation, and a steep relief. Network density depends on climatic characteristics, and it varies with mean annual precipitation in the same way as sediment yield because high sediment delivery corresponds to a well-developed channel network. Drainage density is inversely related to precipitation-effectiveness Thornthwaites index P-E which adjusts monthly precipitation by a function of monthly average daily temperature to account for evapotranspiration losses. This relation shows the effectiveness of vegetative cover in erosion control. Other basin characteristics such as lithology and land use, and in particular, rock permeability, influence drainage density because they affect the infiltration–runoff rate. Network density is an important factor in the formation of flow. As it increases, peak discharge per unit area increases, and time-to-peak decreases, so that a basin that has a high drainage density is characterized by an efficient drainage system and rapid hydrologic responses.

Stream Order. A channel network may be described by designation of a stream order using with one of the systems developed by Strahler and Shreve to determine the position of a stream in the hierarchy of tributaries (Fig. 3c). In the Strahler system, all fingertip tributaries have order one; two first-order channels joining produce a second-order segment, and so on; if two channels of different order join, the resultant link has the order of the tributary of higher order. In the Shreve system, all fingertip tributaries have magnitude one, and each downstream channel segment has a magnitude equal to the sum of all the first-magnitude segments that are tributary to it. The basin order is a measure of the branching within the basin and is related to the size of channel network and to the amount of stream flow. Stream order is very sensitive to map scale which should always be specified together with the method of ordering used. The Strahler method is the most widely used method today, especially combined with the laws of drainage composition, whereas the Shreve method gives a description of a drainage network closer to physical reality with regard to stream discharge.

Horton's laws of drainage composition relate stream numbers, stream lengths, and drainage areas to stream order by simple geometric relationships. The bifurcation ratio R_B is defined by

$$R_B = \frac{N_u}{N_{u+1}}, \tag{7}$$

where N_u is the number of streams of a given order and N_{u+1} is the number of the next higher order. Bifurcation ratios tend to be constant in a given basin and assume characteristic values between three and five. The law of stream numbers is expressed by

$$N_u = R_B^{k-u}, \tag{8}$$

where k is the highest order within the basin. Similarly, the laws of stream lengths and drainage areas indicate a geometric progression of order:

$$\overline{L}_u = \overline{L}_1 R_L^{u-1}, \overline{A}_u = \overline{A}_1 R_A^{u-1}, R_L = \frac{\overline{L}_u}{L_{u-1}}, R_A = \frac{\overline{A}_u}{A_{u-1}}, \tag{9}$$

where L_u is the mean length of streams of order u, A_u is the mean area of basins of order u, R_L is the length ratio, and R_A is the area ratio, whose ranges of values are 1.5–3.5 and 3–6, respectively.

An alternative model has been proposed by Shreve using the probabilistic–topological approach. It assumes that in the absence of climatic and geologic constraints, channel networks evolve at random; all topologically distinct channel networks (TDCN) of a given magnitude are equally probable. Shreve used the term "link" for stream segments between nodes (sources, junctions, or outlet) and distinguished exterior links, which extend from a source to the first junction, from interior links, which connect two successive junctions or the last junction with the outlet. Furthermore, he assumed that exterior and interior link lengths are random variables whose separate probability distributions are independent of position within the basin. Shreve showed that the most probable network in a random population closely conforms to Horton's law of stream numbers.

More recently a new approach has been developed for analyzing drainage network composition, which shows that river basins have a self-similar organization, that is, the same shape is found at another place in another size. This property can be interpreted by Mandelbrot's fractal theory which introduces fractals as irregular geometric shapes that have identical structure on all scales.

RIVERS. Rivers are natural streams typically larger than a creek. The distinction may be somewhat subjective, but creeks cannot be traveled by boat and rivers can. Rivers are the result of precipitation and runoff over land surfaces, followed by surface erosion and sediment transport. As water runs off to lower elevations, the erosion of the underlying earth and soil carves channels into the landscape. These natural channels convey the floodwaters from rainfall and snowmelt and also drain the aquifers during periods of low flow. Rivers are perennial when there is flowing water all year round. Rivers that dry out during part of the year are ephemeral streams, also called arroyos. Related nouns include riverbank or riverside to describe the banks of a river, as well as riverbed to designate the stream bottom. Other adjectives related to rivers include riverine, riparian, fluvial, and fluviatile.

The discharge, or rate of outflow, of a river depends on the channel width, flow depth, and flow velocity. The flow velocity depends on the flow depth, or hydraulic radius, the slope of the river, and the roughness of the riverbed. The volume of water that flows through a river is affected by the duration and intensity of rainfall precipitation or snowmelt in the drainage basin of the river. Over geologic times, it is possible for rivers to be deflected into a different drainage system. This phenomenon is called a capture and results in an increase in drainage area.

Traditionally river systems have been classified as young, mature, or old depending on their stage of development over geologic times. A young river typically flows in a steep valley and has a steep bed slope and numerous riverbed irregularities. Cliffs or escarpments and differences in the resistance of rocks create irregularities in a riverbed and can thus cause rapids and waterfalls. Young systems are characterized by discontinuous longitudinal profiles, lakes, and variable hydraulic geometry. At a mature stage, the river valley has a wide floor and flaring sides and more pronounced erosion by its tributaries. An old river system tends to have regular longitudinal profiles and a gradual decrease in riverbed slope in the downstream direction. Geologic discontinuities such as faults and active tectonics can cause sudden changes in bed elevation that effectively can rejuvenate old fluvial systems. The age classification of rivers is diminishing in popularity now that quantitative studies of river behavior are more common.

The topography of natural rivers depends on the balance between the quantity of sediment in the stream and its transport capacity. A river is alluvial when it can transport its own riverbed sediment and can form its

own channel geometry. The weathering process of the land of a given watershed produces large masses of alluvium that can be carried by rivers over geologic periods. An alluvial river tends to eliminate irregularities and form a smooth gradient from its source to its base level. The lowest level to which a river flows is called the base level. Sea level is the ultimate base level, but a lake or reservoir may serve as a local and temporary base level.

Slight changes in sediment transport capacity or in sediment supply to a stream can result in a significant change in bed elevation and planform geometry. For instance, if a stream receives more sediment than it can transport the result is aggradation, or a raise in riverbed elevation through time. Conversely, when the sediment transport capacity exceeds the upstream supply, the water will erode the riverbed and riverbanks and degrades the riverbed.

Similar changes normally take place laterally in river bends. Typically, the velocity increases on the concave riverbank and the increased sediment transport capacity results in erosion and lateral migration of a meandering channel. Simultaneously, the decreased flow velocity near the convex bank of the river decreases transport capacity and results in sediment accumulation and aggradation through time to form point bars. As it approaches base level, downward cutting is replaced by lateral cutting, and the river widens its bed and valley and develops a sinuous course that forms exaggerated loops and bends called meanders. A river may open up a new channel across the arc of meander, called a neck cutoff, thereby cutting off a river segment and creating an oxbow lake as shown in Fig. 1

River velocity is one of the primary factors that control the quantity and size of rock fragments and sediment carried by the river. When rivers reach oceans, lakes, or reservoirs, the decrease in flow velocity results in net deposition of the sediment load. Part of the load carried by the stream is deposited in the riverbed or on the floodplain beyond the channel. The flow of water during floods exceeds the conveyance of the stream channel, and the water level increases to overtop the riverbank and flood adjacent floodplains. As the velocity reduces further on the floodplain, the deposition of sediment forms natural levees. Over long periods of time, landforms produced by deposition include floodplains, deltas, and alluvial fans.

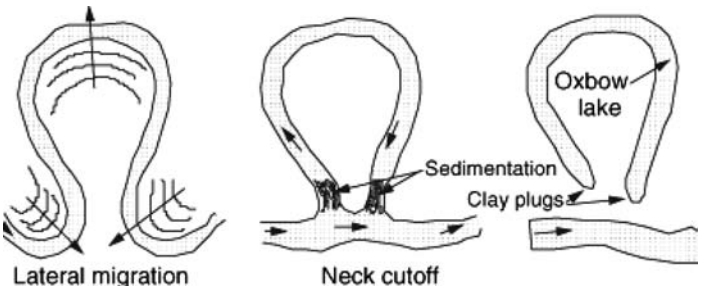

Fig. 1. Oxbow lake formation process.

Some typical characteristics including the watershed size, the water and sediment discharges of large rivers are presented in Table 1. The flow and drainage area of the Amazon far exceed that of any other river. On the other hand, the Yellow River (Huang Ho) and the Ganges have tremendous sediment concentrations for very large streams. Several textbooks describe the mechanics of river formation. See also **Earth**.

TABLE 1. WATER AND SEDIMENT LOADS OF SELECTED RIVERS

River	Catchment Area	Discharge			
		Water		Sediment	
	10^6 km^2	m^3/s	mm/yr.	10^6 ton/yr	mm/yr
Amazon	7.0	100,000	450	900	90
Mississippi	3.9	18,000	150	300	55
Congo	3.7	44,000	370	70	15

ROBBER FLY *(Insecta, Diptera)*. A predacious fly of the family *Asilidae*. Many of these flies are large and all capture living insects as prey, including bees of all kinds. Most of the included species have smooth slender bodies but some are quite hairy and one group is characterized by stout form and dense vestiture. These last mimic bumblebees closely and furnish an apparent case of aggressive mimicry, since the bumblebees are said to be among their victims.

On balance, the robber fly is classified as an economically beneficial insect for food producers.

ROBERVAL PRINCIPLE. A number of low-capacity scales incorporate a principle discovered by Gilles Personne de Roberval, a French mathematician, in 1670. A good scale must weigh as accurately when the load is placed on any of the four corners as it does when the load is placed directly over the center of the platform or platter. A scale that does not perform in this manner is either out of adjustment or is of inherently poor design. Any error of this type is known as shift error. The Roberval principle is one means for avoiding shift error.

The principle is applied in the counter scale shown in Fig. 1. Parallelogram *ABCD* always maintains the weight and load platters in a horizontal plane. Stems *AD* and *BC* are integral parts of the parallelogram. These stems always remain vertical regardless of load position. Links *CE* and *ED* prevent tipping of the platter and aptly are termed check links. Although the parallelogram may assume different relative positions and dimensions in scales of various designs, the check links are always present, since the Roberval principle applies only to a completed parallelogram.

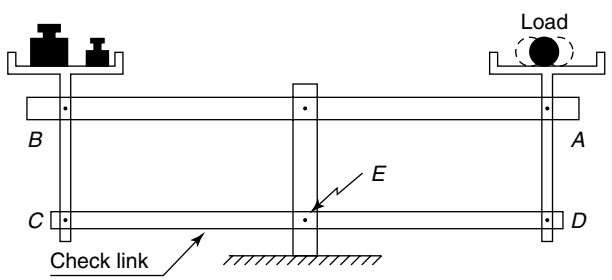

Fig. 1. Counter scale that utilizes the Roberval principle to avoid shift error.

The principle can be proved by kinetics or by statics. Proof by statics is based upon the fact that the rigid arms extending from the connecting stems may be considered to be cantilever beams. Because the extending arms are rigidly fixed to the connecting stems, the force system is identical to that of the cantilever beam shown in Fig. 2. The system resolves itself into two couples, one comprised of W_1 and W_2 and the other by R_1 and R_2. The lateral position of W_1 along the extending arm does affect the values of R_1 and R_2, but since R_1 always equals R_2, it follows that W_2 always equals W_1 regardless of position. Since it is the value of W_2 that tends to disturb the equilibrium of the balance, the value and not the point of application of the force along the extending arm determines the equilibrium of the balance. Thus, so long as the weight of the mass suspended from the left arm equals the weight of the mass suspended from the right arm, the relative lateral positions of these masses have no significance insofar as the point of balance is concerned.

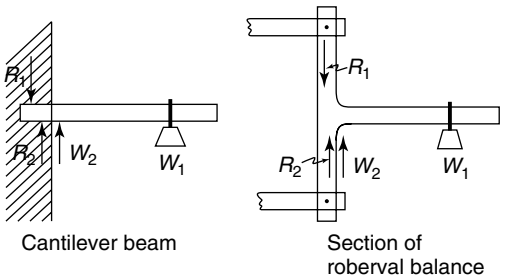

Fig. 2. Static proof of Roberval principle.

ROBIN *(Aves, Passeriformes)*. 1. The European redbreast, *Erithacus rubecula*, a warbler, and a related species of the Canary Islands. 2. The American robin, *Turdus migratorius*, a thrush. 3. In Australia, a species related to the wheatear; in New Zealand, other birds of the same group.

ROBINSON, ROBERT (1885–1975). Robert Robinson was a British organic chemist who synthesized many natural substances and was a pioneer of the electronic theory of organic chemistry.

Robinson was born in Chesterfield, England, on 13 September 1885. Educated at Fulneck School and Manchester University, he graduated in 1905 and gained his PhD in W. H. Perkin's laboratory for research on brazilin and hematoxylin. From 1909 he worked with Arthur Lapworth who stimulated his interest in an electronic theory of organic chemistry. In 1912 Robinson took the Chair of Chemistry at Sydney, Australia, but four years later he returned to England as Heath Harrison Professor of Organic Chemistry at Liverpool. Here he worked on the alkaloids with Perkin, speculated about the biogenesis of natural products from simple precursors and synthesized tropinone, an optically inactive cycloheptanone related to atropine and cocaine, by combining smaller molecules. During World War I, he worked to revive the British dyestuffs industry, languishing since the 1880s, and in 1919 he became Research Director of British Dyestuffs in Huddersfield.

In 1920, elected FRS, Robinson accepted the Chair of Chemistry at St Andrews, where he began to formulate his electronic theory using the ideas of Lapworth, G. N. Lewis and Irving Langmuir. When Lapworth became Head of Department at Manchester in 1922, Robinson accepted the Chair of Organic Chemistry there and during the next six years he consolidated his earlier work on the alkaloids and developed his electronic theory. First published with W. O. Kermack in 1922, Robinson's paper contained many insights, including his notion of the "electromeric effect" and an electronic interpretation of aromaticity to explain substitution in the benzene ring. In 1925 he introduced the "aromatic sextet," the six-electron system characterizing the properties of the benzene ring. Robinson published his work in little-known journals and there were many acrimonious arguments with C. K. Ingold, who developed Robinson's ideas in a large number of well-publicized papers.

In 1928 Robinson moved to University College London. Then in 1930 he became Waynfleet Professor of Chemistry at Oxford, where his presence made the Dyson-Perrins Laboratory a mecca for organic chemists. He was knighted in 1939 and elected President of the Chemical Society. During World War II he worked with Howard Florey and Ernst Chain on the chemistry of penicillin, but from 1945 he returned to his studies of the steroids and alkaloids. His determinations of the structures of strychnine and brucine were the epitome of classical organic chemistry, confirmed by R. B. Woodward's total synthesis of strychnine in 1954. His work on the steroids, begun in 1932, continued for two decades. For synthesizing the ring systems of these compounds he either assembled all four rings and made the necessary modifications, or built tricyclic structures with features that could be closed to form the fourth ring. It is this annulation reaction for which he is best remembered by many chemists. Robinson was elected President of the Royal Society in 1947 and in the same year received the Nobel Prize for Chemistry. In 1949 he was admitted to the Order of Merit

and on his retirement from Oxford in 1955 he became a director of the Shell Chemical Co. Ltd. In 1957 he founded the journal *Tetrahedron*, now one of the leading international journals of organic chemistry. See also **Antibiotics**; **Chain, Ernst Boris**; and **Florey, Howard Walter**.

ROBITZSCH ACTINOGRAPH. A pyranometer developed by M. Robitzsch. Its design utilizes three bimetallic strips, which are exposed horizontally at the center of a hemispherical glass bowl. The outer strips are white reflectors, and the center strip is a blackened absorber. The bimetals are joined in such a manner that the pen of the instrument deflects in proportion to the difference in temperature between the black and white strips.

ROBOTS AND ROBOTICS. A robot may be defined as a "reprogrammable, multifunctional manipulator to move materials, parts, tools, or specialized devices, such as welders and paint sprayers, through variable programmed motions to accomplish a variety of tasks."[1] It follows that *robotics* is the technology of designing, applying, and maintaining robots.

Generally, a robot is a specifically designed piece of production hardware that is used predominantly to execute what may be termed "handling" operations — that is, such tasks as "picking up," "setting down," "putting into place," "locating and positioning," and "transferring" objects from one location to another. For these duties, the province of the robot is geometric (usually three-dimensional) in nature and the robot is programmed in the geometric terms of positions (coordinates) and motion (pathway). When robots are used in this manner, they must be capable of the same order of dimensional and positional precision that also applies to the machines that they serve.

Although each robot may operate under its own specific preprogrammed control schedule, it is common in large manufacturing facilities to lump groups of machines and the robots that serve them into *cells*, which adds another layer of computer control.

It is interesting to note that, after the late 1970s, when robots were introduced with great flair by the nontechnical news media, intense interest in robots by managers of discrete-piece manufacturing was created in their quest to cut production costs. Thus, during the 1980s, many hundreds of costly robots were procured and installed in large manufacturing facilities, as exemplified by the automotive, aircraft, and other parts manufacturing and assembly industries. Unfortunately, in numerous cases, the results did not meet the expectations. Two principal factors contributed to the disappointments and to the long periods of "debugging." One factor simply was undue haste to use a new technology that would offset international competition, and this led to the second factor — namely, basing this transfer of a new and highly specialized technology on shallow studies and failing to sufficiently develop detail and test plans for integrating robotics into existing facilities. These difficulties were present not only in retrofit situations, but also in connection with entirely new production facilities. It was found that robots cannot be treated as simple "add-on" hardware.

As of the present time (1993), robotics is better understood and now is viewed with an improved perspective, as the result of over a decade of experience. The unrealistic "rush" to robotize and computerize in discrete-piece manufacturing generally has yielded to more meticulous economic and practical scrutiny by users and potential users. Today, robotics is on a much firmer foundation and obviously will continue to progress.

[1] Adapted from the *Robot Institute of America*.

Chronology of Robotics

The image of robotics over past centuries was burdened by an aura of mystique and romanticism that eventually led to an "overworked" comparison of robots with people — an image that still persists in the general press, but to a much lesser degree. During the late 1700s, for example, there existed an exceptional fascination with androids, which essentially were mechanical "people," so to speak. In 1774, Jaquetdroz exhibited three "mechanical marvels" — a musician, a writer, and a draftsman. These and other charmingly attired mechanical people were presented at court like visiting dignitaries. During that period, Diderot in his *Encyclopedie* observed that in the construction of machines, engineers should look to monsters for inspiration, but that instead the eighteenth century engineers looked to man and built beautiful automatons.

As recently as 1923, this general approach was carried on by Karel Čapek a Czech playwright who used the Czech word *robot* (for worker) to describe humanoid creations in his play, "Rossum's Universal Robots." In the 1940s, the science-fiction writer Isaac Asimov coined the word *robotics*.

Early industrial use of robots, which resembled machines more than people, dates back some 20 to 30 years. Although these robots performed well for certain applications (mainly for handling large and heavy loads under adverse conditions), their use did not commence to bloom until the 1970s.

In the discrete-piece manufacturing industries (metalworking and automotive, for example), many of the operations now performed or assisted by robots were formerly accomplished by what is referred to as *fixed* or *hard* automation. Such systems, still widely employed, use limit switches, relays, photoelectric sensors, and other electromechanical and magnetic devices for controlling the motion- and position-related geometric variables. The principal constraint of fixed or hard automation is a lack of *flexibility*. Transfer lines, for example, commonly used in the automotive and machinery industries and which were tailored to earlier continuous production and assembly line concepts, were representative of fixed automation. In connection with model changes (usually on an annual basis) and with manufacturers who produced only limited runs of many different products, the lack of flexibility was a major problem. Fixed systems required costly retooling when going from one product to the next.

This shortcoming was considerably relieved by the introduction of programmable relay logic systems (adjustable plugboard memories) and, in the late 1960s, by the entry of the *programmable controller*. These tools brought a degree of flexibility and universality to pre-robot industrial automation systems. See also **Programmable Controller**.

Classes of Robots

Because there are numerous types of robots, they are difficult to place in neat groups. Some useful classifications are by their: (1) axes of motion; (2) control system; (3) programming (and teaching) system; (4) load capacity and power requirements; (5) dynamic properties, including stability, resolution, repeatability, and compliance; (6) end-effectors (grippers) used; (7) workplace configuration; and (8) appropriate applications for a given robot design.

Axes of Motion. A robot is movable from one factory location to another (like a machine) as may be dictated by factory layout changes or major alterations in job assignment. However, for any given task that will be repeated again and again over a long period (usually months or more), a robot will be *firmly fastened* to the operating floor (in some cases, to the ceiling). This establishes a firm *geometric location of reference*, a very important, unchangeable position that will *geometrically relate* precisely with associated fixed machinery. In the case of a work cell, each of several robots will precisely relate geometrically with each and every machine that the robot serves. For moderate changes in use, the average robot will incorporate within its design sufficient operating flexibility and adjustments obviating the need to alter the installed robot's *fundamental reference location*. In the case of a so-called "smart robot," final very small changes in the positioning of the arm will be made by inputs from a machine vision

or tactile system. Intentionally designed, movable robots are special cases (described later).

Once installed, a robot's ability to move parts and materials will be established by the built-in axes of motion, sometimes called *degrees of freedom*. The axis of motion refers to the separate motion a robot has in its manipulator, wrist, and base. The robot designer will usually select one of four different systems of geometric coordinates for any given need. These coordinate systems are: (1) revolute (jointed arm); (2) Cartesian (X, Y, Z); (3) cylindrical (rectilinear); and (4) spherical (polar).

Where revolute (jointed-arm) coordinates are used, the robot arm is constructed of several rigid members connected by *rotary joints*. As illustrated by Fig. 1, three independent motions are permitted. In some robots, these members are analogous to the human upper arm, forearm, and hand, while the joints are, respectively, equivalent to the human shoulder, elbow, and wrist. The arm incorporates a wrist assembly for orienting the end-effector (gripper) in accordance with the workpiece. See Fig. 2. These three articulations are pitch (bend), yaw (swing), and roll (swivel). In some applications, fewer than six articulations may suffice, depending upon the orientation of the workpiece and the machine(s) which the robot is serving.

Where Cartesian coordinates are used, all robot motions travel in right-angle lines to each other. There are no radial motions. Consequently, the profile of a Cartesian robot's *work envelope* is a rectangular shape. See Fig. 3. Some systems utilize rotary actuators to control end-effector orientation. Robots of this type generally are limited to special applications. A robot also can incorporate rectilinear-Cartesian coordinates. In one example, a continuous-path extended-reach robot offers the versatility of multiple robots through the use of a bridge and trolley construction that enables it to have a large rectangular work envelope. When ceiling-mounted, a device of this type may service many stations with several functions, thus leaving the floor clear. The X and Y motions are performed by the bridge and trolley; the vertical motions are performed by telescoping tubes.

In a Cartesian coordinate system, the location of the center for the coordinate system is the center of the junction of the first two joints. Except for literally moving the robot to another factory location, this center *does not move*. In effect, it is tied to the "world" as if anchored in concrete. If the X measurement line points toward a column in the area where the robot is placed, the X line will *always* point toward that same column no matter what way the robot turns while performing its programs. These are known as the *world coordinates* for a given robot installation. See Fig. 4.

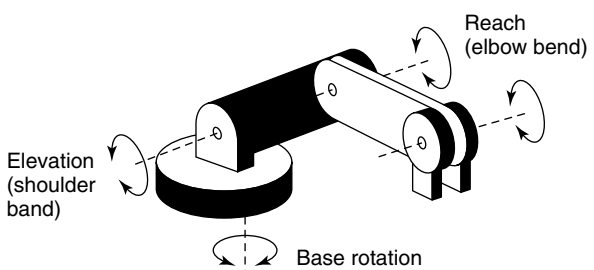

Fig. 1. Jointed-arm manipulator incorporating revolute coordinates.

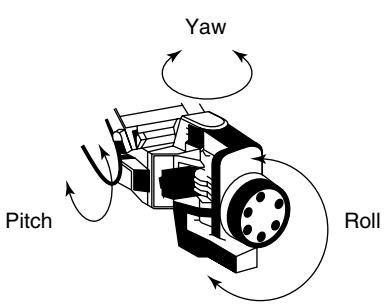

Fig. 2. Wrist assembly on robot arm for orienting the end-effector in accordance with requirements of workpiece.

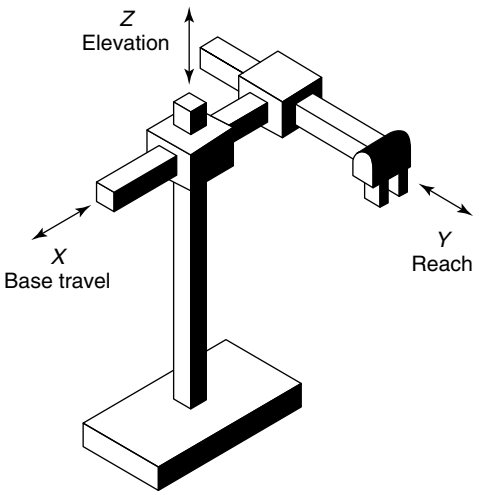

Fig. 3. A manipulator incorporating Cartesian coordinates.

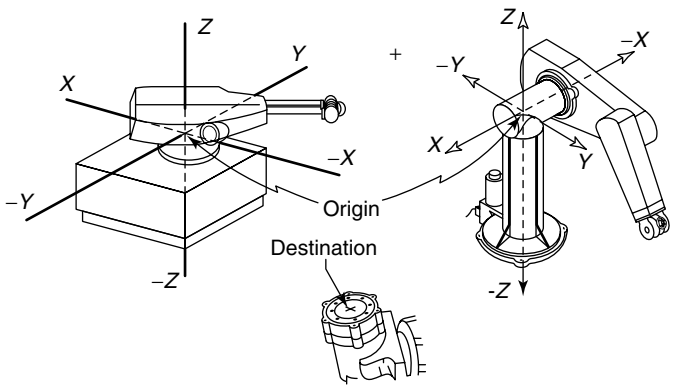

Fig. 4. World coordinate system of a robot using Cartesian coordinates. (*Westinghouse*.)

However, in the operation of a robot, having an origin for a measurement reference is not sufficient. We also need a reference to the point where we are measuring. This measurement is made from the origin of the coordinate system to a point that is exactly in the center of the circle on which the tool (end-effector) is to be mounted. This system moves with the tool and is aptly called the tool coordinate system. See Fig. 5.

Robots incorporating cylindrical coordinates have a horizontal shaft that goes in and out, and rides up and down, on a vertical shaft that rotates about the base. See Fig. 6. Additional rotary axes sometimes are used to allow for end-effector orientation. Cylindrical-coordinate robots are often well suited where tasks to be performed or machines to be serviced are located radially from the robot and where no obstructions are present. A robot incorporating cylindrical coordinates has a working area or envelope that is a portion of a cylinder.

Robots using spherical (polar) coordinates may be likened to a tank turret, i.e., they are comprised of a rotary base, an elevation point, and a telescoping extend-and-reach boom axis. See Fig. 7. Up to three rotary wrist axes (pitch, yaw, and roll) may be used to control the orientation of the end-effector. The arm moves in and out and is raised and lowered through an arc while rotating about the base. The end-effector moves in a volume of space that is a portion of a sphere.

The *work envelope* of a robot is that area in *space* that the robot can touch with the mounting plate on the end of its arm. Actually, the envelope will be somewhat larger, depending upon the dimension of the end-effector that is fastened to the tool mounting plate. See Fig. 8.

Robot Control Systems. Robots may be classified as (1) non-servo controlled; or (2) servo controlled.

In a non-servo controlled robot, the directional controls are fully off or fully on, causing essentially constant speed movement along an axis in one direction, or in the reverse direction. Some form of limit switch

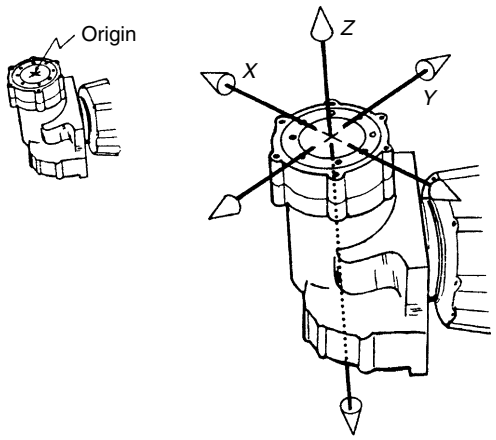

Fig. 5. Tool coordinate system of robot using Cartesian coordinates. In this system, the *X* and *Y* lines lie at right angles flat on the tool mounting surface. The *Z* line is the same as the axis of rotation for the joint, i.e., it points directly through the tool in one direction and through the wrist in the other direction. This system is *not* tied to the "world." While the origin of this system is thus allowed to move around, the destination (where it measures to) is left to the discretion of the user. Sometimes the tool coordinate system is actually used to measure where the tip of the tool lies relative to where it is mounted. Sometimes it is used to measure where one position in space lies relative to some other point in space. (*Westinghouse*.)

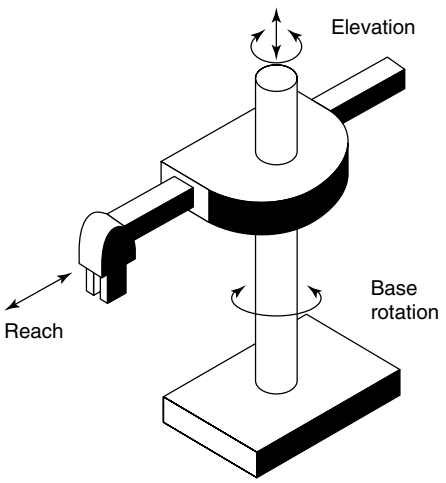

Fig. 6. A manipulator incorporating cylindrical coordinates.

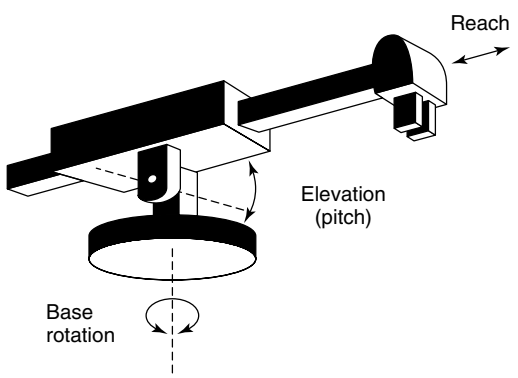

Fig. 7. A manipulator incorporating spherical polar coordinates. Operation is similar to that of a tank turret.

is used to stop the movement at the desired point. Non-servo controlled robots are the least complex of all robots. They move in an open-loop fashion between two exact end points on each axis, or along predetermined paths in accordance with fixed sequences. Such robots can operate over

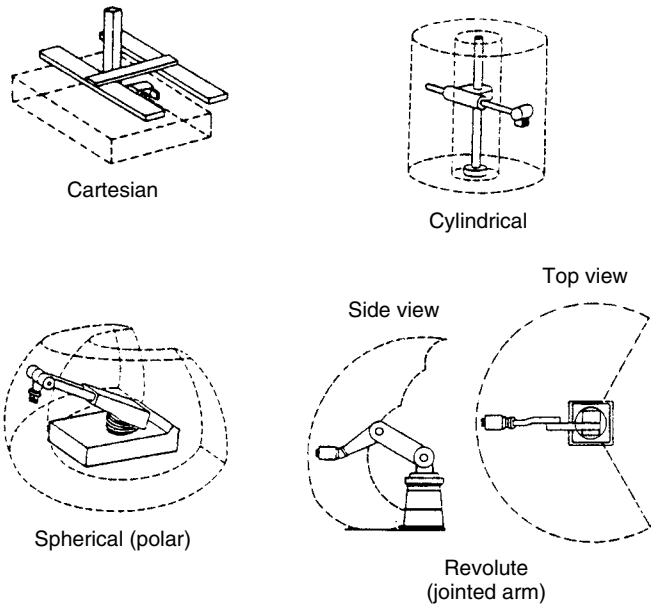

Fig. 8. Work envelope of a robot is that volume in space that the robot can touch with the tool mounting plate on the end of its arm.

an infinite number of points enclosed within their operational envelope. Non-servo controlled robots are given start and end points on each axis which must be passed. There is little or no control of end-effectors between these points. Technically, controlled trajectory is possible on a non-servo controlled robot only if the unit is given the coordinates of all points lying between the start and end parameters. This specific type of programming will allow the system to perform motions, such as straight lines and circles.

Non-servo controlled robots are sometimes called *limited-sequence* robots. The number of limb articulations is usually few. Because of their control characteristics, the non-servo controlled robot is also sometimes called a "bang-bang" device or a *pick-and-place unit* (a common designation for robot used for picking up an object, transporting it to a predetermined location, and placing the object at that location). Robots of this type are capable of high speed and usually have good repeatability.

The servo controlled robot incorporates one or more servomechanisms that enable the arm and gripper to alter direction in mid-air, without having to trip a mechanical switch. Servo controlled robots generally have larger program and memory capacity than their non-servo counterparts.

In a system of this type, upon start of program execution, the controller addresses the memory location of the first command position and also reads the actual position of the various axes as measured by a position feedback system. These two sets of data are compared and their differences (error signals) are amplified and transmitted as command signals to servo valves for the actuator of each axis. Thus, a servo controlled robot is a *closed-loop* system.

This closed loop refers to the robot system per se and does not embrace the total machine system that is served by the robot. The latter would require feedback of measurements made on the product of the handling operation and adjustments of the total system (machine plus robot) required to assure desired control of the total system. This requires additional inspecting, gaging, and other hardware and, in more sophisticated systems, may require *machine vision*.

Servo valves, operating at constant pressure, control flow to the manipulator's actuators. As the actuators move the manipulator's axes, feedback devices, such as encoders, potentiometers, resolvers, and tachometers (see also **Position and Displacement Measurement**), send position (and in some cases, velocity) data back to the controller. These feedback signals are compared with the desired position data and new error signals are generated, amplified, and sent as command signals to the servo valves. This process continues until the error signals are effectively reduced to zero, whereupon the servo valves reach *null*, and flow to the actuators is blocked and the axes come to rest at the desired position. The controller then addresses the next memory location and responds to the data stored

there. This may be another positioning sequence for the manipulator or a signal to an external device.

Generally, the memory capacity of a servo controlled robot will be sufficient to store up to 4000 and more points in space. Specific program select and sequence activity points for a given operating scheme. Programs can be varied to maintain the scheme while changing the activity points. Both *continuous-path* and *point-to-point* capabilities are possible. In this regard, robot system control is similar to numerical control of machine tools. (See also **Numerical Control**.)

Accuracy can be varied, if desired, by changing the magnitude of the error signal, which is considered *zero*. This can be useful in "rounding the corners" of high-speed continuous motions. Programming is accomplished by manually initiating signals to the servo valves to move the various axes into a desired position and then recording the output of the feedback devices into the memory of the controller. This process is repeated for the entire sequence of desired positions in space.

A servo controlled robot can be one of two types: (1) point-to-point; and (2) continuous path.

With a *point-to-point robot*, there are two main commands: (1) attitude of all limbs at the start of the move; and (2) the new attitude of those limbs when a particular move has been completed. While making the move as fast as possible and while moving all limbs simultaneously to fulfill a given command, there is no precise definition of the paths which the robot limbs will traverse. Thus, the term, point-to-point. In programming a robot of this type, the system designer must consider all possible *intervening points* between start and destination. For example, the robot may have to clear an object that may fall in its "direct line" path, or it may be desired for the robot arm to approach its destination at the best angle (for instance, in picking an object up from a pallet). Point-to-point robots can do any job performed by a limited-sequence robot previously described and, with sufficient memory capacity, these robots can handle jobs, such as palletizing, stacking, and spot welding, among others.

Continuous-path robots are required for applications where it is required to control, not only the start and finish points of each robotized steps, but also to control the path traversed by the robot hand as it travels between these two extremes. Seam welding is an example of where a robot wields a welding gun and moves it along some complex contour at the correct speed to produce a strong and neat weld. Theoretically, the continuous-path robot is an extension of the point-to-point concept because the curved path is made up of numerous straight-line segments. This requirement, of course, calls for a very substantial memory.

Programming Robots. With the availability of sophisticated electronic hardware and system software during the past decade, programming represents one of the most advanced segments of robot technology. Early in the development of automated systems, at a time when robots and other automation techniques were largely associated with *replicating the skills of human operators*, the guidance of robots was essentially a "copy cat" technique. The "playback" concept was used exclusively. With certain robots, this technique is still used.

In the playback method, the robot is programmed through a procedure known as "teaching." When one considers the numerous variables and complexities that can be encountered in applying robots, the need for a short cut to programming becomes evident. For example, in any reasonable volume of factory space, there are literally many thousands (depending upon resolution needed) of points that may become part of a robot program, particularly in the case of continuous-path systems. If Cartesian (X, Y, Z) coordinates are used, the storing of three coordinate values for each point of travel rapidly adds up to a lot of data to be stored. Further, in planning a robotic system, the designer who does not have a short cut method must visualize just how the system will operate in three-dimensional space and express design objectives in terms of *very long* lists of coordinate positions.

In the early days of robotics, of course, the designer did not have computer graphics and computer systems with large memories that approached even in a small way the abilities of present minicomputers and microprocessors. Thus, early designers developed a clever, innovative "teach-and-playback" methodology for robot programming. In the *teach mode*, the robot is directed through various movements in sequence, this accomplished by actually manually guiding the robot through its complete act so to speak. During the period, the sequence of movements is recorded in memory. In the *playback mode*, the robot simply repeats, as desired, the sequence of movements, as taught, from the memory system.

Levels of Programming for Robots. Ranging from simple to complex, there are three levels of robot programming:

Level 1 Programming — Manual, lead-by-hand teaching and front-panel programming. Applications include some spot welding and pick-and-place tasks.

Level 2 Programming — Programs are written in simple robot programming languages, i.e., techniques that assist programmers in entering motion, branching, coordinate-transformation, and signal instructions. Such systems may also provide a number of the lead-by-hand and control-panel operations that are characteristic of Level 1 programming. These programming capabilities permit running of *user programs* that are more complex than those at Level 1. Representative applications are found in some palletizing and arc welding tasks.

Level 3 Programming — These are the most modern and expanding methods for robot programming. The programming languages incorporate extended capabilities, including structured constructs, full arithmetic functions, external robot-path modifications, and supervisory computer-communications support. Since these systems support the functions and features found on the two lower programming levels, Level-3 systems can handle Level-2 applications as well as modifying the robot arm's path, based upon data transmitted from external sensing devices, including machine vision in the more complex systems.

Shown in Fig. 9 is a microprocessor-based, operator-friendly programming system. In this system, a lightweight hand-held teach pendant is used to lead the robot through its required moves. A controlled-path motion feature of the controller automatically coordinates all six axes to move the robot from one point to the next in world coordinates at the programmed velocity. An average of 3000 points can be programmed and stored within the control memory.

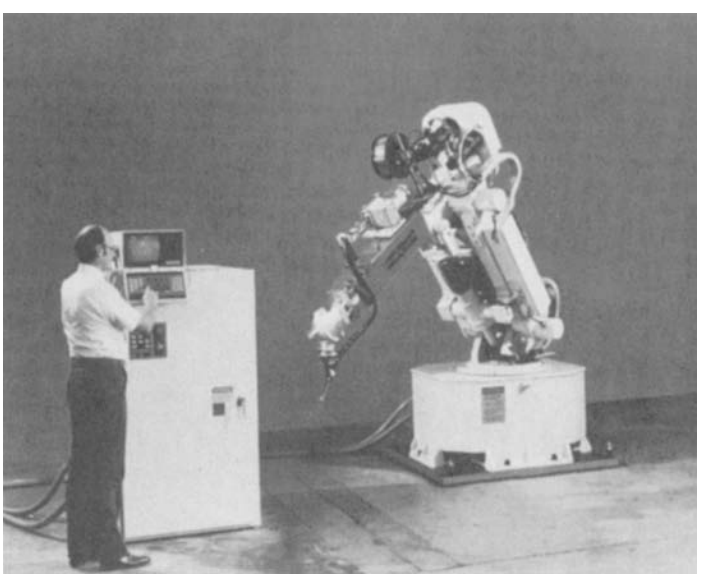

Fig. 9. Microprocessor-based, operator-friendly programming system. Menu-driven keyword approach to programming provides a simple interface with the robot. Keyboard commands permit creation and editing of application data. While teaching, the status of the robot's program and operating statistics, input/output or available memory may be examined. The communications interface provides a bridge to an FMS (flexible manufacturing system). The interface allows communication with host computers as well as intelligent sensors. (*Cincinnati Milacron*™.)

Large manufacturers and users of robots are aware of the importance of a day of lost production. Thus, manufacturers are concerned with robot downtime attributed to the normally slow process of entering program logic statements for machine, peripheral and sensor interfaces, conditional and unconditional program branching, looping, register manipulation, digital

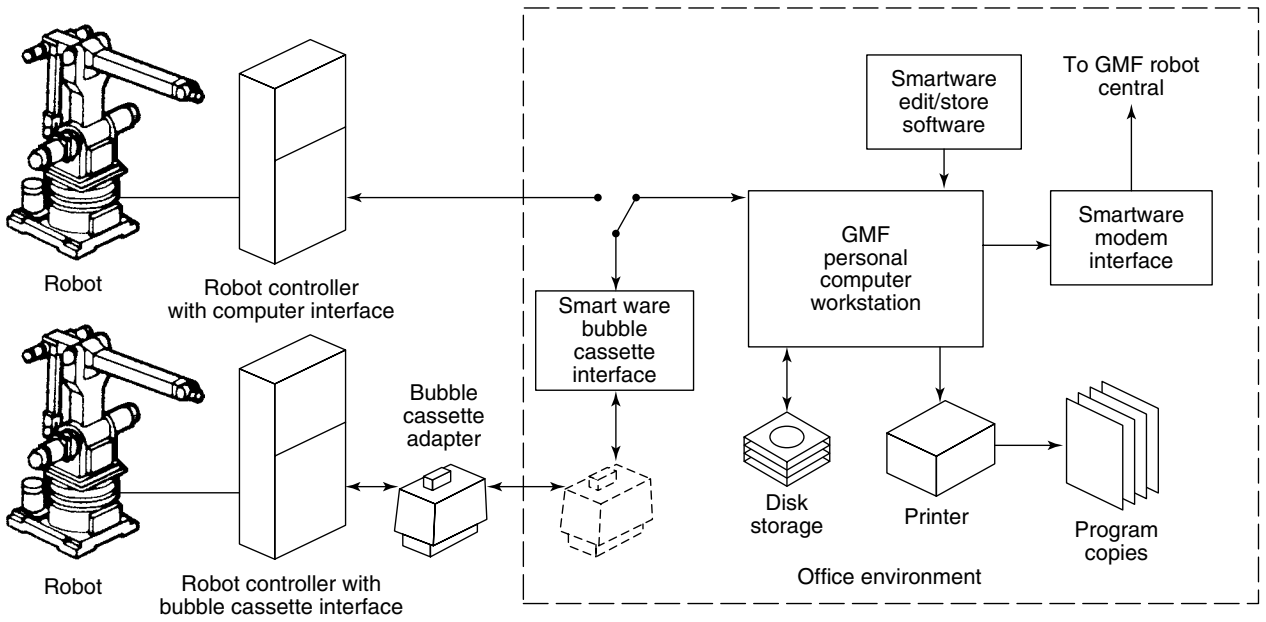

Fig. 10. Off-line personal computer (PC) workstation robot programming system. (*SmartWare*™, GMF Robotics Corp.)

input/output, indirect addressing, timers, macro instructions and other commands. This input is essentially the same for all robots performing a similar task and can represent up to 80% of total programming requirements. This problem essentially can be solved, by installing a system that permits the logic portion of a program to be generated *off line* before robots are installed.

One approach is shown in Fig. 10. The personal computer workstation shown consists of four modules, which are supplied in either of two basic combinations to fit a user's needs: (1) a turnkey system, including a 32-bit CPU (central processing unit), CRT, keyboard, dual disk drives and printer, plus an Edit/Store software package and an interface unit; (2) an interface unit and a Store software package for use with certain personal computers. The latter option provides upload/download, storing, copying and printing capabilities as well as the ability to view programs on a remote CRT screen and change program names. At the personal computer workstation, the operator can create and modify programs off line, even while the robot is working in the plant (or before installation). The user can edit stored programs and enter, store and display programming or editing comments, notes, and reminders.

A six-axis robot, the motion control of which uses 15 microprocessors, 6 optical encoders, and 6 stepper motors is shown in Fig. 11. Six degrees of freedom are required to minimize the demands on the construction of the robot workstation. In the interest of cost and speed, a distributed processing system is used. Stepper motors are used because of their relatively low cost and ease of control. Problems of accuracy and motor control are solved by software.

Some of the tasks assigned to software include calibrating the arm, control of end-effectors (grippers) and safety devices, and image processing analysis by an integrated machine vision system. (See also **Machine Vision (Recognition and Applications)**.) The software is also responsible for motor control functions and software control of motion. Although the robot is built with as much mechanical accuracy as possible, considering cost restraints, the arm-parameter calibration, for example, can make up for certain manufacturing tolerances. Nearly 20 sources of mechanical error have been identified. These errors, however, are constant for a given robot; they may vary from robot to robot. Once these constants are determined for a specific robot, they can be used by the software to perform calculations that accurately position the robot.

The robot shown in Fig. 12. is an electric-drive, overhead gantry configuration that incorporates tactile sensor technology. As designed, the machine is a fully self-contained workstation that allows either stand-alone or integrated assembly line adaptation. It has a high level of dexterity of the kind required for the assembly of disk drives, printed circuit boards (PCBs), wire harnesses, and telecommunication and electromechanical devices. The

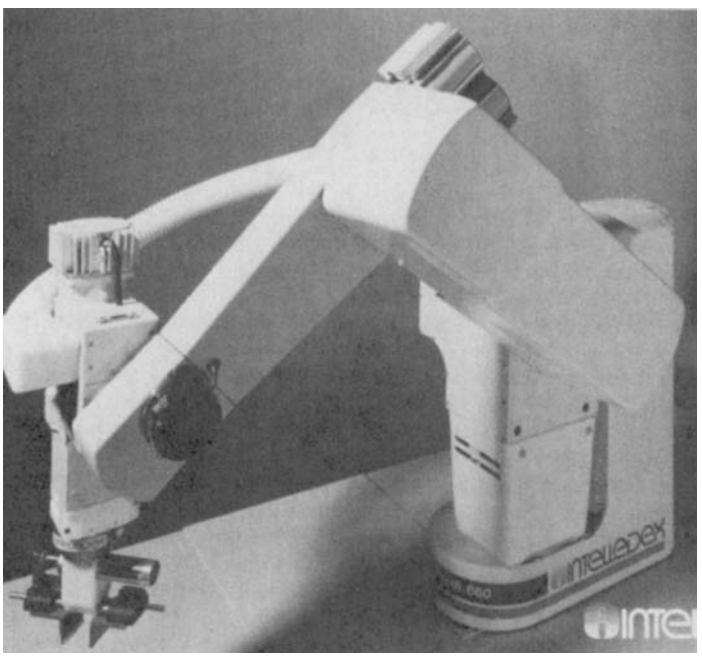

Fig. 11. A six-axis robot with a humanlike (anthropogenic) joint configuration, giving it exceptional dexterity and allowing it to approach any point in the work envelope from any angle, thus providing easy adaptability to existing workstations. (*Intellidex*™.)

system has the potential of automatic laser inspection. The intelligent gripper incorporates both optical sensing and a strain gage that allows force-sensing thresholds to be programmed in three orthogonal axes. Parts that are out of tolerance or that are not properly oriented are detected quickly, enabling the robot to respond as required. Intelligent action based on the specific "force signatures" programmed into the gripper recognize and accommodate specific assembly tasks.

Load Capacity and Power Requirements of Robots. A recent survey of manufacturers of robots in the United States, Europe, and Japan indicated that models available (not total units installed) were designed to handle loads ranging from about one pound (0.5 kg) upwards to about 2300 pounds (1043 kg). These Figures, of course, do not bracket all robots ever made, either in terms of very heavy or very light loads. Applications included in the survey were found in die casting,

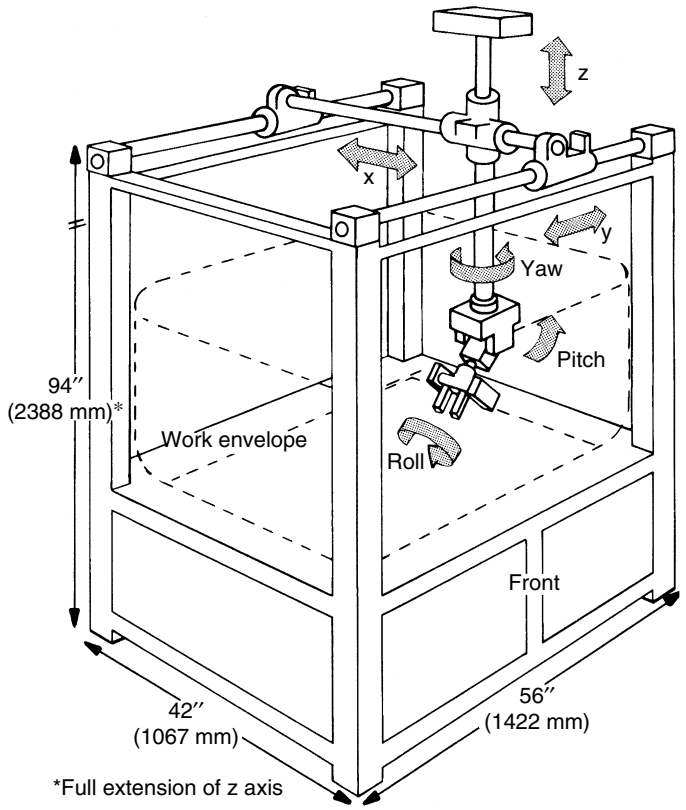

Fig. 12. Intelligent, high-precision parts-assembly robot that incorporates both optical (vision) and force (tactile) sensors for feedback. Modular work-station concept of overhead gantry, as shown at right, facilitates integration into assembly flow. The six-axis configuration consists of three linear axes (X, Y, Z) and three rotary axes (yaw, pitch, and roll). All are driven by direct current servomotors. Accuracy and repeatability are ± 0.002 and ± 0.001 inch, (0.05 and 0.03 mm) respectively. Resolution is specified as 0.0005 inch (0.013 mm).

A teach pendant is provided for on-line programming and reprogramming to accommodate production line changes. A hand-held tool allows production personnel to control all robot movements, time delays, high-level commands for self-calibration, and to call up complex subroutines. Supporting the teach pendant, including on-line and off-line programming through an IBM PC compatible computer, is a special programming language developed by the manufacturer. Programs can be written and tested interactively on line or written off line and downloaded from disk for implementation. (*Adaptive Intelligence Corp.*)

forging, plastic molding machine tools, investment castings, spray painting, welding, and machining, among many others. It is well established that the use of robots in light manufacturing and inspection operations is expanding, particularly in the electronics manufacturing industry.

Many electric robots utilize direct current stepping motors. (See also *Servomotors.*) Hydraulically powered robots usually employ hydraulic servo valves and analog resolvers for control and feedback. Digital encoders and well-designed feedback control systems can provide hydraulically actuated robots with an accuracy and repeatability generally associated with electrically driven robots. Pneumatically driven robots normally are found in light service, limited-sequence, and pick-and-place applications.

Electric Drives for Robots. Electric motors provide the greatest variety of choices for powering manipulators in the low- and moderate-load range, and for low-speed, high-load operations. They are relatively easy to control and a number of control techniques can be used. Electric motors are not as responsive as hydraulic systems and are considerably stiffer than pneumatic systems, unless the latter are operated under very high pressure.

Motors generally operate at speeds that far exceed those desirable for manipulator joints. Thus, speed reducers are required. Although speed reducers have the advantage of amplifying available torque and in preventing or inhibiting back driving, they are usually a major source of inefficiency and error. In demanding applications, the most important factors in selecting a motor include the power-to-weight ratio and torque-speed characteristics. The ability to accelerate and decelerate the working load quickly is a very desirable attribute. Also required is the ability to operate at variable speeds.

The development of microstepping techniques, pioneered by the office automation and instrument industries, contributed to the knowledge of an effective use and control of electrical stepping motors. For example, microstepping had led to the use of stepping motors in applications requiring incremental rotary motion of only a fraction of the particular motor's primary step angle. Hybrid step motors combine the fast response of variable reluctance motors with the detent torque of permanent-magnet step motors. Step motors are easily used in closed-loop servo systems and also may be operated in a synchronous mode at their slow speed.

Because electric robots do not require a hydraulic power supply, they conserve floor space and decrease factory noise. In an electric manipulator, the motors generally connect to the joints through a mechanical coupling, such as a leadscrew, pulley block, spur gears, or harmonic drive. This is because electric motors generally produce much less force or torque than a hydraulic actuator of the same size and thus require a mechanical impedance matcher between them and the joint if they are to overcome the loads that are encountered in a typical manipulator. A hydraulic actuator usually can drive a joint directly.

Permanent-magnet direct current motors have proved a good choice for medium- and small-size manipulators. They are generally more efficient, less costly, lighter, and smaller than wound-field motors. These servoed motors have been and continue to be a good choice for many applications. The brushless, electronically commutated versions have long lives. Printed circuit motors have high torque relative to their rotor inertia and thus have fast response time. These motors are capable of driving at low speeds without the need for speed reducers.

Hydraulic Actuators for Robots. Hydraulic actuators are either (1) linear piston actuators, or (2) a rotary vane configuration. Hydraulic systems are relatively easy to control because the low compressibility of hydraulic fluids results in the systems being very stiff. The high power-to-weight ratio makes the hydraulic actuator an attractive choice for moving moderate-to-high loads at reasonable speeds. Hydraulic systems are characterized by fast response time, high natural frequencies, and low signal noise levels. A major disadvantage of hydraulic systems is their need for an energy storage system, including pumps and accumulators. Several years ago, for machine tools, a switch was made from hydraulic to electric drives mainly because of better reliability and leakage problems associated with hydraulics. In some applications, such as paint spraying, hydraulics do not present an explosion hazard.

Dynamic Properties of Robots. Included among these properties are: (1) stability; (2) resolution; (3) repeatability; and (4) compliance. Considering these factors, the design of a robot is innately complex because of the manner in which these properties interrelate. Stability is associated with the oscillations in the motion of the tool. The fewer the oscillations, the more stable the operation of a robot. Lack of stability increases wear and sometimes inconsistencies in performance. Resolution is function of the design of the robot control system and specifies the smallest increment of motion by which the system can divide the working space. Repeatability is the ability of the robot to reposition itself to a position to which it was previously commanded or trained. The compliance of a manipulator is indicated by its displacement relative to a fixed frame in response to a force (torque) exerted on it. High compliance means the tool moves a lot in response to a small force (the manipulator is then said to be spongy or springy). If it moves very little, the compliance is low (the manipulator is said to be stiff).

These matters are dealt with in considerable detail in the Considine reference listed.

End-Effectors (Hands or Grippers). The end-effector is the device fastened to the free end of a manipulator. It provides the means for the manipulator to interact with its surroundings. The function of the end-effector is first to grasp an object or a tool, then hold it while the manipulator moves — thereby also moving the object — and finally to release the object.

Four main methods are used for holding parts or tools: (1) mechanical clamping; (2) vacuum suction; (3) magnetic attraction; and (4) plug-in or

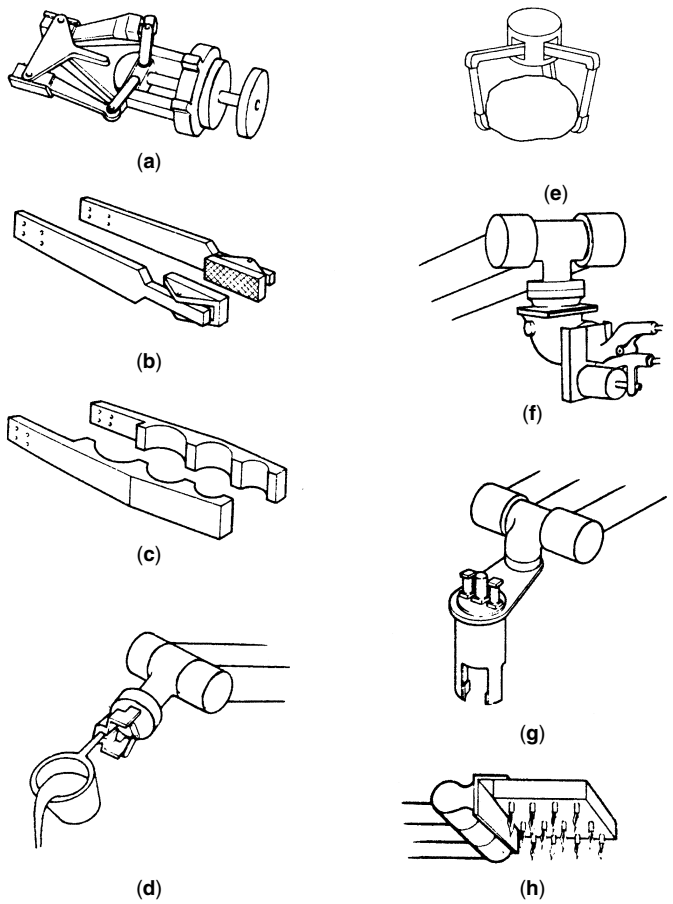

Fig. 13. Representative end-effectors (hands or grippers) used by robots for various applications: (**a**) *Standard hand* — inexpensive, all-purpose design. Will accept a wide variety of custom fingers, tailored to the parts to be manipulated or moved. Parts should be of moderate weight. Simple linkages provide both finger action and force multiplication needed to grip object with just the right force. (**b**) *Self-aligning pads* for fingers are valuable for assuring a secure grip on a flat-sided part. "Cocking" of the part is unlikely when pads like these are used. (**c**) *Multiple fingers* for grasping different-size parts. Thus, a particular finger design need not be restricted to parts within a given size range. (**d**) *Ladle* for moving hot fluid materials, such as molten metal. (**e**) *Three-finger gripper*. (**f**) *Sportwelding gun*. (**g**) *Pneumatic nut-runner*. Similar configurations can be used for holding drills and impact wrenches. (**h**) *Heating torch* as may be used to bake out foundry molds by playing the torch over the surface. Scores of standard and special robot end-effectors are used.

detent fittings. Scoops, ladles, and sticky fingers using adhesives are among numerous specialized types of end-effectors. A montage of representative grippers is given in Fig 13.

In the robot shown in Fig. 14, the end-effector, instead of taking the form of a gripper for grasping pieces, is an inspection sensor used to test tubes in steam generators.

Workplace Configuration and Environmental Factors

Robots must cope with the same environmental hazards as other industrial instruments and controls on the factory floor. Among the most important of possible adverse conditions are: (1) high temperature; (2) dusty, dirty, corrosive, and sometimes potentially explosive and fire prone atmospheres; (3) shock and vibration; and (4) electromagnetic interference, among others. In turn, robots contribute their share to the environmental problems, not the least of which is noisy operation in numerous instances. Further, safe shutdown of robots (fail-safe protection) is required because a meandering, heavily loaded robot can constitute a dangerous threat to both personnel and equipment. All workers who are in the vicinity of a robot must know and respect the full robot's working envelope which in most cases is impractical to screen. As the use of "stock" robots becomes more popular, increasing care and attention to their safe operation must be given.

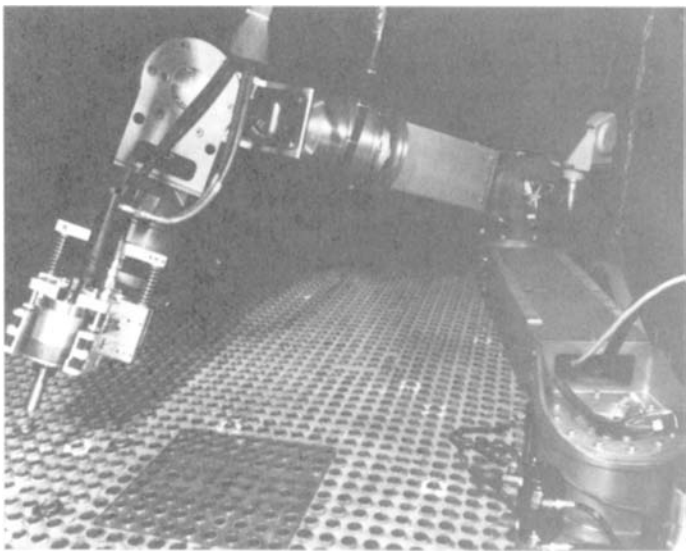

Fig. 14. Robot used for inspecting tubes in a steam generator. (*Westinghouse*.)

Packaging. In many applications, it is acceptable to package the robot as a self-contained entity, but there are advantages in mounting the electronics separately. In extreme shock conditions, it may be desirable to mount the control console on a shock-absorbing pad in a remote location as protection against hostile atmospheres. If the power supply of a robot can be separated from the robot's arm, then it is possible to introduce only the arm into an explosive atmosphere, such as a paint room, or some potentially dangerous area as may be found in a nuclear facility. Following the design practices for inherent safety is always worthwhile. Particularly for protection against abrasive dust, the joints of the robot may be booted. Nonflammable fluids for lubrication and hydraulics represent good robot design. Where atmospheric air is particularly dirty, cooling air should be well filtered and enter enclosures to provide positive internal pressure. Robot logic design must be well protected from power line spikes and noise pickup that may enter through any of the robot's communication links with surrounding equipment.

The Robot Setting

There are four basic situations pertaining to the flow of work and the location of the robot: (1) work may be *arranged around* the robot, (2) work may be *brought* to the robot, (3) work may *travel past* the robot, and (4) the *robot may travel* to the work. Arrangement (3), of course, is a variant of (2).

Work Is Around the Robot. In the early installations of robots, the work was usually arranged around the robot. This arrangement causes the least commitment of space and the least disruption of plant procedures. The system is still used and frequently found in such operations as forging and trimming, press-to-press transfer, plastic molding, and investment casting. See Fig. 15.

Work Is Brought to the Robot. Flexibility has been enhanced through the use of computer control. For example, the robot can be made to track a workpiece that is being carried by a conveyor and thus the robot performing its task as the work passes by. The versatility of such a system can be extended to accommodate variations in conveyor speed. Automatic robot welding systems are of this variety. This is illustrated in the article on **Automation**. The configuration is sometimes called "stationary-base line tracking."

In a contrasting situation, the robot(s) may be mounted on some form of transport system, such as a rail and carriage, which moves parallel to the line at line speed. This type of system requires a powerful drive system so that the robot can be returned to its starting point from the other end of its tracking range in the shortest possible interval. The designer also must guard against interference problems that may arise from adjacent stations.

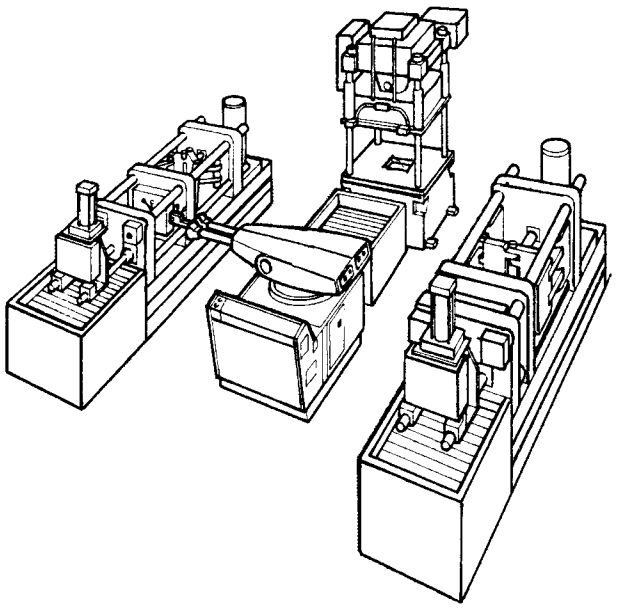

Fig. 15. Die casting installation to unload, quench, and dispose of parts. In this installation, quite exemplary of earlier robotics, the work is arranged around the robot. (*Westinghouse*.)

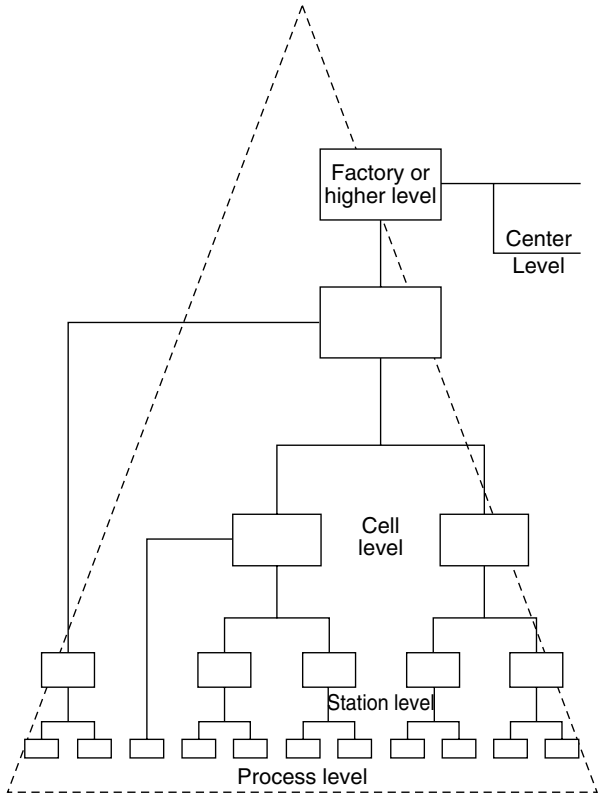

Fig. 16. Pseudopyrimidal hierarchy where communications are predominantly vertical rather than horizontal.

Robot Travels to the Work. When machining cycles are quite long, a robot can be mounted on a track to enable it to travel among more machines than can be conveniently grouped around a stationary robot.

Work Cells. A robotic work cell may be defined as a cluster of two or more robots and several machine tools or transfer lines which are interconnected in such a way that they work together in unison. All of the necessary accessory equipment is embraced within the work cell. Criteria for justifying a robotic work cell include: (1) the system must be capable of performing required machining functions on a limited number of parts of sizes within predetermined limits; (2) one worker must be capable of operating the work cell with minimal skill needed; (3) selection of operator personnel from the shop floor must be possible; (4) manual parts fabrication in the work cell must be feasible in cases of system failure; (5) compliant end-effectors must be used because of inherent inaccuracies of available commercial robots; (6) part programming must be done on line; (7) safety sensors must be installed for protection of personnel, equipment, and work in process; (8) consistent quality must be maintained on parts; (9) productivity must be increased to make the system economical; and (10) early implementation must be made for quickest payoff.

As reported in a survey of productivity in the United States, it was noted that (1) of the time consumed in manufacturing a part, only 5% is actually used by a given machine tool; and (2) of that time, only 1.5% is used in making chips. Thus, 95% of the time is used for handling, record-keeping, and similar nonproductive activities. These observations have led to three criteria for assuring profitability from work cells: (1) work cells should not be isolated from the remainder of the plant; (2) the product should be made with automation in mind (from the start); and (3) the work cell should be designed for maximum product-making flexibility. Further studies have shown that maximum profitability is obtained when work cells can communicate with the remainder of the plant. A pyramidal hierarchy, where communications are exclusively vertical rather than horizontal, is the most desirable arrangement. See Fig. 16.

Overview of Contemporary Robots

Robots used for a number of different industrial applications are illustrated and described in Fig. 17. See also **Artificial Intelligence: Robotics**.

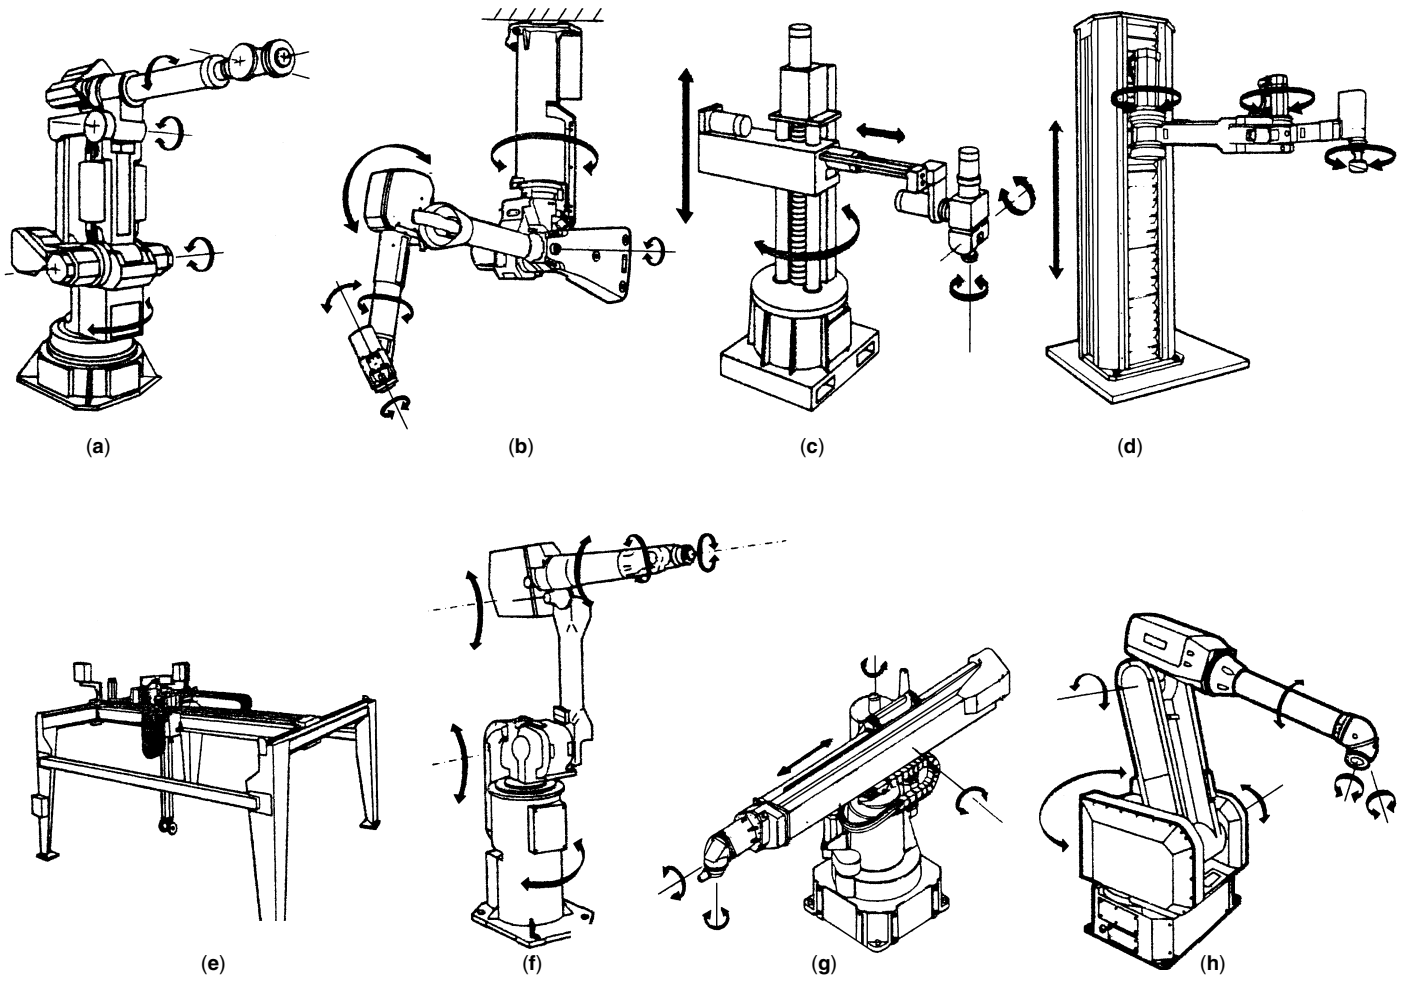

Fig. 17. Representative industrial robots. (*Courtesy of GM Fanuc Robotics Corporation.*)

(**a**) Spot welding, heavy part or tool handling, parts transfer, palletizing, material removal. Payload 120 kg (264 lb). Six axes of motion; floor-or wall-mounted; repeatability ±0.5 mm (0.02 inch); base rotation 300°; vertical travel 2731 mm (107.5 inches); reach 2413 mm (95 inches). (*S-420*)

(**b**) Arc welding of large parts on conveyors and fixtures. Payload 5 kg (11 lb). Six axes of motion; overhead-mounted; repeatability ±0.1 mm (0.004 inch); base rotation 300°; reach 1309 mm (51.5 inch). (*ArcMate OH*)

(**c**) Material handling, machine loading, palletizing, mechanical assembly in severe environments. Payload 50 kg (110 lb). Three to five axes of motion; floor-mounted; repeatability ±0.5 mm (0.02 inch); base rotation 300°; vertical travel 550 or 1300 mm (21.6 or 51.2 inches); horizontal travel 500 to 1100 mm (19.7 to 43.3 inches). (*M-100*)

(**d**) Palletizing and machine loading. Payload 50 kg (110 lb). Four to five axes of motion; floor-mounted; repeatability ±0.5 mm (0.02 inch); vertical travel 1850 mm (72.8 inches); radius reach 1930 mm (76 inches); access to two or more conveyors. (*M-400*)

(**e**) Gantry robot for medium- to heavy-payload machine load and unload uses. Also palletizing, mechanical assembly, parts transfer. Cartesian coordinates. Area (shown) or linear configurations. Payload 50 kg (110 lb). Repeatability ±0.5 mm (0.02 inch); very large work envelope; two to four axes of motion for linear design; three to five for area design. (*G-500*)

(**f**) Multipurpose material handling; light-payload applications. Payload 10 kg (22 lb). Six axes of motion; floor-, ceiling-, or wall-mounted; repeatability 0.2 mm (0.008 inch); base rotation 300°; front reach 1529 mm (60.2 inches). (*S-10*)

(**g**) Laser robot for integration with a laser generator. For precision-path laser processing — welding, cutting, heat treating, and cladding. Payload 5 kg (11 lb). Five axes of motion; floor-mounted; antiback-lash drive; repeatability ±0.05 mm (0.002 inch); base rotation 200°; vertical travel 1968.5 mm (77.4 inches); horizontal travel 3964 mm (156 inches). Complete robotic laser cells available. (*L-100*)

(**h**) Industrial and automotive paint finishing of stationary or moving parts. Payload 7 kg (15.5 lb). Six or seven axes of motion; floor-or rail-mounted; repeatability ±0.5 mm (0.02 inch); maximum reach 2613 mm (103 inches), large work envelope. Robot also used for dispensing and applying antichip sealers and underbody deadeners. (P-155)

ROBUSTNESS. In statistical tests, robustness is the property of being insensitive to small departures from the assumptions from which the test was derived.

ROCHE LOBE. See **Binary Stars**; and **Neutron Stars**.

ROCHES MOUTONNÉES. The term given by the Saussure, in 1796, to glaciated rock hills resembling the wigs which were fashionable during the late eighteenth century. Typical roches moutonnées have rounded surfaces sloping gently in the direction of the ice movement with steeper slopes on the lee side, due to the plucking action of the ice.

ROCK. In geologic usage, rock is the material composing the outer part or "crust" of the earth. It is a popular concept that the term rock is restricted to hard or firm substances. To a geologist, however, a body of clay or of volcanic ash is as truly rock as is a mass of hard granite. In general, a rock consists of one or more definite minerals. However, natural glass (obsidian), which has no definite composition and structure, makes large rock masses, as in Yellowstone National Park. Rocks composed of definite minerals may be either simple or compound; for example, the purest marble is formed entirely of the one mineral calcite, whereas granite consists of feldspar and quartz mixed in varying proportions, usually with minor quantities of mica and other accessory minerals.

All rocks are divided into three major classes, according to mode of origin. Igneous rocks are those that have been formed by cooling and solidification of molten masses derived from within the earth. Because of their origin they are sometimes called the primary rock. In part they are lavas and other products of volcanoes; other masses solidify slowly below the earth's surface to form granite and other crystalline types of igneous rock whose mineral content depends chiefly on the chemical composition of the parent molten mass. Sedimentary rocks consist of material that formed a part of pre-existent rocks, and that was moved from its former position, deposited by the action of water, the atmosphere, or glacier ice, and subsequently converted into rock. Examples are conglomerate, sandstone, and limestone. Metamorphic rocks are those that were originally igneous or sedimentary, but have been changed either in mineral composition or in texture, or in both, so that their original characters have been radically altered. Slate, formed by alteration of shale, and marble, derived from pre-existent limestone, are familiar examples.

See also **Igneous Rock**; and **Metamorphic Rocks**.

ROCKET ENGINE. A reaction engine that contains within itself, or carries along with itself, all the substances necessary for its operation or for the consumption or combustion of its fuel, not requiring intake of any outside substance and hence capable of operation in outer space. Also called *rocket motor*. Chemical rocket engines contain or carry along their own fuel and oxidizer, usually in either liquid or solid form, and range from simple motors consisting only of a combustion chamber and exhaust nozzle to engines of some complexity incorporating, in addition, fuel and oxygen lines, pumps, cooling systems, etc., and sometimes having two or more combustion chambers. Experimental rocket motors have used neutral gas, ionized gas, and plasmas as propellants.

ROCKET LIGHTNING. See **Lightning**.

ROCKET PROPELLANTS. Chemical rocket propellant can be classified in several ways, including liquid or solid, monopropellant, bipropellant or tripropellant, cryogenic or storable, hypergolic or nonhypergolic, double-base, composite or composite double-base. Propellant classification frequently influences the classification of rocket engines — for example, monopropellant rocket, liquid rocket, solid rocket, and hybrid rocket (usually using a liquid oxidizer and a solid fuel). Propellants for chemical rockets serve two primary functions as contrasted to one function for nuclear, solar, electrical or laser heated rockets. In chemical propellant rockets, the propellant is both the energy source and the ejected mass or "working fluid."

Compared with the almost limitless number of chemical compounds that exist or can be formed, the number of chemical propellants in common use is relatively few. This situation arises from criteria including costs, source availability, toxicity, resistance to shock, and other requirements imposed by the vehicle application and the propulsion system design. Another practical reason is that extensive overlap of physical, chemical, and economic properties are displayed by many of the theoretically possible propellants. During the 1960s, the universities, industry, and government in the United States pursued extensive research programs for synthesizing new chemical compounds viewed as candidate propellants, which would increase the performance capability of chemical rockets. Although dozens of compounds were synthesized, few results reached the production line. This does not mean, however, that a scientific breakthrough in increasing the molecular energy of a propellant may not be ultimately obtainable.

The characteristics desired of a rocket propellant are several in number and can be divided into economic, safety, materials compatibility, engine-cycle needs and vehicle requirements.

In general terms, the engine-cycle needs ideally are: (1) a propellant or propellant combination that has a high heat of reaction per unit weight (also called heat of combustion). Most vehicles add a requirement for high heat of reaction per unit volume of propellant to minimize the vehicle size. (2) reaction products that are all gaseous, that have a very low molecular weight and that have a very high temperature of dissociation.

In addition to specific impulse, the vehicle requirements usually influence propellant selection in terms of storability, density, toxicity, and other hazards, and other application-sensitive factors, including exhaust plume properties and radar cross section and radiation emissions. Other factors being essentially equal, the higher the heat of reaction of a propellant (or combination), the more attractive the propellant. Sharp exceptions to this rule occur in some missiles because of volume limitations, the need for smokeless exhaust or similar restraints.

The heat released by a propellant is the difference in heat between the constituents and the end-products of combustion.

$$\Delta H_r^\circ = \left[\sum_{k,\ \text{products}} \eta_k (\Delta H_f^\circ)_k - \sum_{j,\ \text{reactants}} \eta_j (\Delta H_f^\circ)_j \right]$$

where ΔH_r° is the heat generated; ΔH_f° is the standard heat of formation of the constituent at reference temperature (298K); and η is the number of moles of each j reactant or k product. Large heat release is afforded by reaction products having large negative values, while the reactants should have positive, or at least small negative values, if possible. The heat of reaction is often noted in energy/weight units, such as kilocalories/gram.

Specific impulse, I_{sp}, the universally accepted measure of rocket engine performance, can also be used to indicate the performance of propellants. The most commonly stated expansion ration is $1{,}000 \rightarrow 14.7$ giving "sea-level specific impulse at 1,000 psi chamber pressure." Sometimes the expansion ratio is $1{,}000 \rightarrow 0.2$ to indicate specific impulse for high-altitude or space flight.

By definition, specific impulse I_{sp} is:

$$I_{sp} = \frac{F}{\dot{W}}$$

with the I_{sp} units being seconds; the short designation for units of thrust (force) per units of propellant mass flow per second.

For an ideal rocket with the nozzle exhaust pressure being the ambient pressure, the thrust, recognizing Newton's second law of motion, is:

$$F = \frac{\dot{W} c_e}{g}$$

where W is propellant flow rate in pounds per second; c_e is exhaust velocity in feet per second; and g is the gravitational constant in feet/second/second.

In practice, only about 10% of the elements on the periodic chart are adaptable to chemical rocket propellants. Propellants have made little use of elements other than hydrogen, carbon, nitrogen, oxygen, chlorine, fluorine, aluminum, boron, and beryllium.

Liquid propellants fall into two broad classes: (1) earth storable (monopropellants and bipropellants), and (2) cryogenic, depending upon whether they can be kept in the vehicle tankage for months and years, or must be used in a few hours or days. The theoretical performances of storable and cryogenic bipropellants combusting ideally at 1,000 psia chamber pressure and expanding to sea-level pressure without loss, assuming shifting chemical equilibrium of the combustion products during expansion in the engine exhaust nozzle, are listed in Tables 1 and 2. For comparison purposes, a

TABLE 1. STORABLE LIQUID BIPROPELLANT COMBINATIONS

Oxidizer	Fuel	Oxygen-Fuel Ratio by Weight for Maximum I_{sp}	Bulk Specific Gravity	Theoretical I_{sp}[a]
Nitrogen tetroxide	50/50 Hydrazine/ Unsymmetrical dimethylhydrazine	2.0	1.19	289

Ethylene oxide	0.89	199	20.50

[a] 1,000 → 14.7 psia, shifting equilibrium (chemical composition of exhaust gases changes during nozzle flow).

Solid propellants fall into three general types: (1) double-base, (2) composite; and (3) composite double-base. Double-base propellants form a homogeneous cured propellant, usually a nitrocellulose-type of gun-powder dissolved in nitroglycerin plus minor percentages of additives. Both the major ingredients are explosives and both contribute to the functions of fuel, oxidizer, and binder. Composite propellants form a heterogeneous propellant grain with the oxidizer crystals and a powdered fuel (usually aluminum) held together in a matrix of synthetic rubber (or plastic) binder such as polybutadiene. Normally, composite propellants are less hazardous to manufacture and handle than double-base propellants. Composite double-base propellants are a combination of the two aforementioned types — usually a crystalline oxidizer (ammonium perchlorate) and powdered aluminum fuel held together in a matrix of nitrocellulose-nitroglycerin. The hazards of processing and handling this type of propellant are similar to those experienced with the double-base propellants. The characteristics of several common solid propellants are given in Table 4.

Al Aluminum
AP Ammonium perchlorate
CTPB Carboxy-terminated polybutadiene
DB Double base
HMX Cyclotetramethylene tetranitramine
HTPB Hydroxy-terminated polybutadiene
PBAA Polybutadiene-acrylic acid polymer
PBAN Polybutadiene-acrylic acid-acrylonitrile terpolymer
PU Polyurethane
PVC Polyvinyl chloride

Notes: [a] AP/Al optimized with 40% DB as binder.
[b] AP/Al optimized with 20% binder.
[c] AP/Al optimized with 15% binder.

Ingredients are generally classified according to their function, e.g., fuel, oxidizer, binder, curing agent, burn-rate catalyst, etc. Ingredients used in small amounts are called additives and usually have functions other than the fuel, oxidizer, or binder. For example, an additive can reduce the viscosity of the propellant during mixing and casting (pouring) of the propellant, increase the burning rate of the propellant, or improve the storage stability. Often an ingredient serves or affects more than one function, the most diffused situation relating to composite double-base ingredients where the binder is a nitrocellulose-nitroglycerine complex with each of these two ingredients having its own fuel and oxidizer chemical elements. The binder contributes also as a fuel and in some propellant formulations, such as asphalt-base nonmetallized propellants, the binder is the fuel.

Ammonium perchlorate, NH_4ClO_4, is the most widely used crystalline oxidizer in solid propellants. Because of its characteristics, including compatibility with other propellant materials, specific impulse performance, quality uniformity and availability, it dominates the solid oxidizer field. Both ammonium and potassium perchlorate are only slightly soluble in water, a favorable trait for propellant use. Nitronium perchlorate is objectionably hygroscopic, is relatively incompatible with available binders, and detonates easily. All of the perchlorate oxidizers produce hydrogen chloride in their reaction with fuels. Their exhaust bases are toxic and corrosive to the extent that care is required in firing rockets, particularly the very large rockets, to safeguard operating personnel and communities in the path of exhaust clouds. Ammonium perchlorate is available in the form of small white crystals and close control of the size range and percentage of several sizes present in a given quantity or batch is required, since particle size influences propellant processing and the physical and ballistic properties of the finished propellant.

Inorganic nitrates are relatively low-performance oxidizers as compared with the perchlorates. However, ammonium nitrate is used in some applications for economy and because of its smokeless and relatively nontoxic exhaust. Its main use is in low-burning rate, low-performance applications, such as gas generators for turbine pumps.

One or two crystalline high explosives, such as HMX (cyclotetramethylene tetranitramine) and RDX (cyclotrimethylene trinitramine), are sometimes included in a propellant formulation to achieve a specific performance characteristic. Depending upon the objectives, the percent can range from 5 to 50%.

The one prominent solid fuel is powdered aluminum, and it is used in a wide variety of composite and composite double-base propellant formulations, usually being between 14 and 22% of the propellant by weight.

Boron, even though it appears as one of the high-energy fuels and is lighter than aluminum, has not proven to be a practical fuel because it is so difficult to burn with high efficiency in combustion chambers of reasonable length. Beryllium burns much more easily than boron and improves the specific impulse of a solid propellant motor, usually by about 15 seconds, but as a powder or dust it is highly toxic to animals and humans. The technology with composite propellants using powdered beryllium fuel is sufficiently advanced for vehicle application, with space travel being the most likely application.

Theoretically, both aluminum hydride, AlH_3, and beryllium hydride, BeH_2, are attractive fuels because of their high heat release and gas volume contribution. Both are difficult to manufacture and both deteriorate chemically during storage due to loss of hydrogen. Because of these difficulties, coupled with relatively modest I_{sp} gains, these compounds remain experimental.

Hybrid rocket propellants are various combinations of solid and liquid propellants, usually a solid fuel and a liquid oxidizer. Sometimes, a third propellant, liquid hydrogen, is added, not for energy release, but as a low-molecular-weight working fluid. The main advantages of a hybrid rocket are: (1) use of liquid and solid propellant combinations offering the highest performance attainable with chemical rockets; (2) simplicity of a solid grain (usually fuel); (3) a liquid for nozzle cooling and thrust modulation (compared with a solid rocket); (4) restart capabilities; and (5) good storability and safe storage characteristics.

The chemical bond energy present in propellant molecules is the energy source used by chemical rocket engines to date. This source affords energy densities of approximately 3 kilocalories/gram in the liquid hydrogen/liquid oxygen combination, and up to about 5.7 kilocalories/gram with the lithium/fluorine combination. Theoretically, supplemental energy can be added to molecules or molecular fragments that, upon recombination or relaxation to their normal energy state, release significant amounts of energy. For example, 52 kilocalories/gram is theoretically released when two hydrogen atoms (free radicals) recombine to form hydrogen. Even higher energy densities, as much as 100 kilocalories/gram, are theoretically available from lightweight molecules, such as helium, that are in an excited state.

Metastable, in the sense of propellant ingredients, means that the "energized" molecule, atom, or molecular fragment, tends to promptly return to its normal state. Some molecular species distinctly assume a metastable state upon excitation with the lifetime at room temperature being 10^{-3} to 10^{-2} second as compared with less than 10^{-6} for nonmetastable excited species. Atoms subjected to excitation

move into a more energetic state of translational motion of vibration or into a high-energy electron orbital state; diatomic molecules do likewise. Molecules containing more than two atoms can experience higher translational rotational motion, as well as higher electron orbital state.

Most of the research to date on metastable propellants has been with gaseous atoms and molecules. Obviously, energized ingredients in a condensed phase, solid or liquid, would be needed for most rockets. The primary objectives to be reached, if metastable ingredients are to benefit rocket propulsion, are: (1) an efficient process for energizing the ingredients; and (2) a means of storing the ingredients for days at a time without appreciable energy loss. Actual use of metastable ingredients in a rocket is envisioned in the company of liquid hydrogen, or other low-molecular-weight working fluid.

Limited research has been conducted on two approaches to generating and storing (stabilizing) metastable propellant ingredients: (1) free radicals, specifically, atomic hydrogen; and (2) helides, which are excited states of helium. In the late-1950s, the U.S. National Bureau of Standards produced low concentrations of free radicals and stored them in inert matrices at very low temperatures. More recently, an approach has been taken to generate hydrogen atoms, immediately condensed at liquid-helium temperature, in the presence of a high density (70 to 100 kilogauss) magnetic field for the purpose of stabilizing the hydrogen atoms. Theoretically, the high-strength magnetic field is capable of aligning the spin of the electron of the hydrogen atom so as to prevent recombination into the hydrogen molecule.

Triplet helium has a theoretical energy level of 114 kilocalories/gram above the ground state. Assuming release of this energy and subsequent expansion through a rocket nozzle gives a specific impulse of 2,800 seconds. Techniques for generating activated helium and other noble gases are well known, but concentrating and storing these metastable species is quite another matter inasmuch as they revert to their ground state by collision processes. Experimental approaches to activating helium and trapping the helium molecules in a hydrocarbon wax have been reported.

The creation and use of metallic hydrogen (hydrogen derived from normal hydrogen subjected to about 2 megabars pressure) should release about 52 kilocalories/gram upon transitioning from the metallic to the normal solid form. The concept dates back to 1935, but interest has been renewed because some scientists believe that metallic hydrogen exists in some large planets.

Antimatter Rockets. Sufficient atomic particle research has been accomplished to warrant discussion of possible methods of applying energy available from particle mass annihilation to rocket propulsion. Complete conversion of matter to energy would allow exhaust velocities near that of light to be obtained from a propulsion device. Antimatter, by definition is matter made up of antiparticles, such as antineutrons, negatrons (antiprotons), and positrons (antielectrons). An annihilation property is known to exist between particles with one particle termed the antiparticle of the other.

Rocket design concepts envisioned for utilizing the reaction between atomic particles and antiparticles (matter and antimatter) are based upon the following postulations: (1) annihilation products can be accelerated using electrical and magnetic forces (consider the annihilation reaction of a neutrino with an antineutrino, yielding a proton and an electron); (2) annihilation products can be used indirectly to heat a working fluid for thermal expansion through a nozzle (consider the annihilation reaction of hydrogen and antihydrogen, leaving high-energy gamma rays); (3) antimatter possesses negative gravitational mass although its inertial mass may be positive. This could give rise to antigravity propulsion; and (4) annihilation products of ordinary quanta give rise to the possibility of a photon-expelling beam for the direct generation of thrust.

Before any form of antimatter rocket can exist, a lightweight method must be developed for producing antiparticles at a flow rate of grams/second in contrast with the few dozen of antiparticles produced in research laboratory generators. Also, a practical storage or containment method must arise inasmuch as antiparticles explode violently upon contact with normal matter. Reference 5 gives a performance estimate of an I_p of 3.06×10^7 seconds for a rocket propelled vehicle with a thrust/weight ratio of 10^{-7}.

Multiple Uses of Propellants. Propellants, both solid and liquid, are used in many secondary propulsion applications, including crew capsule ejection, attitude control and station-keeping of satellites, braking of reentry vehicles, extravehicular space operations — as well as being essential in rocket engine igniters, signal and illumination flares, and fuel-cell type electric generators. New developments, such as the high-powered gas dynamic laser[6] continue to broaden the field of applications.

ROCKET PROPULSION THEORY. A rocket is defined as an "engine or motor that develops thrust by ejecting a stream of matter rearward, or the missile or vehicle powered by such an engine. "Since the reaction principle involved assumes a self-contained source of energy, a rocket can operate in any medium including space outside the earth's atmosphere, where there is no oxygen to support combustion." See also **Rocketry**.

Governing Laws

The operation of rocket engines and motors and the vehicles that they propel are primarily governed by Newton's laws of motion.

Newton's first law, often called the law of inertia, states that there is no change in the motion of a body unless a resultant force acts on it. A number of forces act on a launch vehicle throughout its flight. The gravitational force (weight of the vehicle), lift, drag, and the thrust of the rocket engine all act on the vehicle to cause the resultant motion. The net amount of the resultant force and its direction determine the acceleration on the vehicle and the path of the flight trajectory, in accordance with Newton's second law.

Newton's second law of motion states that whenever a net (unbalanced) force acts on a body, it produces an acceleration in the direction of the force; the acceleration is directly proportional to the force and inversely proportional to the mass of the body:

$$a = \frac{F}{m}. \tag{1}$$

This relationship is more typically seen in the form,

$$F = ma. \tag{2}$$

As stated in the definition, a rocket develops its thrust by expelling a mass rearward. Examining this in the context of this equation, a mass is accelerated rearward by some means that accelerates its velocity from near zero to thousands of meters per second. The force for this acceleration is proportional to the mass of the exhaust gases and the acceleration per Newton's second law. The force acting on the exhaust gases is in the direction of the accelerating mass, but produces a thrust in accordance with Newton's third law, which states that for every acting force, there is a reacting force that is equal in magnitude but opposite in direction.

Therefore, the force of accelerating the fluid internal to the rocket has an equal but opposite external force which is the thrust produced by the rocket.

The magnitude of this force (thrust) can be determined by examining the change of momentum in the device and the sum of the forces that act on a closed duct or control volume, as shown in Fig. 1. The flow internal to the rocket experiences a change of momentum that is equal to the mass flow rate times the change in velocity of the gases:

$$\Delta\text{momentum} = \dot{m}(V_{\text{exit}} - V_{\text{inlet}}) \tag{3}$$

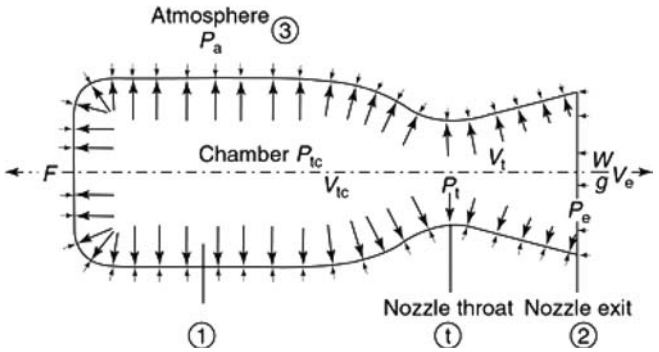

Fig. 1. Pressure balance on the rocket chamber and nozzle wall (© American Institute of Aeronautics and Astronautics, printed with permission).

Assuming that the inlet velocity into the device is low, the momentum at the inlet can be considered negligible. Thus, the momentum change is

$$\Delta\text{momentum} = \dot{m}V_{\text{exit}}. \tag{4}$$

The sum of all pressures on the surfaces perpendicular to the flow axis of the device reduces to a resultant force due to the pressure differential between the pressure at the nozzle exit plane and the ambient pressure that acts on the exit area of the nozzle:

$$\text{Net pressure force} = (p_{\text{exit}} - p_{\text{ambient}})A_{\text{exit}} \tag{5}$$

The sum of the forces that act on a rocket is equal to the change of momentum in accordance with Newton's second law. By combining Equations (4),(5) and rearranging the terms, we develop the following expression for the thrust of a rocket:

$$\text{Thrust} = \dot{m}V_{\text{exit}} + (p_{\text{exit}} - p_{\text{amb}})A_{\text{exit}}. \tag{6}$$

When p_{exit} equals p_{amb}, expansion is optimum and performance best. When the nozzle exit pressure is less than ambient, the nozzle is said to be over-expanded. If exit pressure is greater than ambient, the nozzle is said to be under-expanded. Because the rocket, generally, flies through the atmosphere, it experiences variations in the ambient pressure, so it operates at optimum expansion at only one altitude. The choice of the rocket exit area ratio then becomes the result of trading off a number of design and flight considerations.

Newton's laws are applied in analyzing the acceleration of a vehicle propelled by a rocket as well. Examining vehicle flight in a vacuum free of gravitational forces, the rocket produces an unbalanced force and a resultant acceleration in accordance with Newton's second law. Here, it is written in a way slightly different from that in Equation (2). The thrust is the net accelerating force that is equal to the instantaneous mass of the vehicle, and its instantaneous acceleration is written as the time rate of change of the velocity:

$$F = M\frac{dV}{dt}. \tag{7}$$

The thrust of the rocket F can also be expressed in terms of the mass flow rate $\dot{m}$ from the rocket and its effective exhaust velocity V_e assuming that nozzle exit pressure equals the ambient from Equation(6):

$$F = \dot{m}V_e, \tag{8}$$

where

$$\dot{m} = -\frac{dM}{dt}. \tag{9}$$

The negative sign indicates that the mass of the vehicle is decreasing as the propellant exits the engine.

Substituting for thrust F from Equation (8) and mass flow rate $\dot{m}$ from Equation (9) and rearranging,

$$dV = -V_e\frac{dM}{M}. \tag{10}$$

Integrating, we obtain the result that is commonly called the "rocket equation" that is used to calculate the velocity increment added to a stage in terms of its effective exhaust velocity and its initial and final masses:

$$\Delta V_{\text{ideal}} = V_{\text{final}} - V_{\text{initial}} = V_e \ln\frac{M_{\text{initial}}}{M_{\text{final}}} \tag{11}$$

This solution assumed flight in a vacuum free of any gravitational field; thus, the value calculated is an ideal velocity increment. Introducing the effects of atmospheric drag and gravity result in reducing the velocity increment achieved. The gravitational field has a component of force acting along the flight path of the vehicle (g cosine θ). The net loss due to the gravity field is computed by integrating this component along the path during the flight in the form of the equation,

$$\Delta V = V_e \ln\frac{M_{\text{initial}}}{M_{\text{final}}} - \int_0^t g\cos\theta\, dt. \tag{12}$$

The drag component is introduced as a drag coefficient C_d that is applied to the incompressible flow dynamic pressure $1/2\rho\ V^2$ and the cross-sectional area of the vehicle and evaluated along the flight path:

$$\text{Drag} = C_d A(1/2\rho V^2). \tag{13}$$

The drag coefficient is a function of the vehicle flight Mach number and its angle of attack (Fig. 2).

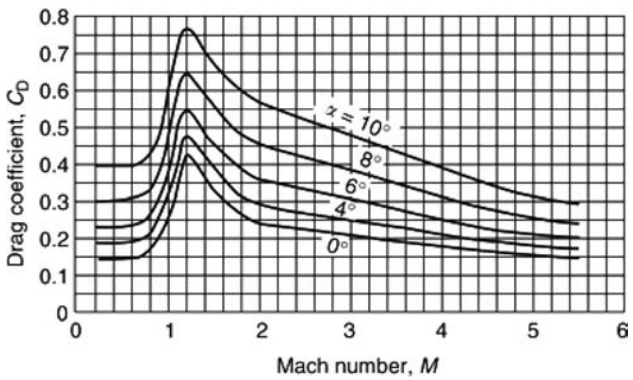

Fig. 2. Drag coefficient vs. Mach number as a function of angle of attack (Sutton G.P.: *Rocket Propulsion Elements*, 6th ed., John Wiley & Sons, Inc., New York, NY, 1992, Fig. 5-3a, p. 126).

Finally, the velocity increment added to a single stage during flight can be determined from the equation,

$$\Delta V = V_e \ln\frac{M_{\text{initial}}}{M_{\text{final}}} - \int_0^t g\cos\theta - \text{Drag}. \tag{14}$$

The initial mass of a stage includes the inert mass of the vehicle (structural dry mass plus engines), the mass of propellants and pressurant gases, and the payload mass:

$$M_{\text{initial}} = m_{\text{inert}} + m_{\text{propellant}} + m_{\text{payload}}. \tag{15}$$

The final mass of the stage includes the dry weight of the vehicle, any residual (unburned) propellant and pressurants, and the payload:

$$M_{\text{final}} = m_{\text{inert}} + m_{\text{residuals}} + m_{\text{payload}}. \tag{16}$$

The rocket equation can be applied to multiple-stage vehicles by solving the equation for each stage and adding the velocity increments for all stages as follows:

$$\Delta V_{\text{ideal}} = \left[V_e \ln \frac{M_{\text{initial}}}{M_{\text{final}}} \right]_{\text{stage1}} + \left[V_e \ln \frac{M_{\text{initial}}}{M_{\text{final}}} \right]_{\text{stage2}} + \cdots + \left[V_e \ln \frac{M_{\text{initial}}}{M_{\text{final}}} \right]_{\text{stagen}} \tag{17}$$

Care must be exercised in considering the masses of the individual stages. The payload for the first stage of a multiple-stage vehicle is the mass of the stages above it. Only in the final stage is the payload the mass that is placed in orbit.

Specific Impluse

The usual measure of performance of a rocket engine is its specific impulse. This is a measure of how much thrust (lbf or Newtons) is generated by the engine when the flow rate is 1 unit (lbm/sec or kg/s):

$$I_{\text{specific}} = I_{\text{sp}} = \frac{F}{\dot{m}}. \tag{18}$$

The units of specific impulse are seconds in SI but lbf/lbm/sec in the U.S. Customary units (USCS). "Seconds" is still used as the terminology for specific impulse in the USCS system but is not correct technically and must have the correct units for use in solving any equations. Specific impulse is related to the exit velocity of the nozzle V_e through the relationship,

$$I_{\text{specific}} = \frac{V_e}{g_c} \tag{19}$$

Specific impulse can also be determined as a function of the properties of the working fluid and the operating conditions of the rocket nozzle. In simplified terms, we see that the specific impulse is proportional to the square root of the temperature of the working fluid divided by its molecular weight:

$$I_{\text{specific}} = \text{const}\sqrt{\frac{T_c}{M}}. \tag{20}$$

The constant in this equation is a function of the thermodynamic properties of the combustion gases and the ratio of nozzle exit pressure to combustion chamber pressure. Therefore, the objective in any rocket engine is to achieve the highest possible temperature of the working fluid and the lowest possible molecular weight. In chemical rockets, this is typically achieved by using reactants that produce large quantities of hydrogen or steam at high temperature as their products. Beamed energy and nuclear rockets choose hydrogen for the working fluid because it is a good coolant and has the desired low molecular weight. The choice of a working fluid for electric rockets depends, in some cases, on other properties of the fluid such as ionization potential. Hydrogen is still of interest for an arcjet.

Vehicle Staging

The ideal velocity increment equation can be manipulated into the following form to examine the sensitivity of the stage performance to various aspects of rocket engine performance and stage design:

$$\frac{\Delta V}{e^{g_c I_{\text{sp}}}} = \frac{M_{\text{initial}}}{M_{\text{final}}}. \tag{21}$$

From this equation, we can see that the higher the engine specific impulse, the more closely the final mass approaches the initial mass of the stage (less propellant is consumed).

A measure of stage design efficiency is the propellant mass fraction λ defined by the equation,

$$\lambda = \frac{m_{\text{propellant}}}{m_{\text{propellant}} + m_{\text{inert}}}. \tag{22}$$

The higher the value of λ, the greater the structural efficiency of the stage. Now, we can manipulate Equations (18) into a form that presents the ratio of the initial mass of the vehicle to the payload delivered in terms of the propellant fraction, specific impulse, and ideal velocity increment:

$$\frac{M_{\text{initial}}}{M_{\text{payload}}} = \frac{\lambda e^{\frac{\Delta V}{g_c} I_{\text{sp}}}}{1 - e^{\frac{\Delta V}{g_c I_{\text{sp}}}} (1 - \lambda)}. \tag{23}$$

We can illustrate the sensitivity of stage and vehicle performance to engine specific impulse and stage structural efficiency by conducting a parametric study of two vehicles, single-stage-to-orbit (SSTO) and two-stage-to-orbit (TSTO). First, one must estimate the ideal velocity increment for the mission. A low Earth orbit typically requires about 30,000 ft/sec (9144 m/s). In the SSTO case, three specific impulses were assumed, one representative of liquid hydrogen/liquid oxygen rocket performance (460 s), a second chosen as a conceivable increase in chemical rocket performance (500 s) and the third representative of predicted nuclear rocket performance (850 s). By assuming different values for the propellant fraction λ, one can then solve Equation (23) and arrive at the family of curves presented in Fig. 3. The lower the value of the lift-off mass to payload ratio, the better the vehicle performance. The chemical rocket options approach a limit at a value in the vicinity of 10 (10% of the vehicle liftoff mass is effective payload delivered to orbit), whereas the nuclear option approaches a limit in the vicinity of about 3 (33% of liftoff mass). The lower specific impulse vehicle, is seen as quite sensitive to the propellant mass fraction. For example, at a propellant fraction of 0.89, the 40-second difference in specific impulse between 460 s and 500 s results in a twofold difference in the initial weight to payload ratio. So, if a vehicle design were to experience an increase in weight from its initial design to completion of fabrication (and they most always do), the payload capacity of the vehicle will be severely reduced and, conceivably, could become inconsequential, depending upon the magnitude of the growth in weight. For the higher specific impulse cases, the SSTO vehicle is seen as less sensitive to any decrease in propellant mass fraction, and the nuclear rocket is virtually insensitive to propellant mass fraction across the range studied. This illustrates that the higher the delivered specific impulse, the less sensitive the stage design is to its structural efficiency.

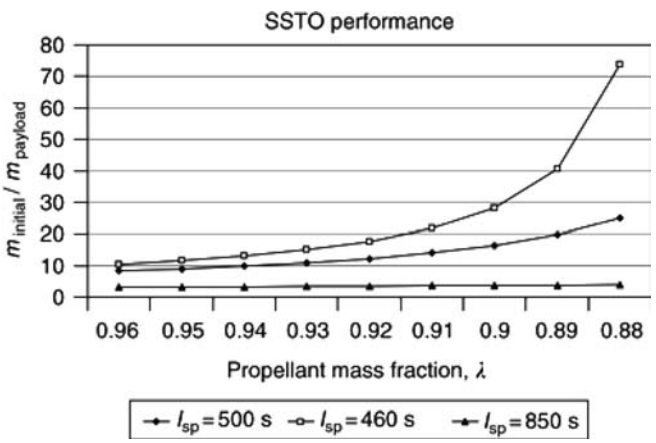

Fig. 3. Payload/initial mass vs. propellant mass fraction for SSTO.

Another way in which the initial mass/payload ratio can be made less sensitive to the propellant mass fraction is through the concept of staging in which two (or more) rocket stages can be coupled, either in parallel or in tandem. As one stage is jettisoned after exhausting its propellant load, the subsequent stage ignites and continues on to complete the mission. Figure 4 presents the results of a parametric study to illustrate the effects of specific impulse and propellant fraction upon the lift-off mass to payload ratio for a tandem two-stage vehicle that has an ideal velocity increment of 30,000 ft/s (9144 m/s.). In this case, it was assumed that the propellant mass fraction was the same for each stage, and the total propellant load was distributed, 80% in the first stage and 20% in the second stage. As in the SSTO case, there is a limit of initial to payload mass ratio of about 10. The maximum ratios calculated are 16 for a specific impulse of 460 s

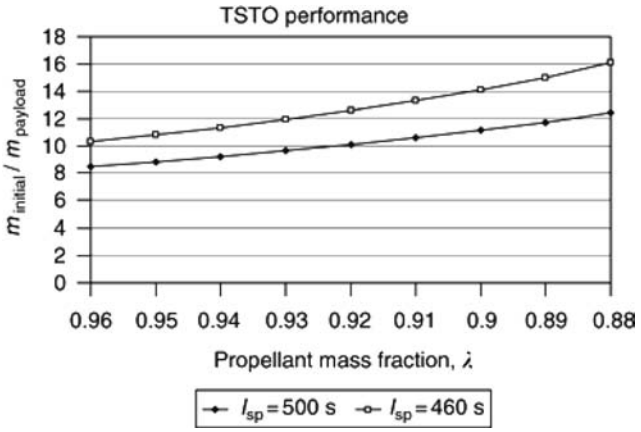

Fig. 4. Payload/initial mass vs. propellant mass fraction for TSTO.

and 12 for a specific impulse of 500 s within the range of propellant mass fraction studied, as contrasted with values of 74 and 25, respectively, for the SSTO. It is easily seen that multiple stages can offer payload gains. The driver for minimizing the number of stages is cost considerations rather than performance.

Energy and Energy Conversion

Energy Conversion Mechanisms in Rocket. The rocket engine is an energy conversion device that converts potential energy to the thermal energy of a high-temperature gas and then to the kinetic energy of a high-velocity exhaust gas. The energy sources for this conversion can be any of several types, chemical, electrical, beamed (solar or laser), or nuclear.

Chemical Rockets. In a chemical rocket, the potential energy is in the chemical bonds of the molecules that compose the fuel and the oxidizer. The class of reactants identified as "fuels" has large concentrations of hydrogen or carbon in the molecule and light metals such as aluminum, lithium, beryllium, magnesium, and boron. The class of reactants identified as oxidizers has large concentrations of oxygen, fluorine, or chlorine in the molecule. When the fuel reacts with an oxidizer in the combustion process, the resultant products are at a temperature significantly elevated over that at which they entered. This thermal energy is extracted for propulsion (thrust) by passing the gases through a converging–diverging (or DeLaval) nozzle that converts the thermal energy to kinetic energy. These chemical reactants are usually in either liquid or solid form.

A liquid-fueled rocket might be of either bipropellant or monopropellant type. In the former, fuel and oxidizer are introduced into the combustion device separately. They are atomized, vaporized, mixed, and combusted in the combustion chamber. The mixture ratio (proportions of oxidizer to fuel flow rate) at which the maximum combustion temperature occurs is called the stoichiometric ratio. This ratio does not yield the highest specific impulse (the ratio of thrust produced by the engine to the rate at which propellant is being consumed), however; this occurs when using fuel-rich mixtures. The excess fuel tends to reduce the combustion temperature somewhat, but more importantly, the molecular weight of the combustion products is reduced. The net effect is to increase the specific impulse, the measure of "goodness" of rocket performance. The most common oxidizers used to date are liquid oxygen, nitric acid (HNO_3), and nitrogen tetroxide (N_2O_4). The most common fuels used to date have been liquid hydrogen, RP-1 (a kerosene-like hydrocarbon), and various amine-based fuels (hydrazine, unsymmetrical dimethyl hydrazine, monomethyl hydrazine, and mixtures of the foregoing). Liquid propellants can also be classified as cryogens or storables. Cryogens are liquefied gases, typically oxygen and hydrogen, and are more energetic reactants. Within the family of cryogens, there are some propellants referred to as "space storable," meaning that they are relatively mild cryogens (boiling point greater than $-238\,^{\circ}\mathrm{F}$ (-150 K). These propellants can be stored in space for long periods of time and have acceptable levels of boil-off without engaging in major efforts to insulate the propellant containers (tanks) or refrigerate the propellants. Storable propellants are those that normally are liquids at standard temperature and pressure and are less energetic.

Monopropellants are generally introduced into a catalyst "bed" or "pack" where the propellant molecule is broken apart, liberates energy, and consequently increases in thermal energy. These reactions tend to be less energetic than bipropellant reactions and are frequently used in selected applications where specific impulse is not the most important characteristic. The most commonly used monopropellants are hydrazine (N_2H_4) and hydrogen peroxide (H_2O_2). The catalyst for hydrazine is iridium coated on an alumina substrate. The catalyst for hydrogen peroxide is silver, generally in the form of a screen.

The selection of a bipropellant combination depends on many factors, for example, the ignition characteristics of the propellant combination. Hypergolic combinations (nitrogen tetroxide and amine fuels, for example) provide a ready ignition source because the fuel and the oxidizer react upon contact. Such combinations are amenable to applications where engine restart may be required or for ignition at an altitude. Combinations such as hydrogen and oxygen require an external source of energy to provide the ignition energy for the main propellant flow. Multiple restarts are possible through appropriate design, as used on the RL-10 engine of the Centaur upper stage vehicle.

Another consideration for propellant selection is the choice of coolant for the rocket chamber. Specifically, the coolant should have a very high specific heat, low viscosity, and be thermally stable. Typically, fuels are used as engine coolants. Several designs have been tested in which oxidizers (liquid oxygen or nitrogen tetroxide) have been used as coolants.

The solid-propellant rocket motor is a device in which the fuel and oxidizer are premixed to form a combustible mixture which, when ignited, burns until all of the propellant is consumed. It burns at a rate that depends on the combustion pressure p and is a function of the propellant type (burn rate exponent n) according to the following relationship:

$$r = ap^n. \tag{24}$$

The burning rate r generally ranges in value from 0.3–0.5 inches per second (0.762 to 1.27 cm/s), and the burning rate exponent n ranges from 0.2–0.5 for modern propellants.

The hybrid is another chemical rocket embodiment. It typically consists of a solid fuel grain and a liquid (or gaseous) oxidizer. Its advertised advantages are that the fuel grain is less susceptible to safety and handling problems because the grain contains no oxidizer and, thus, cannot detonate or sustain combustion by itself. Additionally, using a liquid (or gaseous) oxidizer provides a very simple throttling scheme through oxidizer flow regulation and also provides for thrust termination by simply stopping the oxidizer flow. The fuel grain is typically designed to have several flow passages or ports through it to maximize the fuel surface exposed to the oxidizer, and, consequently, the burning surface and the attendant flow of combustion products. The hybrid has also achieved some attention because it permits eliminating the ammonium perchlorate oxidizer typical of most solid-fueled rockets and the attendant HCl in the exhaust products. The HCl presents a small but persistent environmental concern. The burn rate of a hybrid motor is similar in form to that of the solid-propellant rocket:

$$r = aG_{\mathrm{o}}^n. \tag{25}$$

In this case, r is the burn rate, a is a constant that depends on the reactants, G_{o} is the oxidizer mass flow rate per port, and n is the burning rate exponent whose value is from 0.5 to 0.7. Hybrid rockets have been successfully fired in motors of up to 250,000 lbf (1.11×10^6 N). The problems that exist are achieving high burning rates to minimize the size of the grain and complete consumption of the grain. Residual propellant can amount to 5 to 30% of the initial fuel load depending on the port configuration.

Nonchemical Rockets. In an electric rocket, the energy is collected from some power source (nuclear or solar) and converted to electrical energy. The energy conversion for thrusting purposes may occur by striking an arc between an anode and a cathode and passing a working fluid through the arc to heat it (arcjet). The hot gases are then passed through a nozzle to convert the thermal energy to kinetic energy. Another energy conversion technique might be to use the electrical energy to ionize an easily ionized gas (xenon,

for example) and accelerate the resultant ionized particles across a potential (electrostatic thruster). Another approach may use the interaction of the current and its induced electromagnetic field that produces Lorentz forces to accelerate the gas (electromagnetic thruster). See also **Ion Propulsion (Rockets)**.

Beamed energy depends on capturing a high-energy beam from outside the vehicle and transferring its energy to a working fluid. Solar energy is one such beaming mechanism. Concentrating lenses (or mirrors) located on the vehicle capture the solar radiation and focus it on a blackbody absorber at the focal point. The absorbed energy is then used to heat a working fluid that is subsequently expelled through the nozzle at a high velocity. A laser beam might apply equally for this purpose. The working fluid also cools the absorber/thruster structure to maintain structural integrity at elevated temperatures.

Finally, a nuclear energy source may be used in place of any of the previously mentioned energy sources to heat the working fluid. Here also, the working fluid serves the dual purpose of cooling the structure and generating the thrust, as it is expelled through a nozzle.

Thermodynamics of Rockets

As previously discussed, rocket exhaust velocity is related to the specific impulse through the gravitational constant g_c as follows when the nozzle exit pressure is equal to the ambient:

$$V_e = I_{specfic} g_c. \tag{26}$$

The exhaust velocity must be maximized to maximize the specific impulse. The first law of thermodynamics (conservation of energy) for bulk flow requires that the total energy entering the engine must equal the total energy leaving the engine. In equation form this is:

$$h_o = \frac{V^2}{2_{g_c}} + h. \tag{27}$$

The average stagnation enthalpy per unit mass h_o of all of the flows entering the engine equals the kinetic energy at the nozzle exit plus the static enthalpy h of the exhaust at the exit. The static enthalpy for a chemically reacting system is given in terms of the static temperature T, entropy s and Gibbs free energy f by the equation,

$$h = Ts + f. \tag{28}$$

The Gibbs free energy is a summation of the chemical binding energy (19). Substituting and rearranging, the kinetic energy can be expressed as a function of the stagnation enthalpy Ts and the Gibbs free energy:

$$\frac{V^2}{2_{g_c}} = h_o - Ts - f. \tag{29}$$

By differentiating the kinetic energy with respect to entropy s and Gibbs free energy f, we can find that the exhaust velocity for a given exit pressure increases as exit entropy decreases and Gibbs free energy decreases. From the second law of thermodynamics, the minimum exit entropy is equal to the inlet entropy for bulk flow. Therefore, the maximum exhaust velocity occurs for an exit entropy per unit mass that is equal to the inlet entropy per unit mass. Additionally, the minimum Gibbs free energy occurs under conditions of chemical equilibrium. Chemical equilibrium is achieved as the chemical constituents of the exhaust gases alter their relative proportions in response to the pressure and temperature changes that occur as the gases flow through the nozzle. Energy is liberated to the expansion process as a result. Therefore the maximum specific impulse is achieved for an ideal one-dimensional flow when the exhaust products are expanded to ambient pressure in chemical equilibrium and have total enthalpy and entropy equal to the inlet conditions.

The reality of rocket operation is that none of the processes occurs ideally. The combustion process is irreversible and has entropy increases attendant to it. Viscous boundary layer effects and nonequilibrium expansion of the combustion products also introduce irreversibilities. Figure 5 presents the enthalpy versus entropy diagram for an oxygen–hydrogen reaction in chemical equilibrium at 3000 psia (20.7 MPa). Process 1 to 2 is the irreversible combustion of oxygen–hydrogen reactants at 3000 psia (20.7 MPa). The equilibrium products are then expanded in a constant entropy (isentropic) process to local ambient pressure (0.101 MPa) from point 2 to point 3.

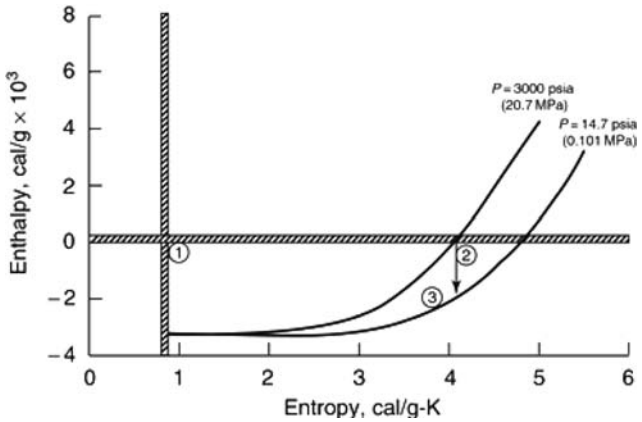

Fig. 5. Enthalpy vs. entropy for flow in a rocket engine (*courtesy Boeing, Rocketdyne Propulsion and Power*).

Nozzle Theory

The nozzle is the mechanism for accelerating the hot gases in all of the devices described, except those that use electrostatic or electromagnetic forces. Applying the first law of thermodynamics across the nozzle, the change in enthalpy equals the kinetic energy of the exhaust gases at the exit:

$$\frac{V_{exit}^2}{2_{g_c}} = h_o + h_{exit} \tag{30}$$

Applying the idealization of isentropic, one-dimensional flow, the exhaust velocity of the nozzle is

$$V_{exit} = \sqrt{\left(\frac{2\gamma}{\lambda - 1}\right)\left(\frac{\overline{R}}{M}\right)T_c}\left[1 - \left(\frac{p_{exit}}{p_{chamber}}\right)^{\frac{\gamma-1}{\gamma}}\right]. \tag{31}$$

The nozzle is typically identified by its geometric area ratio (exit area/throat area), but the pressure ratio across the nozzle is important in determining its performance in accelerating the gas flow, as seen by examining the equation for exit velocity. The term γ is the ratio of specific heats of the hot gases, "R" is the universal gas constant, and M is the molecular weight of the gases that exit the nozzle. Optimum expansion of the gases occurs when the exit pressure of the nozzle equals the local ambient pressure.

The typical shape of a DeLaval nozzle is shown in Fig. 6. In the subsonic region (flow velocities less than Mach 1), the gases are accelerated by decreasing the area of the flow passage. Continuing the decrease of the flow area increases the gas velocity until a point is reached at which the maximum mass flow rate per unit area is achieved. At this condition, the flow is at the speed of sound or sonic (Mach number equal to 1). This location is called the throat of the nozzle, and the flow is referred to as "choked." The ratio of chamber pressure to pressure at the throat (critical pressure ratio) is approximately 2:1 for this condition. From that point on, the flow passage must increase in area to permit continuing acceleration of the flow in the supersonic regime (Mach numbers greater than 1). Once the nozzle achieves the choked condition, the chamber pressure remains constant regardless of the back-pressure from the flight altitude. If the exit pressure exceeds the local ambient, it is underexpanded; if it is less than the local ambient, it is overexpanded. Selection of the nozzle area/pressure ratio is a compromise to provide the best performance across the vehicle's flight regime. One way to examine this design choice is through the nozzle thrust coefficient C_f. The thrust coefficient is a measure of nozzle performance and can be used to determine the thrust of a rocket engine as a function of the throat area and the chamber pressure from the equation,

$$F = C_f A_t p_c \tag{32}$$

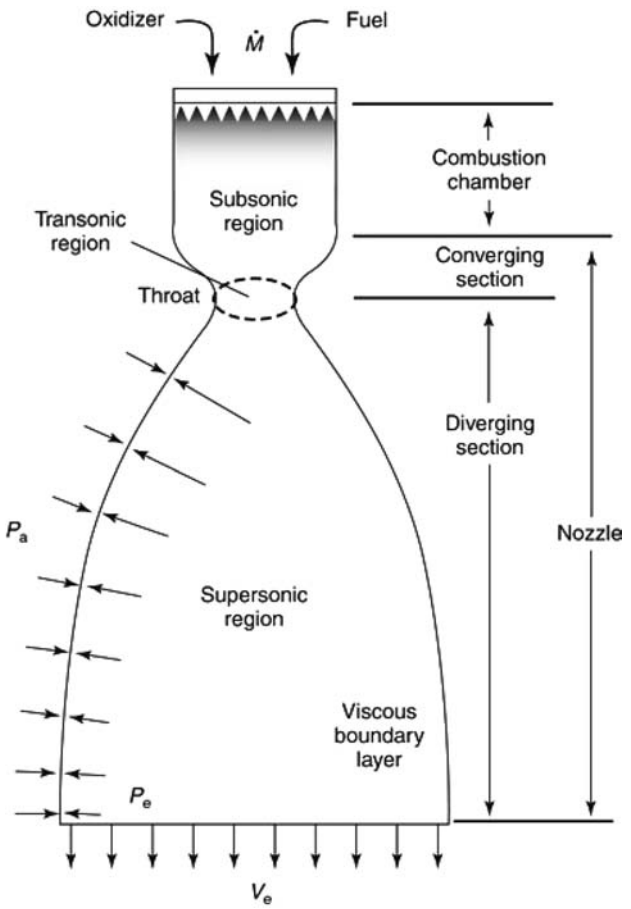

Fig. 6. The DeLaval Nozzle (*courtesy Boeing, Rocketdyne Propulsion and Power*).

For a given ratio of specific heats, the optimum geometric area ratio corresponds to a given pressure ratio across the nozzle. For example, at a nozzle area ratio of 10, the design pressure ratio for a ratio of specific heats of 1.3 is 100, and the corresponding thrust coefficient is 1.6. If a rocket has a nozzle of area ratio of 10, it is operating at its optimum condition only when the pressure ratio is 100. Because a rocket flies through the atmosphere and is subject to varying ambient pressure, the delivered performance will be less than optimum at all other points in the trajectory than when the pressure ratio is 100. Therefore, the choice of design area ratio (pressure ratio) is a compromise in which the designer knowingly accepts less than optimum performance at some portions of the trajectory.

The nozzle designer must make compromises in choosing the design pressure ratio and also in the shape of the nozzle. However, the most common nozzle design practice uses the Rao optimum contour nozzle also known as the "bell" nozzle. This design yields a shorter design than a simple 15° half-angle conical shape and has lower divergence losses because the gases are exiting the nozzle at a divergence angle of less than 8°.

The losses in a rocket nozzle consist of the divergence loss (nonaxial velocity vector for the exiting gases), finite-rate kinetic losses, and drag losses, in accordance with the equation,

$$\eta_{\text{nozzle}} = \eta_{\text{divergence}}\eta_{\text{kinetic}}(1 - \eta_{\text{drag}}). \tag{33}$$

Inserting typical values into this equation, we can find the overall efficiency of a modern rocket nozzle design:

$$\eta_{\text{nozzle}} = (0.992)(0.999)(1 - 0.986) = 0.997. \tag{34}$$

There are nozzle designs that are intended to compensate for altitude as the rocket flies through the constantly varying pressure of the atmosphere. This includes mechanical means in which nozzle "skirts" are moved into place at selected times in the flight profile; each increases the area/pressure ratio to approximate optimum expansion more closely. There are also aerodynamic designs such as the "aerospike" shown in Fig. 7 that have a free jet boundary that adjusts to the local ambient pressure through a Prandtl–Meyer or corner expansion. Such an expansion process constrains the nozzle gases to expand to the local ambient at the outside lip of the nozzle. Consequently, the flow cannot overexpand, and the nozzle flow is always optimum until the nozzle design pressure ratio is exceeded. In practice, these nozzle designs do not operate with perfect altitude compensation. A procedure has been developed to determine the degree to which the aerospike type of nozzle approaches optimum expansion. This procedure is illustrated in Figs. 8 and 9. Figure 8 presents the thrust efficiency C_T (the ratio of measured C_F to ideal C_F) of both an altitude compensating and bell nozzle versus pressure ratio. Both nozzles have the same area ratio (design pressure ratio), the same thermodynamic properties of the flowing gases, and the same maximum thrust efficiency. At a given pressure ratio, the percentage of maximum thrust efficiency C_T achieved by the altitude compensating nozzle is compared to that of the fully flowing bell nozzle. The results of this comparison are presented in Fig. 9. The 45° line across the graph represents the performance of a bell nozzle in which the flowing gases do not separate. All points above that line represent some degree of altitude compensation. The point identified by $C_{\text{TADV}}/C_{\text{TMAX}} = 1$ and $C_{\text{TN-S}}/C_{\text{TMAX}} = 1$ represents the design point for both nozzles. The line where $C_{\text{TADV}}/C_{\text{TMAX}} = 1$ represents perfect altitude compensation. The crosshatched area is representative of the altitude compensation performance of the aerospike type of nozzle. In general, the data indicate a compensation capability in excess of 50%, as determined by the ratio of the distance from the aerospike family of curves to the line where $C_{\text{TADV}}/C_{\text{TMAX}} = 1$ divided by the distance from the 45° line (nonseparating bell performance). The line identified as the "80% bell" illustrates the fact that a bell nozzle can have some separation of the flow at the low end of its operating regime, and the result is that it has some altitude compensation. The breadth of the aerospike band results from the range of nozzle lengths from 16% of an isentropic spike at the upper end to 0% at the lower end.

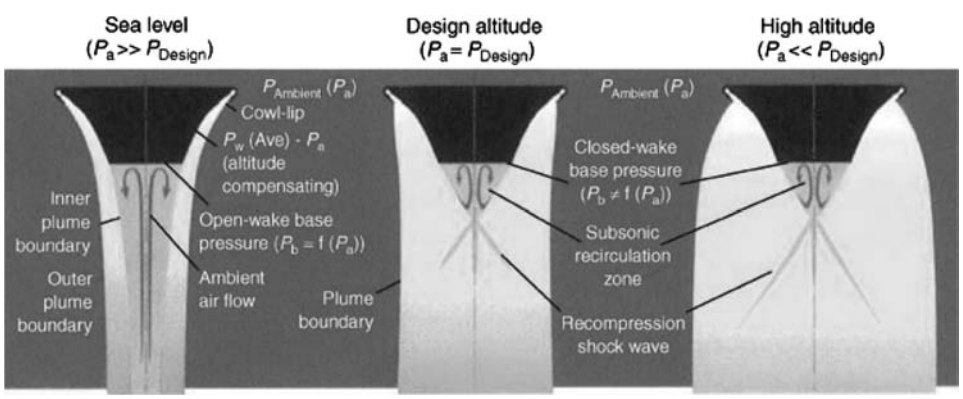

Fig. 7. Aerospike nozzle and its operating modes (courtesy Boeing, Rocketdyne Propulsion and Power).

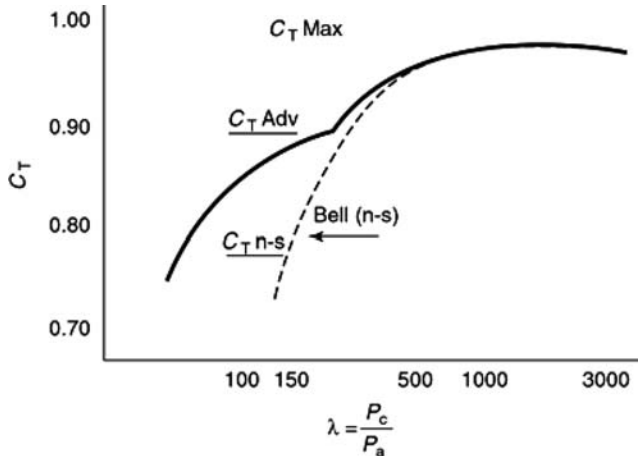

Fig. 8. Nozzle altitude compensation determination.

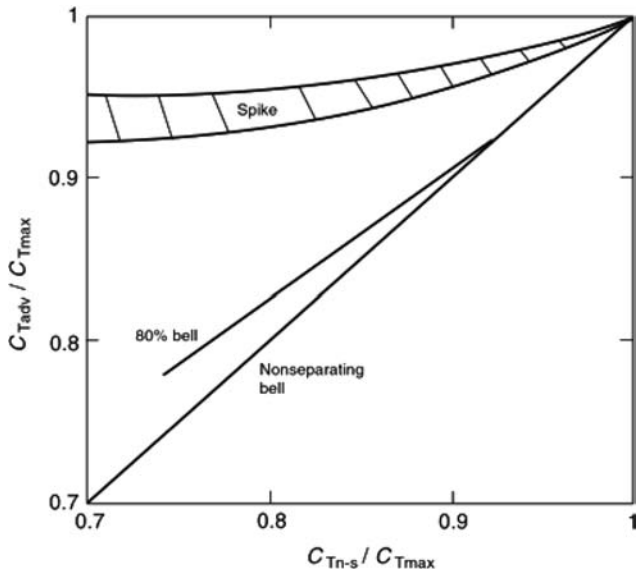

Fig. 9. Nozzle altitude compensation comparison.

Additionally, the aerospike nozzle length is about 25% that of the Rao optimum nozzle length for the same thrust capability. This allows reducing in vehicle length or including more propellant in the vehicle.

The same Prandtl–Meyer expansion process occurs in the external flow aft of the flight vehicle that produces a pressure at the nozzle lip (the flow controlling pressure) that is lower than the ambient at the flight altitude. Thus, the nozzle behaves as though it were operating at an altitude higher than actual. This is most noticeable in the Mach 1 to Mach 3 range of flight operations. In that flight regime, the time spent in off-design conditions is considered negligible compared to bell nozzle performance capabilities. The added performance of optimized nozzle expansion across the full flight trajectory opens the possibility of single-stage-to orbit operations.

Rocket Engine Efficiencies. The overall efficiency of a rocket engine is generally presented as a percentage of the theoretical specific impulse. The calculated theoretical value is based on shifting equilibrium, a case in which the reaction products remain in equilibrium (their proportions change) as the pressure and temperature decrease during the expansion process in the nozzle. This efficiency is composed of the combustion and nozzle efficiencies, generally, it is greater than 90% and can be as high as 95–96%. The nozzle efficiency depends on design, but can be expected to be close to the 98% value previously shown. The combustion efficiency of the propellants is quite sensitive to the propellant combination used and plays the major role in overall efficiency. The liquid oxygen/hydrocarbon combination of the early space launch engines typically had combustion efficiencies in the low 90s% range. The efficiencies of today's hydrogen/oxygen engines are much higher and approach 97%.

ROCKETRY. Rocketry, based on mathematics, physics, and formulae, is an exacting science. One might trace humanity's interest in rocketry back to the fourth century when Aulus Gellius described a mechanical pigeon made to move by jets of steam escaping from its tail. Others might say the Chinese deserve credit for discovering rocketry. As early as 1232, the Chinese used rockets in their war against the Mongols who were besieging the city of Kai-fung-fu. Called *arrows of fire*, these primitive rockets were propelled by *black powder*.

The Tartars, who invaded Europe in the 13th century, also knew how to build primitive rockets. Moreover, they knew how to frighten their enemies. In 1241, the Tartars defeated a group of Polish knights by carrying a dragon head that spewed smoke and fire. More concerned with practical improvements than with psychological advantage, the English monk, Roger Bacon, developed an improved form of gunpowder during the first half of the 13th century. This improvement enabled rockets to be transformed into incendiary projectiles with a relatively long range.

Far beyond the borders of England, the Mongols used their "fire arrows" while capturing the city of Baghdad in 1258. More than 20 years later, the Arab, Hassan er-Rammah, completed a manuscript which included directions for making a torpedo that could be used against a land target. The manuscript resulted in nothing tangible. By the Seventh Crusade,

however, the Arabs were ready to use rockets against their French invaders.

Throughout the 14th and 15th centuries, medieval rocket pioneers focused on using rockets as weapons. In 1420, Joanes de Fontana authored a sketch book which contained suggestions for making military rockets. Jean Froissart (1338–1410) proposed the use of tube-fired rockets. Manuscripts ranged from those proposing rockets with crude parachutes to rockets that would dive and explode underwater. In 1577, the German armorer, Leonhart Fronsperger, wrote a book on firearms that historians believe resulted in the modern word "rocket." Fronsperger described a device called a "roget," made from powder with a base of saltpeter, sulfur and charcoal tightly wrapped in paper. Less than 100 years later, Colonel Friedrich von Geissler, a Polish field artillery commander, fired a 120-pound rocket near Berlin, using a mixture similar to that described by Fronsperger.

In 1687, Sir Isaac Newton published his *Principia Mathematica*. Newton's Third Law of Motion stated that for every action there is an equal and opposite reaction. Therefore, the rocket is a reaction device. Minute particles are thrown out through a nozzle as a propellant is burned in a suitable chamber. The reaction to the discharge makes the rocket fly in the opposite direction. Newton's discoveries would provide the classical physical basis for future generations of rocket theorists. Kazimierz Siemienowicz, a Polish general, also contributed to 17th century intellectual achievements in rocketry. In 1650, he published the theory of multistage rocketry in a book called *Artis Magnae Artileria*. The Age of Reason also provided a glimpse of the day when man might use rockets for civil purposes. In 1784 a Prussian master weaver, Ehrgott Friedrich Schaefer, drew up plans for a lifesaving rocket that sailors might use to throw a small anchor across the surf. About 20 years later, Claude Ruggieri, an Italian with an apparent interest in rocketry and fireworks as public entertainment, rocketed small animals into space. His payloads were recovered by parachute. Years later, Ruggieri's rockets were able to lift a full-grown ram.

Most major developments in rocketry in the 18th and 19th centuries, however, focused on military rather than civil applications One of the first major engagements with rockets involving Europeans took place in India in the year 1792 when the British cavalry was repulsed with 6.5-pound rockets mounted on bamboo sticks. The lessons on rocketry in India were not lost on the British. In 1807, Sir William Congreve (1172–1828), a British artillerist, developed the 3.5-inch diameter incendiary rocket, using black powder, an iron case, and a 16-foot guide stick. In 1805 Congreve had been allowed to bombard Boulogne with rockets fired from boats. The fires, which started in the town, burned a day and a night. In 1807, Congreve directed a rocket attack against Copenhagen in which approximately 25,000 rockets were fired, leaving much of the city burned. In 1813 at the Battle of Leipzig, the English bombarded a village held by five battalions of French infantry.

Czar Alexander I of Russia was among those who appreciated the role that Congreve's rockets had played at Leipzig. In 1815 the Russian, Alexander Zasyadko based his blueprint for a fighting rocket on a British model. Following Zasyadko's suggestion, the Russians ordered the formation of the nation's first rocket company of soldiers in 1826. The unit was attached to the St. Petersburg Rocket Works. Two years later, under Zasyadko's guidance, the Russians employed warhead rockets with occasional success against the Turks.

In 1814, the United States militia opposed the advance of British regulars on Washington. At the Battle of Bladensburg, less than 10 miles northeast of Washington, the British put their rockets into action. A special rocket squad, partially concealed in underbrush, fired the projectiles causing the Americans to retreat. Discourse and experimentation with rocketry continued in Britain. The British had depended on rockets in battle. However, they were not always ready to accept the possibility that they might be used for other purposes. Critics caricatured a rocket conceived by the Englishman Charles Golighty in 1841. A cartoon described his rocket as a "steam-horse on which one may ride from Paris to St. Petersburg."

William Hale's invention of the stickless rocket in 1846 was taken more seriously. Congreve's rocket had carried a 16-foot stick. Although the stick helped guide the rocket and kept it from moving erratically, it also added extra weight. Hale's rockets eliminated the stick. Instead, he inserted three metal vanes in the exhaust nozzle, slightly inclined so the exhaust itself caused the rotation.

Rockets were used to a limited extent in the American Civil War. On July 3, 1862, the Confederates, under Jeb Stuart, fired rockets at McClellan's troops. The Confederates also placed rocket batteries in service in Texas in 1863-64. Union troops formed the New York Rocket Battalion, and in 1864 Union rockets were fired in South Carolina at picket boats and other vessels in the harbor.

It is not possible to say exactly when man began to seriously consider the possibility that rockets might be used for space travel as well as for military purposes. Advances in technology were needed before rockets could use liquid propellants instead of solid propellants. The liquid propellants would increase man's capability to guide and control the rockets. One of the foremost rocket pioneers was Konstantin Tsiolkovskii, a Russian school teacher with a hearing affliction. Although he never built a rocket, his grasp of rocketry and space fundamentals has been described as extraordinary. In 1903, he published "Exploration of Cosmic Space by Rocket Devices," providing data on liquid propellants for rocket propulsion. The work, which was written in 1898, also considered the possibility of space travel.

By the time of Tsiolkovskii's work, other writers and intellectuals had begun to imagine the possibility of rockets that might allow men and women to leave the confines of Earth. In 1897, the German Kurd Lasswitz focused his imagination on the planet Mars. His writings were based on the assumption that if a life-form of higher intelligence existed on Mars, then the first space trip would be from Mars to the Earth. More well known than Lasswitz, the French author Jules Verne anticipated flights into outer space as well as a host of other 20th century scientific achievements. Verne's imagination would inspire an entire generation of rocket scientists including Dr. Wernher von Braun.

In 1906, Alfred Maul, a German engineer, employed rockets to take a camera to high altitudes. His 1912-model rocket carried an 8 inch by 10 inch photographic plate stabilized by a gyroscope. During World War I,

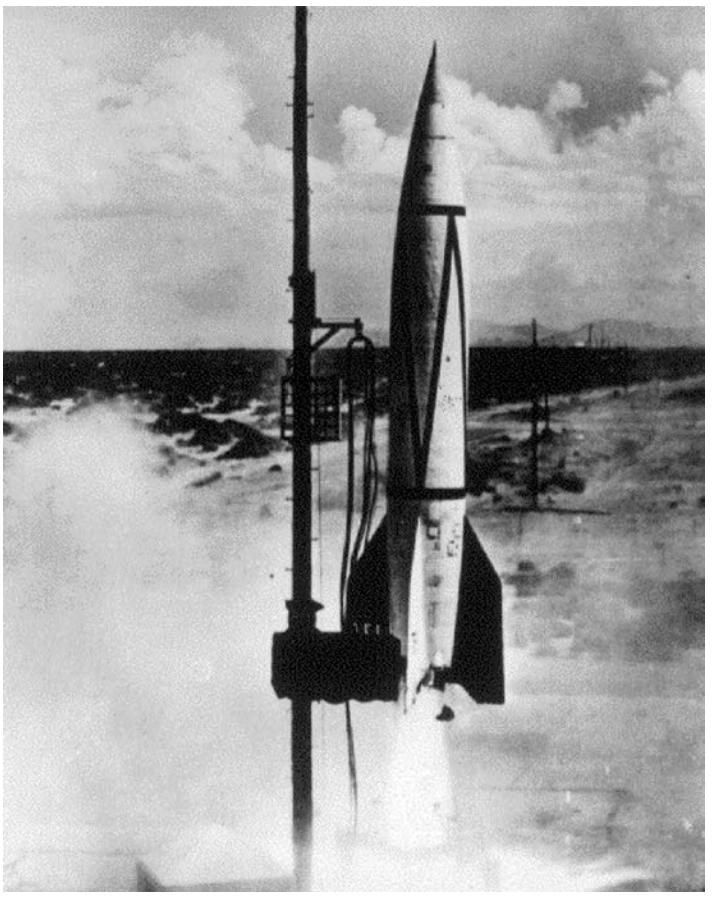

Fig. 1. The V-2 became one of the best known of all early missiles. The 46-foot rocket utilized alcohol and liquid oxygen as fuel and could carry a 1,650 pound warhead 225 miles. (*MSFC*.)

however, rocketry was again employed for military purposes. Rocket flares were used to illuminate trenches at night, and in 1916 the French fired rockets against German zeppelins, destroying at least one. A year later, the French fired incendiary rockets against hydrogen observation balloons.

As America entered the 20th century, the United States manifested an interest in designing aircraft rather than rockets. The Advisory Committee for Aeronautics, later named the National Advisory Committee for Aeronautics (NACA), was founded in 1915 to study the problems of flight and recommend practical solutions to basic aircraft design and construction.

While NACA engineers pursued their work in aeronautics in the early part of the century, other Americans, like Robert H. Goddard, dedicated themselves to new achievements in the area of rocketry. On March 16, 1926, Goddard launched a liquid-fueled rocket that traveled 184 feet in 2.5 seconds. See also **Goddard, Robert H**.

Interest in rocketry was also growing outside the United States. In 1928, Max Valier, a spaceflight popularizer, developed a rocket-propelled car in collaboration with Fritz von Opel, the automobile tycoon. The two developed the world's first rocket-powered car, which reached speeds of 180 miles per hour in Germany. Other novel applications of rocketry were also tried. In 1931, Friedrich Schmiedl used rockets to operate a postal service in Austria. Schmiedl used a 6-foot powder rocket that he manufactured. The rocket was designed to eject the mailbag by parachute shortly before crashing.

The foremost authority on rocketry, outside the United States, was Dr. Hermann Oberth, a Hungarian-born (Transylvanian) German. Near the end of 1923, he published his famous work, *The Rocket Into Interplanetary Space*, the genesis for considerable discussion regarding rocket propulsion. From 1926–30, Oberth experimented with liquid rocket propellants. He also worked as an advisor to the company making a film called, "Girl in the Moon," which increased interest in the potential of rocketry in Germany.

In the Spring of 1930, a young Wernher von Braun assisted Oberth in his early experiments in testing a liquid-fueled rocket stage with about 15 pounds of thrust. In September 1930, Oberth returned to a teaching post in Romania while Von Braun continued experiments under the sponsorship of the German Society for Space Travel. During July and August 1932, the society impressed officers of the German Army Ordnance by successfully firing a rocket to a height of 200 feet. As a result, the German Army formalized the rocket development program. In 1937 Von Braun was named technical director of the Peenemuende Rocket Center where he and his growing team of specialists worked on the development of the V-2 rocket, the first of which was launched in 1942. See Fig. 1. Some historians would later estimate that by the end of World War II, the Germans had fired nearly 3,000 V-2 weapons against England and other targets.

As the war ended, the United States was interested in the technical capability of the Germans, and a team of American scientists was dispatched to Europe to collect information and equipment related to German rocket progress. Arrangements made under "Project Paperclip" enabled the German rocket specialists to come to the United States to initiate advances in American rocketry. Initially assigned to Fort Bliss, Texas, and later to Redstone Arsenal in Huntsville, AL, the German and American members of the team developed the Redstone Rocket, also known as "Old Reliable" because of its many diverse missions. See Fig. 2.

On October 4, 1957, the Russians launched a 23-inch-diameter ball designated *Sputnik*, the world's first artificial satellite. The news of the Soviet success created shock waves across the United States. The Soviet Union had inaugurated the Space Age. It had also presented American planners with the painful realization that there was no launch vehicle in the U.S. stable capable of orbiting anything approaching Sputnik's weight.

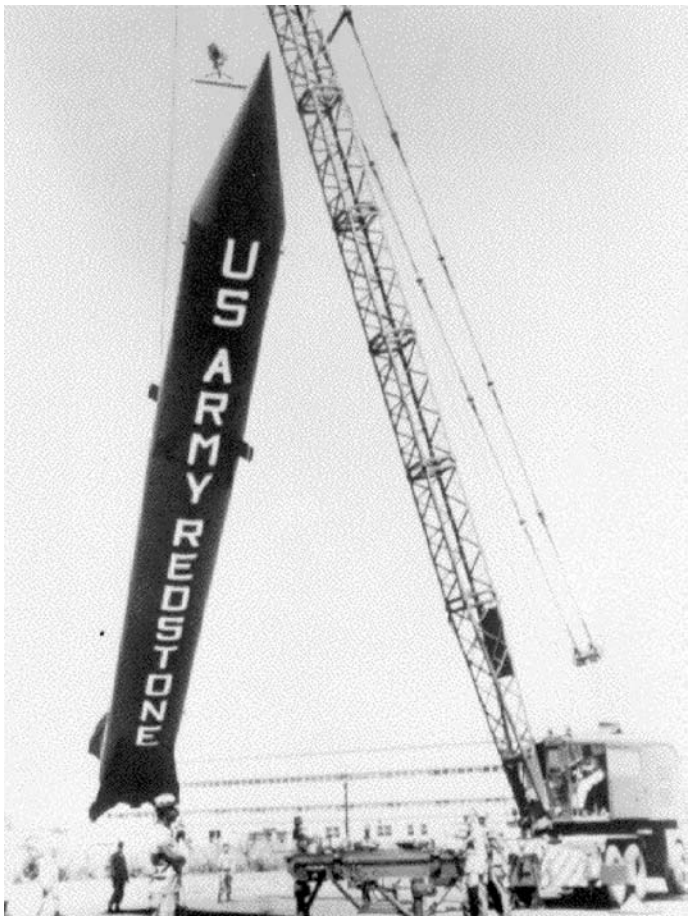

Fig. 2. The Redstone was a high-accuracy, liquid-propelled, surface-to-surface missile. The Von Braunteam developed and launched the first Redstone missile in August 1953. (*MSFC*.)

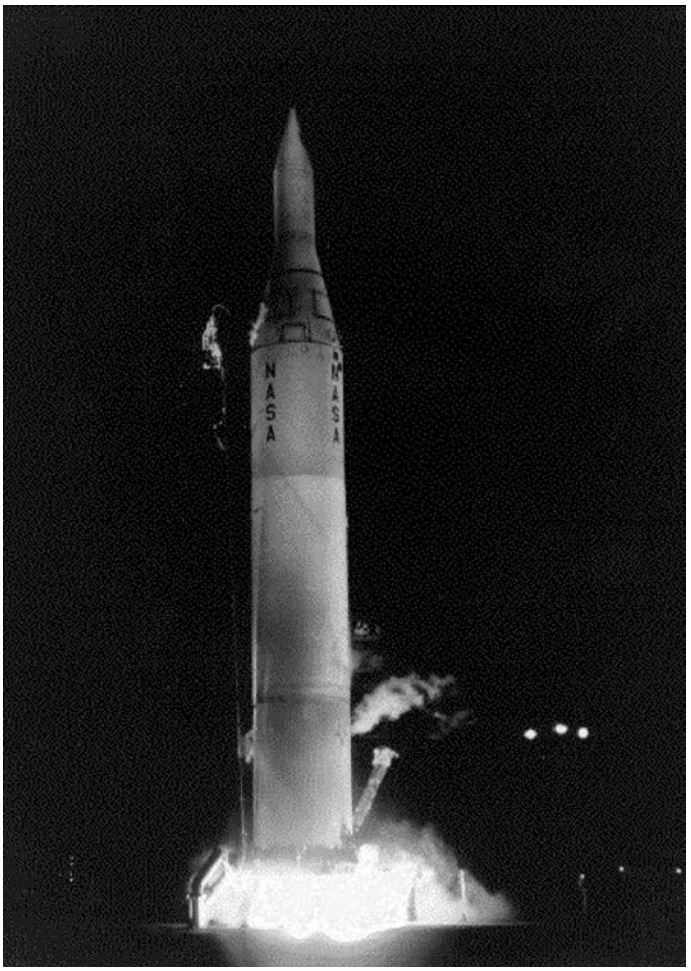

Fig. 3. Redstone, known as Jupiter-C. The family of launch vehicles, developed by Von Braun and his team, also came to include the Juno II used to launch the Pioneer IV satellite on March 3, 1959. Pioneer IV passed within 37,000 miles of the moon before going into solar orbit. (*MSFC*.)

Before the end of the year, the Soviets had also successfully launched *Sputnik 2* carrying the space dog, "Laika."

Only a few months after *Sputnik*, the Von Braun team used a modified Redstone, known as Jupiter-C, to launch the United States first artificial Earth satellite, *Explorer I* on January 31, 1958. Von Braun and his team were responsible for the Jupiter-C hardware. See Fig. 3. The satellite's principal scientific achievement was a major one — the discovery of the Van Allen Radiation Belts surrounding the Earth. The satellite dispatched information from space to Earth stations until May 23, 1958, when its batteries were exhausted. The vehicle, however, continued to orbit for several years, reentering the Earth's atmosphere on March 31, 1970.

Soon after the success of *Explorer 1*, their research would begin focusing on the development of new launch vehicles, the Saturn family, to carry heavier payloads into space. But throughout 1958, the Nation's leadership in Washington had to face a series of decisions on how to manage the U.S. space program.

As a result of the debate in Washington, the National Aeronautics and Space Administration (NASA) came into being on October 1, 1958, with a broad charter for civilian aeronautical and space research. The new agency absorbed the existing National Advisory Committee for Aeronautics and made broad transfers from other government programs including the Von Braun team in Huntsville.

Launch vehicle development occupied much attention in NASA's early years leading to the Scout, Centaur, and Saturn launch vehicles.

On April 12, 1961, the Soviet, Yuri Gagarin became the first man in space.

Less than a month later, a Mercury-Redstone launched Alan B. Shepard, the first American astronaut, into space. Astronaut Gus Grissom followed him on an identical mission shortly thereafter. In 1962, a Mercury-Atlas launched Friendship 7, carrying John Glenn, who became the first American to orbit the Earth.

The Gemini Program, America's next major activity in space, used a modified Titan intercontinental ballistic missile. Its two-stage design permitted two men to ride into space together so they could conduct extra-vehicular activities (EVA). Astronaut Ed White made the first United States EVA in 1965, the same year that the Soviet cosmonaut, Aleksey Leonov, made the first Soviet space walk. On May 25, 1961, President Kennedy had announced a national goal of "landing a man on the Moon and returning him safely to Earth" within the decade. The Apollo program vastly expanded man's knowledge about the Moon and the Earth. Six Apollo expeditions explored the Moon, the last in December 1972. The

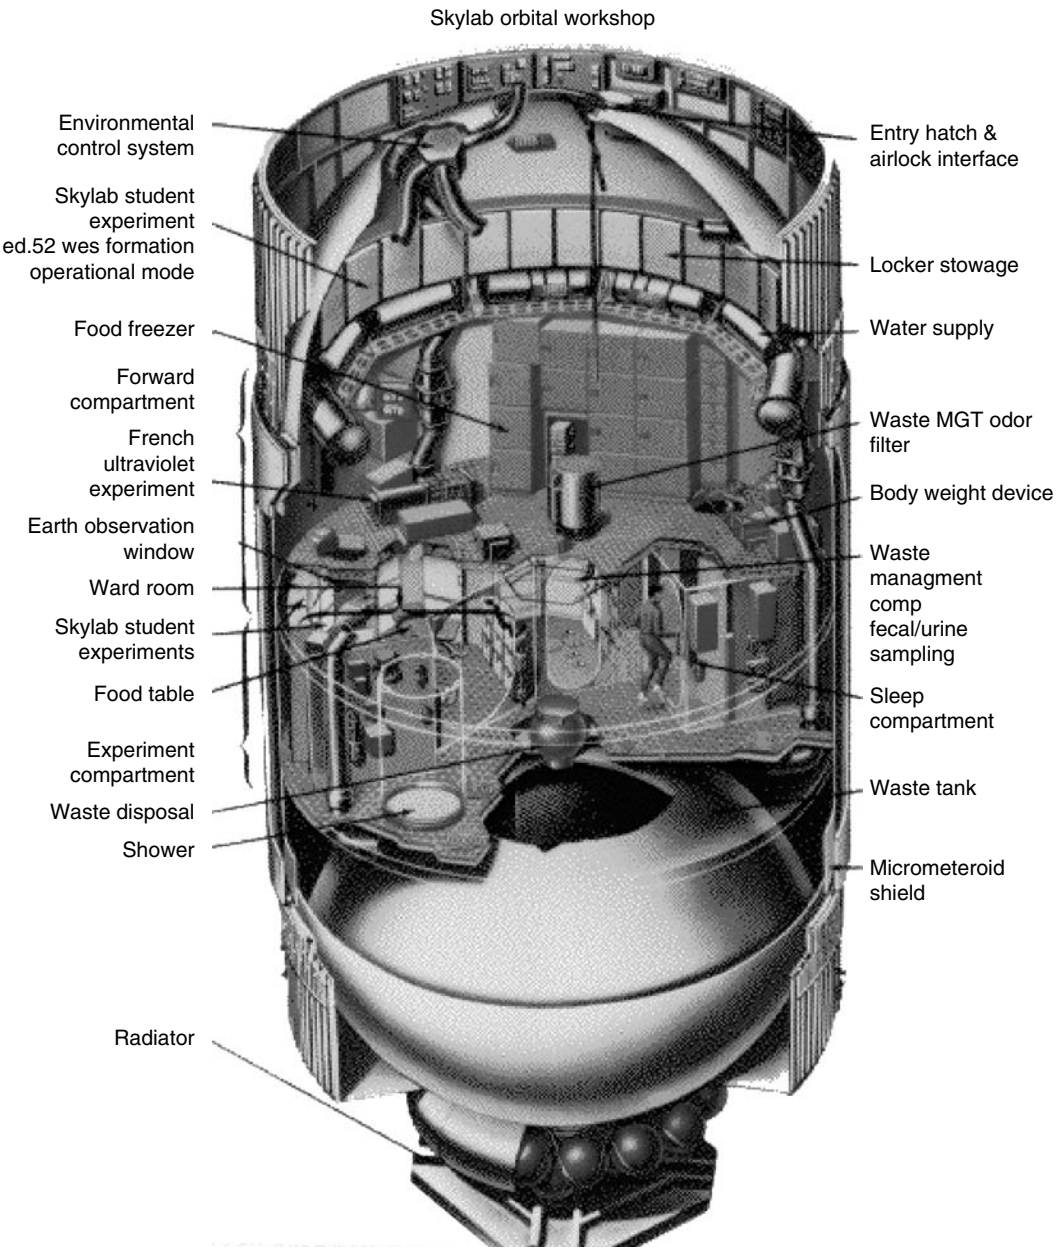

Fig. 4. *Skylab*, America's first Space Station. (*MSFC*.)

lunar landings required an entirely new launch vehicle, the Saturn V. This new vehicle, developed by the Von Braun team at NASA's Marshall Space Flight Center, evolved in three phases. The Saturn I provided NASA with significant new payload lifting capabilities. The Saturn IB had even more power, enough for orbital missions with the Apollo spacecraft. The Saturn V was clustered with five F-1 rocket engines burning liquid oxygen and kerosene and generating 1.5 million pounds thrust per engine.

In 1973, a two-stage Saturn V rocket also launched Skylab, America's first space station, designed to investigate long-duration spaceflight. See Fig. 4. Skylab's three different three-man crews, also launched into space by Saturn IB rockets, spent up to 84 days in Earth orbit and performed a variety of more than 100 experiments.

The final launch of a Saturn V rocket came on July 15, 1975, as part of the Apollo-Soyuz Test Project. Earlier that day, a Russian Soyuz spacecraft lifted off its launchpad at a Soviet launch site carrying three cosmonauts. Seven and one-half hours later, the U.S. Apollo spacecraft was launched with its crew of American astronauts. Rendezvous and docking of the two ships were accomplished on July 17. The two ships remained docked for two days, conducting joint.

The Apollo program demonstrated that men could travel into space, perform useful tasks there, and return safely to Earth. But space had to be more accessible. This lead to the development of the Space Shuttle. See Fig. 5.

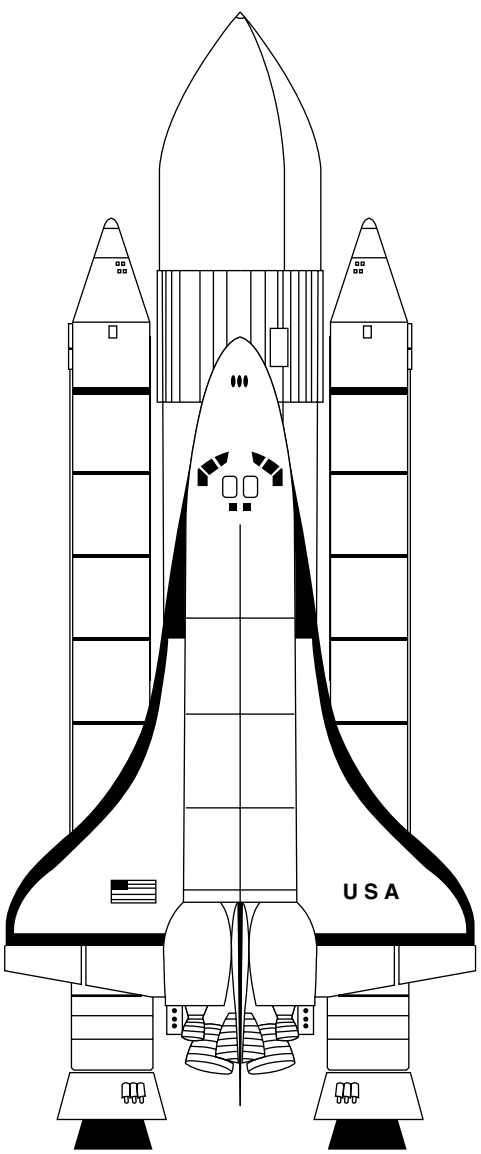

Fig. 5. Illustration, showing the Space Shuttle. (*MSFC*.)

Fig. 6. Launch of Space Shuttle Columbia. (*MSFC*).

With the launch of the Space Shuttle Columbia on April 12, 1981, the United States entered a new era in transportation for living and working in space. See Fig. 6. Described by NASA as the first "true aerospace vehicle," the space shuttle takes off like a rocket. The winged orbiter then maneuvers around the Earth like a spaceship. But unlike earlier manned spacecraft, which were good for only one flight, the shuttle orbiter and solid rocket boosters can be used again and again. Only the external tank is expendable on each mission. See also **Rocket Engine**; **Rocket Propellants**; **Satellites (Scientific and Reconnaissance)**; **Space Shuttle**; **Space Station**; and **Von Braun, Wernher**.

ROCK FLOUR. A peculiar and distinctive white mud, the product of the grinding action of glaciers. When deposited in lakes, rock flour forms an important constituent of varves, or the type of annual cyclic stratification used by glaciologists in determining glacial time. When desiccated and transported by wind this material may form extensive deposits of loess.

ROCKWELL SCALE. See **Hardness**.

RODENTIA *(Mammalia)*. Gnawing mammals characterized particularly by the two chisel-like incisor teeth in each jaw. These teeth oppose each other and are worn down by use to maintain a keen enamel edge on the front, while the softer dentine slopes away inward. Most species are small, but the beavers and capybara are moderately large animals. The rats and mice are the most familiar species, with squirrels, chipmunks,

and woodchucks scarcely less known. Because of their vegetarian habits and their destructive gnawing, many rodents are serious crop pests, and as household nuisances and disease carriers they are all too common. The rabbits and their allies at one time were included under *Rodentia*, but now are placed in their own, separate order, *Lagomorpha*. See also **Rabbits and Hares**.

The general organization of *Rodentia* is given in Table 1. The common nomenclature applied to *Rodentia* is confusing, with such terms as rat, squirrel, gopher, etc. applying to numerous species. The principal species among the Sciuromorphs are described in this volume under **Beaver**; or **Squirrels and Other Sciuromorphs**. In the latter entry, there are descriptions of the chipmunk, gopher, marmot, prairie dog, spermophile, squirrel, and woodchuck. Mouse is a term used to describe pocket mice species as found under the Sciuromorphs and so-called ancient and modern mice under the Myomorphs. The term is loosely applied to numerous species of small burrowing and gnawing rodents with slender bodies, long tails, and either the front legs or both pairs short. The sewellel is a Sciuromorph although commonly called the mountain beaver or boomer. This is a broad, stout animal with short legs, found in mountain forests in the western part of the United States. Of the genus *Apolodontidae*, it is a burrowing species that feeds on bark, twigs, and leaves. The animal is more closely related to the squirrels than to the beavers.

Only a representative number of Myomorphs can be described here. The hamster is a burrowing animal found in Europe and Asia and known for its complex underground dwellings. The common hamster, *Cricetus*, attains a length of about 1 foot (0.3 meter). When numerous in an area, the animal can be a serious pest to farmers, damaging crops of almost all kinds. The fur is used and the flesh can be eaten. The animal is light brown above and black underneath. Hamsters are also used widely in medical laboratories. These are usually *Mesocricetus auratus*, of Syrian origin. Hamsters are extremely prolific, a female producing several litters per year. The gestation period is a brief 2 to 3 weeks. The young are born blind and naked, but they mature rapidly and are fully on their own in about 3 weeks. As a diet, the hamster prefers fruits, vegetables, and grain and occasionally small rodents or birds.

The dormouse is a small arboreal rodent of the Palaearctic and Ethiopian regions. The animal has a squirrel-like appearance, with long hairy, bushy tail. The common dormouse is *Muscardinus avellanarius* and is sometimes called a sleeper. Unlike the squirrel, the dormouse does not have cheek pouches. The animal is not much larger than an ordinary house mouse. The eyes are large and the head disproportionately large for the body size. Color is rusty-red above and white underneath. The animal hibernates during the colder season, during which time the body temperature may drop close to freezing temperatures. The heart beats but a few times per

minute, the blood pressure is extremely low, and breathing is difficult to detect.

The muskrat is a moderately large amphibious rodent of North America. It is stoutly built, short-legged with partially webbed hind toes, and a compressed tail. The muskrat inhabits swamps and streams, making houses of sticks, while also burrowing in the banks. Two species are recognized, one a dark brown animal, *Ondatra rivalicia*, of the coastal part of Louisiana; the other *O. ziebethica*, found over most of the continent. Muskrat fur consists of a fine woolly undercoat and long glossy hairs. It is probably the best of the inexpensive furs and because of the ability of the animal to withstand extensive trapping is an important commercial fur. Several million pelts are taken annually in North America, many from fur farms. The fur is marketed in its natural colors, as well as in the form of Hudson seal after being plucked, clipped, and dyed black.

The lemming is a small animal of northern latitudes. The European lemmings resemble the woodchuck in form, but are much smaller. The American species, *Synaptomys*, looks like a short-tailed mouse. The common lemming, *Lemmus lemmus*, of northern Europe is noted for its occasional migrations. Many thousands of the animals take part in such migrations, crossing mountains, fording streams, and always pushing straight on until they enter the sea and are drowned.

The jerboa is a small jumping desert animal of Asia and northern Africa. It resembles a mouse, with long tufted tail and very long hind legs. The small forelegs are not used in locomotion. The Asiatic jerboas have five toes on the hind feet; the African, three. The ears vary considerably in shape. The fur is long, soft, and silky. The most common Asiatic species, also called the alagdaga, is *Alactaga indica*.

The vole is a meadow or field mouse, constituting the genus *Microtus*. The genus is limited to the Northern Hemisphere and in Asia does not extend south of the Himalayas. Voles are characterized by rootless molar teeth, formed of two rows of alternating triangular prisms. About 20 species occur in North America.

The wood rat is a moderately large rodent, more common in the western states, but represented by a few species in other sections. The wood rat is well and unfavorably known for its habit of invading houses and camps and carrying away anything edible. The wood rat differs from true rats in the shorter, furry tail and the larger eyes and ears. Ten species have been described, all in the genus *Netoma*. These animals also are called pack rats and trade rats, the latter from their habit of replacing what they take with some other object.

The jumping mouse is a small mouse-like rodent with very large hind legs and long tail. It differs from the kangaroo mouse in the absence of cheek pouches. Several genera have been recorded, all related to the jerboas of the Old World.

The kangaroo rat is a burrowing rodent of the western United States, with long tufted tail and long hind legs. Several genera of these animals are related to the pocket mice and kangaroo mice.

The gerbil is a small burrowing animal of Asia and Africa. Gerbils resemble rats, but have long hind legs and large eyes and move about by jumping. In these points, they resemble the jerboas, but they are less extreme.

A rat, in the strict sense, is an animal of the genus *Rattus*, a term that is widely applied to many small gnawing animals. The true rats are dull-colored animals with long scaly tails, short legs, small ears, and a pointed muzzle. The common brown rat, *R. norvegicus*, is a typical example. This species was introduced from Europe into the United States during Colonial times and has been a troublesome and often dangerous pest ever since. It is much more aggressive than the related black rat, *R. rattus*, and has almost crowded the latter out. The roof rat, *R. alexandrinus*, is a third species found in the southern United States. Still other species of the genus are found on other continents. Some of the closely related genera include the bandicoot rats, bush rats, bamboo rats, kangaroo rats, and cane rats. The name, American pouched rat, is sometimes applied to a group containing the pocket gopher.

The Hystricomorphs tend to number larger animals than found in the two foregoing families of *Rodentia*.

The porcupine is an animal with many modified hairs resembling quills in form. These hairs are sharp-tipped, finely barbed, rigid spines which penetrate flesh very readily and serve as an almost impregnable defense. North America has two species of porcupines, one ranging from the eastern half of the continent as far south as Virginia and the other, *Erethizon epixanthus*, in the far west, from Alaska to Mexico. The common eastern species, *E. dorsatum*, is also called the hedgehog. Both species are partial to the leaves, twigs, and bark of evergreen trees as food. The tree porcupines differ in having long prehensile tails. They are found in Mexico and South America. See Fig. 1. Still other species live in Eurasia, Africa, and the Oriental Region.

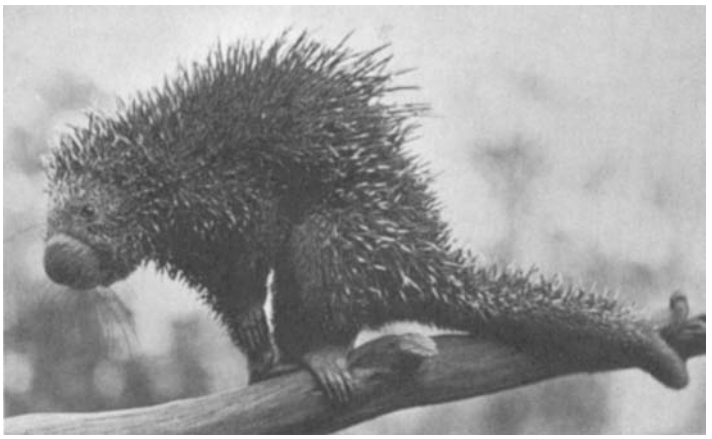

Fig. 1. Brazilian tree porcupine with prehensile tail. (*New York Zoological Society*.)

Guinea pigs are widely kept as pets and are useful to medical science as laboratory animals. Because of their high rate of reproduction, they have also been bred for studies in heredity. The guinea pig is one species of cavy. Among other species are the capybara, largest of the rodents and aquatic in habits, although most of the species are small and terrestrial. All cavies are native to South America. The domesticated guinea pig achieves a length of about 10 inches (25 centimeters) and a weight of about 2 pounds (0.9 kilograms). The animal has no tail. There are 4 toes on the forefeet; 5 toes on the hindfeet. The size and color vary considerably. In nature, the animal feeds on grass and vegetables. As a pet, the animal will consume some kinds of dog or cat food, but requires a lot of water. They can be bred 2 to 3 times per year. There are from 2 to 8 young per litter. Gestation period is from 63 to 75 days. The life span is from 6 to 7 years.

The capybara is a large South American species, *Hydrochoerus capybara*, of the cava family. These animals attain a length of 4 feet (1.2 meters) and a weight of almost 100 pounds (45 kilograms). They are semiaquatic in habits and while their food usually consists of water plants and other vegetation, they sometimes make inroads on cultivated crops. Locally, they are called capivaras and carpinchos.

The coypu is a large aquatic rodent of South America whose habits are like those of the muskrat. The fur is of commercial value. The animal is now protected by law because it was nearing extinction. The coypu achieves a length of $2\frac{1}{2}$ to 3 feet (0.8 to 0.9 meter). There are nine young in a litter. The hutia is a large arboreal rodent of the West Indies. It is related to the coypu, but resembles a rat, with exception that the muzzle is blunt and the tail is moderately long.

The agouti is a large rodent of the genera *Dasyprocta* and *Myoprocta* found in Central and South America and the West Indies, where they live chiefly in the forests. The natives hunt the animal for its flesh. There are about 15 species, all are brown with yellow coloration. They are about the size of an average American rabbit. The best known species is *Azaras* "acuchi" of Guinea. The animal feeds on nuts, fruits, and sugar cane. Nocturnal in habits, the animal can be quite destructive to banana plantations and sugar fields. The paca is a stoutly built rodent, *Agouti paca*, about 2 feet (0.6 meter) long, marked with rows of light spots on a fawn-to-blackish ground color. The animal is found through most of South America east of the Andes. It is closely related to the agoutis.

The tucotuco is a ratlike burrowing animal of South America. It has gray fur and red incisor teeth. The tail is only moderately long and is clothed

with short fur. A closely related form with vestigial ears is known in Chile as the cururo.

The chinchilla is a small squirrel-like rodent related to the porcupines. The animal lives in communal burrows at high altitudes in the mountains of South America. The fur of the common chinchilla has commercial value. There are two genera, *Chinchilla* and *Lagidium*. The chinchilla is about 8 to 10 inches (20 to 25 centimeters) long with a tail of about 5 inches (13 centimeters) in length and with a black streak its full length. The fur is about 1 inch (2.5 centimeters) long, soft, pale gray, and dusky-looking. The diet consists of fruit, grain, moss, and herbs. There are two litters each year, usually with two young per litter. The gestation period is about 110 days. The Chilean chinchilla can be raised in captivity, but is very sensitive to excessive humidity. The animal was first introduced into the United States in about 1923 for breeding. The rare Peruvian royal chinchilla is practically extinct. This genus dates back to the age of the Incas, who prized the animal for food.

The viscacha is a large, stout burrowing animal, *Lagostomus trichodactylus*, of the South American pampas and related to the chinchillas. The contrast between these animals has been likened to that between the squirrels and woodchucks, the one gracefully built and the other a clumsy burrowing form.

ROE DEER. See **Deer**.

ROENTGEN. A unit of radiation, that quantity of X-rays or gamma rays which will produce, as a consequence of ionization, 1 electrostatic unit of electricity in 1 cubic centimeter of dry air measured at 0 degrees C and standard atmospheric pressure. See also **Radioactivity**.

ROENTGEN-EQUIVALENT–MAN (abbr rem). A unit of radiation which when absorbed by a human being, produces the same effect as the absorption of 1 roentgen of high-voltage X-rays.

ROENTGEN-EQUIVALENT-PHYSICAL (abbr rep). A unit measuring a purely physical effect of radiation by the number of ion pairs produced per unit volume of target material per time unit. One rep is equivalent to the absorption of 93 erfs per gram of tissue.

ROENTGENIUM. See **Chemical Elements: The History of the Origin**.

ROLL CLOUD. See **Clouds and Cloud Formation**.

ROLLE THEOREM. Let $f(x)$ be a function which vanishes at $x = a$ and at $x = b$, and which has a finite derivative $f'(x)$ at all points in the interval (a, b). Then $f'(x)$ vanishes at some point x_0 between a and b. This theorem is used in calculus to prove mean value theorems.

ROLLING FRICTION. In the rolling of a wheel on a plane surface there is some distortion of the two surfaces in contact due to the normal force between the surfaces. Such distortion smears out the ideal line contact and effectively introduces a force with a component in opposition to the motion. This component of force is called the rolling resistance or friction F_r and is proportional to the normal force N. A coefficient of rolling resistance or friction μ_r can be defined by $\mu_r = F_r/N$, where F_r can be determined experimentally by observing the deceleration on a horizontal surface. See also **Friction (Mechanical)**.

ROLL OUT. In computer terminology, to read out of a storage device by simultaneously increasing by one the value of the digit in each column and repeating this r times (where r is the radix) and, at the instant the representation changes from $(r - 1)$ to zero: generating a particular signal, or terminating a sequence of signals, or originating a sequence of signals.

ROLLS. See **Clouds and Cloud Formation**.

ROMANES, GEORGE JOHN (1848–1894). George Romanes was a Canadian-born British research associate of Charles Darwin and a founder of evolutionary psychology, whose fundamental contributions to speciation theory were ignored for much of the twentieth century.

George John Romanes was born in Kingston, Canada in 1848, where his father, a Presbyterian minister, was Professor of Classics at the newly established Queen's College. In 1850 the Reverend George Romanes inherited "a considerable fortune" from his father, a successful Edinburgh merchant, whose will expressed the hope that there would be a return from Canada. Thus, from the age of two George John Romanes lived in Europe, mainly in London. With independent means, he was free to pursue his own interests. These were in four interrelated areas: religion, neurophysiology, evolutionary psychology and evolution. In each he published books and papers, which were widely distributed. His rise was meteoric. In 1875 Darwin, Joseph Hooker and Thomas Huxley supported his membership of the Linnean Society of London, and in 1879 he was elected a Fellow of the Royal Society. He became known as "The Philosopher." See also **Hooker, Joseph Dalton (1817–1911)**; and **Huxley, Thomas Henry (1825–1895)**.

Only Romanes' pioneering contribution to evolutionary psychology received general recognition in the twentieth century. However, it now seems that Darwin's mantle had been safely entrusted. Four years after Darwin's death Romanes published a paper in the *Journal of the Linnean Society*, entitled "Physiological selection: an additional suggestion on the origin of species." In a display of inductive reasoning paralleled only by that of Darwin himself, Romanes claimed to have resolved the major problems in Darwin's theory, invoking a "physiological peculiarity" of the gonad. Darwin's 'natural selection' was no longer the preeminent force in evolution, a suggestion perceived as hostile to Darwin. The scientific establishment (Alfred Wallace, Huxley and Hooker's son-in-law, Thiselton-Dyer) attacked Romanes, both publicly and privately. However, Romanes' evolutionary ideas were later (apparently unknowingly) adopted by advocates of what has become the "chromosomal" (non-genic) view of the origin of species (William Bateson, Cyril Darlington, Michael White, Max King). Recent work of the present author indicates that the "physiological peculiarity" may relate to the base composition of DNA. See also **Bateson, William (1861–1926)**; and **Wallace, Alfred Russel (1823–1913)**.

DONALD R. FORSDYKE, Queen's University, Kingston, Ontario, Canada

ROMER, ALFRED SHERWOOD (1894–1973). Alfred Romer was an American vertebrate paleontologist and museum director whose textbooks and community leadership shaped his discipline for generations, and who revolutionized the study of fossil reptiles.

Born to Harry Houston Romer and Evalyn Sherwood Romer in 1894, Alfred was a New Englander by birth and culture. He entered Amherst University in 1914, studying German literature and history. In 1917, Romer volunteered for the American Field Service, transporting ammunition, then served in the US Air Service. He returned to New York in 1919, entering Columbia University to study vertebrate paleontology. His

dissertation examined the evolution of locomotion in reptiles. In 1921, Romer taught zoology at Bellevue Medical College, and then moved in 1923 to University of Chicago, succeeding Samuel Williston as vertebrate paleontologist. See also **Paleontology (The History)**.

At Chicago, Romer worked with his preparator, Paul Miller, to collect and study early reptiles and amphibians. They made the Permian "red beds" of Texas famous. Romer wrote general textbooks that brilliantly captured developments in his field. His *Man and the Vertebrates* 1933 was a general audience survey of comparative vertebrate anatomy and evolution, with hints of his social philosophy. For specialists, *Vertebrate Paleontology* 1933 covered the same domain. Both became standard reading and were extensively reprinted.

Paleontology at Chicago was treated as a geological science. Romer's approach was biological. "Quite fed up" as an outsider, in 1934 Romer left for Harvard University and the Museum of Comparative Zoology. Romer directed the museum from 1946 to 1961, working hard to transform this long-neglected institution through increased funding, collections, and caliber of its staff. By Romer's retirement in 1961, the MCZ had become first rate. Romer returned to research and exploration until his unexpected death in November 1973. Nearly half his bibliography was published after his 65th birthday.

Two themes unified Romer's research. One theme was comparative anatomy and the functional implications of anatomy. Romer strove to understand extinct animals as living organisms. This found expression in research on muscle and limb evolution, the development and evolutionary history of cartilage and bone, and the structure and function of the nervous system. A second theme concerned major evolutionary transitions: fish to amphibians, amphibians to reptiles, and reptiles to mammals. Although a solid Neo-Darwinian, Romer preferred empirical studies of evolutionary change to theorizing about evolutionary mechanisms. Likewise for ecological and functional studies, Romer argued that research into evolutionary mechanisms "was worthless without basic structural knowledge of the forms concerned." A nongeologist by preference, Romer occasionally ventured into stratigraphy. His last expedition to the Texas red beds involved detailed mapping of the region's geological history. Romer also was one of the first vertebrate paleontologists to defend the idea of continental drift.

Frustrated by low recognition for his profession, Romer helped organize a Section of Vertebrate Paleontology within the Paleontological Society in 1934. In 1940, this became the Society of Vertebrate Paleontology, http://www.vertpaleo.org/. Romer demanded informality and camaraderie, defending the "Quaker rule" in which everyone attending a meeting had an opportunity to discuss any subject they wished.

Through his research, leadership and devotion to a profession, Romer left a rich legacy. He was fondly remembered by colleagues and students. Stories of his wisdom, friendship and practical jokes abound; prizes and awards commemorate him.

ROENTGEN, WILHELM CONRAD (1845–1923). Roentgen became one of the outstanding experimental physicists of his time. In 1869, he received his doctorate in mechanical engineering from the University of Zurich. He held various positions at higher institutions throughout Germany until, in 1888, he became the chair for the physics department at the University of Wurzburg.

In 1895, Roentgen was the first scientist to observe and record X-rays. While experimenting with a cathode ray discharge tube that was completely enclosed in cardboard so no light could escape, he observed that a sheet of barium platino-cyanide coated paper lying several feet away from the discharge tube was glowing in the dark. Roentgen realized the importance of this accidental discovery and he devoted six straight weeks of working in his laboratory investigating the X-ray. While investigating, he actually saw the image of his bones within his fingers and deduced that his X-rays must be a very short wavelength form of electromagnetic radiation. He published his work in a series of classic papers and the phenomenon of his X-rays had immediate use in hospitals in the diagnosis and treatment of fractures. His discovery could have been patented, but Roentgen gave it to humanity. Later, when he received a cash prize for receiving the first Nobel Prize (1901) in Physics, Roentgen gave the money to the University of Wurzburg.

Roentgen was truly a great scientist and great humanitarian. His discovery of the X-ray changed the world and today it has universal usage.

See also **X-Ray**.

J. M. I.

ROOFING MATERIALS. Roofs are a basic element of shelter from inclement weather. Natural or hewn caves, including those of snow or ice, are early evidence of human endeavors for protection from the cold, wind, rain, and sun. Nomadic people, before the benefits of agriculture had been discovered and housing schemes developed, depended on the availability of natural materials to construct shelters. Portable shelters, eg, tents, probably appeared early in history. Later, more permanent structures were developed from stone and brick. Salient features depended strongly on the availability of natural materials. The Babylonians used mud to form bricks and tiles that could be bonded with mortars or natural bitumen. Ancient buildings in Egypt were characterized by massive walls of stone and closely spaced columns that carried stone lintels to support a flat roof, often made of stone slabs.

As larger and larger structures were desired, building design became an important element in construction. Roofs evolved from a simple covering to roofing systems designed to perform a number of functions to separate indoor and outdoor environments. Selection of roof design depended not only on factors of economy and comfort, but also on the availability of materials and structural and aesthetic factors. Thus, a modern design normally includes a structure to carry loads, insulation to control heat flow, a barrier to control air and vapor flow, and a roofing element to prevent water penetration.

Roofs may be 'pitched', 'domed', 'low slope' or 'flat' in form; however, roofs are rarely truly flat. Flat roofs are commonly found on industrial/commercial type structures while low slope is found on prefabricated or steel structures such as arenas. Pitched roofs are the primary design found on residential homes. The most common type of flat roof for industrial/commercial structures are the conventional built-up-roof (BUR) assembly and the protected roof membrane assembly (PMRA). The most popular roof membranes are the 4ply (felt and asphalt), the 2 ply modified bitumen and the single plies such as the elastomeric (EPDM) and thermal plastic (PVC), drains provide run off for rain and snow.

Roof shapes and pitches are often the product of design, material constraints and/or climatic considerations. Roof designs in mild climates or where there is little precipitation tend to exhibit flat roofs and drainage at the exterior wall; an example of residential flat roof is that of the adobe construction in the American Southwest. In northern climates where temperatures drop below freezing we see major changes in both flat roof and pitch roof design. The need for greater thermal resistance will dictate the type of roof design as well as the waterproofing membrane specification. In areas that have a high accumulation of snow such as; Buffalo USA or Montreal Canada a minimum slope of 4 inches in 12 inches (4/12) of roof surface is required. We often see roof pitches that exceed 45 or 50 degrees. Drainage on cold climate roofs is typically installed at interior locations rather than on the exterior wall as we see in the southern climates. By placing the drains toward the interior freezing of the rainwater leader is avoided. Weight of accumulated snow has been known to cause major damage to structures, freeze thaw cycling plays havoc on the flat roof assembly as well as the pitch roof design. Migrating water during thaw periods enters voids then freezes and expands. Daily repetitions of this cycling effect eventually causes damage to the shingle and/or membrane.

For low slope commercial roofing, bituminous-based roof coverings are the most common systems in the United States. Asphalt-based materials predominate over coal-tar based materials in these systems. For residential roofing materials, various types of roofing products, including asphalt, wood, and tile, are used for both new construction and reroofing.

Continuous or Jointed Systems

Built-Up Roofing. Built-up roofing (BUR) is a continuous-membrane covering manufactured on-site from alternate layers of bitumen, bitumen-saturated or coated felts, or asphalt-impregnated glass mats and surfacings. These membranes are generally applied with hot bitumens or cold applied bituminous adhesives.

The deck may be nailable, eg, wood or light weight concrete, or not, eg, steel or structural concrete. The felts or mats may be organic (cellulose), or fiber glass.

Common BUR systems are installed in different ways: membrane adhered/attached to deck without insulation; insulation adhered/attached to deck with membrane applied to insulation; base sheet adhered/attached to deck, insulation to base sheet, and top membrane to insulation; and membrane adhered/attached to deck and insulation applied over the membrane, the so-called protected-membrane roof.

The components must be anchored as protection against wind uplift, slippage, and membrane movement. Membrane strength is related to felt or glass-mat strengths and the number of plies. Continuous bonding is inadvisable if the elastic limit of the membrane will be exceeded, which results in the development of splits in the membrane and leads to roof leaks. Nailing or spot adhesion of the first layer provides relief from concentrated strains.

Cold applied BUR applications do not require heating to fluidize the bitumen on the job. Simple application and economical maintenance are primary considerations. Bitumens are liquefied by dissolving in a solvent (cutbacks) or dispersing in water (emulsion). The base cutback can be modified by addition of other components, commonly mineral fillers and fibers, to form specialized coatings. At ordinary temperatures, the solvent or water evaporates and forms an adhesive bond.

Protected-Membrane Roofs. Primitive roofs covered with earth and sod over sloping wood decks shingled with bark were early examples of protected-membrane roofs (PMRs). Grass and earth provided insulation and protected the shingled deck from inclement weather.

In modern PMR construction, thermal insulation that is unaffected by water or that can be kept dry in some manner is required. Extruded polystyrene (XEPS) foam insulation boards are commonly employed. See also **Insulation (Thermal)**. They are placed on top of the waterproofing roof membrane, which is next to the deck. The insulation should not be adhered to the membrane. Ballast at the rate of $\geq$48.8 kg/m^2(1000 lb/100 ft^2) holds the insulation in place and offers protection from the sun. The insulation joints are open and drainage must be provided. Various other materials, eg, patio blocks and concrete slabs, are also used as surfacings and ballast.

Asphalt Roofing Components. Asphalt is a unique building material which occurs both naturally and as a by-product of crude-oil refining. Because the chemical composition of crude oils differs from source to source, the physical properties of asphalts derived from various crudes also differ. However, these properties can be tailored by further processing to fit the application for which the asphalt will be used. Softening point, ductility, flash point, and viscosity–temperature relationship are only a few of the asphalt properties that are important in the fabrication of roofing products.

Asphalt intended for roofing can be tailored to perform two separate functions. The first is to saturate the organic fiber-based material. This requires that the asphalt be very fluid at processing temperatures so that it can impregnate the base material completely. The second is to coat the saturated roofing to serve as the medium for adhering mineral granule surfacing to the roofing. In the manufacture of roofing on a fiber glass base material, the saturation step is eliminated.

Organic Felts. Roofing felts consist of fiber mats impregnated and/or coated with bitumen. Earlier felts contained rag fiber. Extensive weathering tests and field experience demonstrated that Asplund wood-fiber/recycled paper felts are satisfactory for BUR and prepared roofing without the addition of variable rag fibers. Organic felts are formed by preparing a water slurry of pulp, after which the fibers are picked up by a rotating screened drum or by a traveling screen. The formed sheet is dried by vacuum suction and steam-heated drums and then calendered and wound into large rolls for subsequent trimming and slitting to the proper width. The organic felt is then saturated by dipping the felt in hot bitumen and passing it over a series of rolls for cooling. The felt is then perforated, marked with guidelines for application, and wound into rolls of convenient size. The small perforations let air and moisture escape during application. Furthermore, the saturant reduces the rate of water vapor absorption. Vapor permeability and water absorption are further reduced by asphalt coatings, stabilized with mineral. A parting agent, eg, sand, talc, or a soap film, is spread on the coating to prevent sticking. See also **Release Agents**.

Fiber Glass Felts. Fiber glass felts are manufactured from glass filaments prepared from a molten mixture of silica sodium carbonate, recycled glass, sand, and other ingredients. The filaments may be short (chopped) or continuous. They may be deposited dry or from a dilute water slurry on a screen conveyor. In either process, a binder is applied. Heat is then applied to set the binder. The formed fiber glass mat is then coated with hot asphalt, surfaced with a parting agent (liquid or mineral), cooled, marked with guidelines, and wound into rolls of the desired length. Excellent dimensional stability and low moisture absorption are derived from fiber glass roofing felts. For the production of mineral-surfaced roofing products or shingles, mineral granules are applied to a heavier-coated top side of the felt. Variations in the manufacturing process also produce venting base sheets and flashings. Fiber glass mats are also used to produce modified bitumen roofing products.

Single-Ply Roofing Membranes. The single-ply roofing membrane category derives its name from the installation technique where a single-ply sheet membrane is applied over the roofing deck/substrate, giving continuous water-tight coverage. These flexible membranes offer light weight, excellent chemical and weather resistance, ease of application and repair, and multiple colors. They can be installed in a number of ways, including the traditional fully adhered, the mechanically fastened, and the ballasted roofing systems. They have been designed to comply with various wind and fire code requirements of the construction industry. Because of the light weight of the adhered and mechanically fastened systems, they sometimes can be installed directly over an existing roof system, thus eliminating the waste that would normally be generated from a roof tear-off. Proper precautions should be taken to remove saturated areas of the old roof before overlaying the new system.

There are two basic categories that these flexible membranes fit into: thermoset and thermoplastic.

Single-ply membranes offer the widest range of systems in the roofing industry. The three basic systems are ballasted, fully adhered, and mechanically fastened. From a cost standpoint, the fully adhered system is the most expensive to install, the ballasted system the least. The protected-membrane roofing system can be used with any of the basic systems. The following gives a brief description of the roof assemblies.

Ballasted. A ballasted roof assembly consists of a membrane or membrane and substrate material (insulation, slip sheet, etc) loosely laid over a deck with the assembly held in place using ballast.

Fully Adhered. The substrate, ie, insulation, cover board, etc, that the single-ply membrane is to be attached to is either fully adhered or mechanically fastened to the deck. However, there are also applications where the membrane is adhered directly to the deck. The membrane is then adhered to the substrate. The typical method for adhering the membrane to the substrate is by applying a contact adhesive to the membrane and substrate, rolling the membrane into place, and brooming once the adhesive is ready.

Mechanically Fastened. The substrate, ie, insulation, cover board, etc, which the single-ply membrane must go over, is typically mechanically fastened to the deck using a low density of fasteners. However, there are also applications where the membrane is applied directly to the deck. The typical method of installing a mechanically fastened roof membrane is to lay the membrane over the substrate and fasten it to the deck using fasteners spaced along only one of the machine edges of the sheet.

Steep Roofing Products

Asphalt roofing shingles and related products are classified under three broad groups: shingles, roll roofing, and underlayment. Shingles and roll roofing are outer roof coverings, ie, they are exposed to the weather and are designed to withstand the elements. Underlayments are inner roof coverings that provide the necessary protection beneath the exposed roofing materials. Asphalt shingles and roll roofing contain two basic components: (1) a base material made of an organic felt or fiber glass mat which serves as the matrix that supports the other components and gives the product the strength to withstand manufacturing, handling, installation, and service conditions; and (2) a specially formulated asphalt coating that provides the long-term weatherability and stability under service temperature extremes.

Shingles. Asphalt shingles are the most common roofing material used in the United States, amounting to more than 80% of all residential roofing products. They are manufactured as strip shingles, laminated (multithickness) shingles, interlocking shingles, and large individual shingles in a variety of weights and colors.

Strip shingles are typically rectangular and may have as many as five cut-outs along the long dimension. Cut-outs separate the shingle tabs, which are exposed to the weather, and give the roof the appearance of being comprised of a larger number of individual units. Strip shingles can also be manufactured without cut-outs to produce a much different appearance. The three-tab shingle is the most common type of strip shingle.

Most of the shingles are available with strips or spots of a factory-applied, self-sealing adhesive, which is a thermoplastic material activated by heat from the sun after the shingle is on the roof. Exposure to the sun's heat bonds each shingle securely to the one below for greater wind resistance. This self-sealing action varies, depending on the geographic location, roof slope, season of the year, and solar orientation.

Weather-resistant mineral granules applied to the top surface of strip shingles during the manufacturing process make possible a wide range of colors. Sand, talc, or mica is applied to the back surface.

The tabs of a strip shingle may be cut either straight or offset to obtain a straight or staggered buttline, respectively. They also may be embossed or built up from a number of laminates of base material to give a three-dimensional effect. Each of these shingle characteristics, ie, staggered buttlines, embossing, and laminate, can be combined in various ways to create textures on the finished roof surface that resemble tile, wood, or slate.

Interlocking shingles are also available and are designed to provide immediate resistance to strong winds. These shingles come in various shapes and have various types of locking designs that provide a mechanical interlock on the roof. Large individual shingles are generally rectangular or hexagonal in shape.

Roll Roofing. As the name implies, roll roofing is manufactured, packaged, and shipped in rolls. It comes in a wide range of weights and measures. Roll roofing products are produced by applying an asphalt coating to the reinforcing core, and finished with either a smooth or mineral granule surface. Some mineral-surface roll roofing are manufactured with a granule-free selvage edge that indicates the amount each succeeding course should overlap the preceding course. The manufacturer's recommendations with respect to the top, side, and end laps should be followed. The amount of overlap determines how much of the material is exposed to the weather and the extent of coverage to the roof surface; ie, whether most of the surface has a single or a double layer of roll roofing. In addition to its use as a roof covering, roll roofing is also important as a flashing material.

Saturated Felts and Underlayments. These products consist of a dry felt which may be impregnated or coated with an asphalt saturant. They are used primarily as underlayment for asphalt shingles, roll roofing, and other types of roofing materials. These types of felts are also useful as sheathing paper. Saturated felts are manufactured in a variety of weights for use as underlayment or heavy-duty underlayment.

Specialty Eaves Flashing Membranes. Specialty eaves flashing membranes are polymer-modified bituminous sheet materials that are used as underlayment to resist leakage of shingle roofs as a result of ice dams. These sheet materials contain an adhesive layer which is exposed by removing its protective sheet. Special eaves flashing membranes can also be useful in warmer climates where a similar backup of water can occur from an accumulation of pine needles and leaves.

Fire Resistance. Asphalt roofing shingles and rolls are tested by independent laboratories in accordance with established fire-resistance standards. The most widely accepted standard for fire resistance in building materials is ASTM E108, Standard Test Methods for Fire Tests of Roof Coverings. If the material meets the standard, the product may carry the testing laboratory's label indicating its class of fire resistance in accordance with the named standard. These classes are Class A, severe exposure to fire; Class B, moderate exposure to fire; and Class C, light exposure to fire. Most glass fiber-based asphalt roofing shingle products manufactured in the United States carry a Class A rating, although many organic felt shingles carry the Class C rating.

Wind Resistance. Asphalt shingles are certified to wind performance test standards on a continuous basis through independent third-party testing laboratories. Shingles that have passed the standard wind performance requirements, such as ASTM D3161, Standard Test Method for Wind Resistance for Asphalt Shingles, are identified by labels from the testing laboratory with whom they are in compliance.

Other Shingle Products. Making up about 20% of the steep market are wood shingles and shakes, concrete and clay tiles, natural and mineral fiber slates, and various styles of metal products.

A versatile product, tile is traced back to ancient Greece, China, and Japan. Tile has high fire resistance and is offered in a variety of textures and styles. Both clay and concrete tiles are relatively heavy and require a more robust structure than those used for asphalt shingles.

Used for hundreds of years, slate comes from different geographical areas and varies in color and weight. Slate (36) is easily split to size and shape; the most common is 4.76-cm (3/16-in.) thick and can weigh 31.71 kg/m^2 (650 lb/100 ft^2) or more. Imitation products of mineral fiber and cement stimulate its durability and style.

Early roofs in the United States were primarily hand-split hickory or cypress shakes. The natural beauty and style of these materials make them popular. Fire-retardant treatment and underlays may be needed to meet local fire codes. Wood shingles are sawn cedar having a uniform thickness. Wood shakes are usually hand-split and resawn.

Metal shingles and stamped panels that imitate wood or tile are available. These are light in weight and come in many colors and styles, from pre-engineered to custom-fabricated.

Roofing System Performance

Performance (effectiveness) of a roof covering is determined not only by environmental conditions, but also by the individual components that make up the roofing system. The design should be such that no component is underdesigned, compromising the overall performance. Each component should be durable to contribute to the overall roof performance. Roof coverings are subjected to external abuse, eg, foot or other traffic, in addition to weather exposure. The majority of roof leaks are attributed to the defects at penetrations or flashings, so care must be taken to design and install flashings properly.

Weathering. Bitumen hardens progressively owing to ultraviolet attack, oxidation reactions, and, to some extent, loss of plasticizing oils, especially with coal tars. Temperature changes cause expansion and contraction of the roof covering. Other weather factors include moisture, ice, and hail. Wind affects shingles as well as BUR membrane performance. Performance is correlated to properties and composition. Low asphaltene and high resin contents are desirable. As weathering progresses, the brittle-point temperature, taken by the Fraass procedure, increases. Blending of fractions or base stocks from different crudes improves performance more than antioxidants.

Thermal Effects. Temperature influences the oxidation rate, whereas temperature changes impart a mechanical stress to roof coverings. Daily temperature changes, sometimes quite abrupt, can result in a fatigue mechanism causing tensile failure. Repeated cycles of straining, especially at a high level, diminish the strength of roofing felts to the rupture point.

Water Effects. Water in its different forms, ie, liquid, vapor, hail, and ice, profoundly influences the performance of roof coverings. Moisture migrations through roof insulation, eg, vapor that accumulates and later liquefies or water that leaks through the roof covering, reduces insulating efficiency and leads to physical deterioration of the roofing material. Moisture can be detected by direct cut tests, electrical-resistance moisture meters, ir scanning techniques, or nuclear moisture meters.

In roof coverings, organic felts are highly susceptible to expansion and contraction movements with moisture change. Shingles, with a low degree of asphalt saturation, especially if the felt has not been uniformly saturated, show warping. This is described as fish mouthing or clawing. Erratic movements in built-up roofing can be produced by moisture–thermal effects and may cause ridging and failure of the membrane by cracking. Roof coverings should be able to withstand $1\frac{1}{2}$ in. diameter hailstones without damage. Icing is a function of the roof slope, roof covering composition, and amount of sun exposure.

Fire and Wind Hazards. Weather resistance of roof coverings is not necessarily correlated to fire and wind resistance. Underwriters' Laboratory and the Factory Mutual System test and rate fire and wind hazard resistance, and some durability tests. Organic felt or fiber glass mat base shingles are commonly manufactured to meet minimum UL requirements, which, in addition to minimum mass, require wind and fire resistance properties.

Fire Ratings. Above-deck fire hazards are rated by following ASTM E108 for propagation of the flame along the surface of the roof covering and on the penetration of the fire into the deck or structure. Surface-burning characteristics are measured by either the spread-of-flame test, for noncombustible decks, or the burning brand and intermittant fire tests for combustible decks. The test deck, with a roofing system applied (either a shingle, BUR, or single-membrane construction), is set at a specific incline or slope and exposed to a standard gas flame or burning brand.

Metal deck assemblies are tested by UL for under-deck fire hazard by using their steiner tunnel (ASTM E84). The assembly, exposed to an under-deck gas flame, must not allow rapid propagation of the fire down the length of the tunnel. FM uses a calorimeter fire-test chamber to evaluate the hazard of an under-deck fire. The deck is exposed to a gas flame and the rate of heat release is measured and correlated to the rate of flame propagation.

Wind Testing. UL employs two wind resistance tests, one for shingles and another for BUR assemblies. ASTM D3161 is a standard procedure for measuring the wind resistance of asphalt shingles. In ASTM D3161 and the UL shingle test, the conditioned test deck is placed at a specified slope and exposed to a wind velocity of 97 km/h (60 mph) for two hours or until either failure by tab or shingle lifting is known.

ROOT LOCUS. The root locus method is a graphical technique applied in control system and feedback studies in an effort to determine the transient response of the system. The objectives of the method are similar to those of the frequency response techniques. In this method, the locus of roots of the system characteristic equation is plotted. In obtaining the locus of roots, the variable parameter is normally system gain. It is, however, possible to vary other system parameters to see their effect on system performance.

A typical root locus diagram is shown in Fig. 1, for a second-order or quadratic equation of the form $s^2 + 2\zeta\omega_n s + \omega_n^2$, where the roots are s_1, $s_2 = -\zeta_n \pm \omega_n\sqrt{\zeta^2 - 1}$. The roots which are in the form of $s = -\sigma \pm j\omega$ may be real or complex, depending on system parameters. When the damping ratio ζ is > 1, the roots are real and unequal and the system is overdamped. When $\zeta = 1$, the roots are real and equal and the system has critical damping. For $\zeta < 1$, the roots are imaginary and the system is underdamped, giving an oscillatory response. The limits for this ideal system are of course when $\zeta = 0$. In this case, the roots are imaginary, and the system will have a continuous oscillation. Thus, if the roots of the equation are known, it is possible to predict the transient response. In an actual system, the damping ratio ζ and resonant frequency ω_n are functions of system gain and other system parameters.

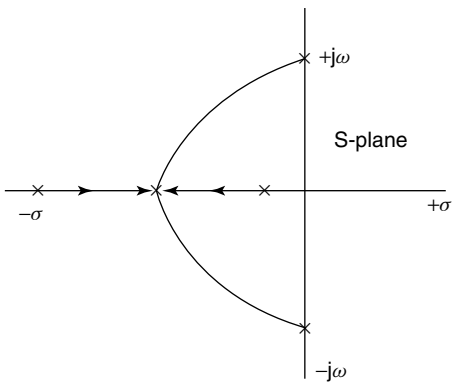

Fig. 1. Root locus plot.

See also **Characteristic Equation**.

ROOT (Mathematics). If a is a real number, n an integer, then x is the nth root if the product of x taken n times equals a. The number of n th roots is n but not all of them need be real. One of them is chosen as the principal nth root in accordance with the following rules: (a) if a is positive and n is even or odd, the one positive root; (b) a negative, n odd, the one negative root; (c) a negative, n even, any one of the complex roots. All of the roots, real or complex, may be found by the De Moivre theorem.

Tables of the positive real roots of numbers are usually given in mathematical handbooks. They may be calculated to any number of significant Figures with logarithms or desk calculating machines; approximately, by the binomial series; numerically, by several methods, usually that of Horner. For properties of the roots of an equation, see **Polynomial**.

See also **Cholesky Method of Solving Equations**; **Radical (Mathematics)**; and **Square and Square Root**.

ROOT-MEAN-SQUARE. The root-mean-square current or voltage is the effective value of the quantity in an alternating-current circuit. The defining equation for current is:

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,dt}$$

where I is the root-mean-square current, T is the interval of integration and i is the current equation as a function of time t. A similar equation defines the voltage.

In statistics, the root-mean-square of the variates $x_1, x_2, \ldots, x_n$ is the average defined as

$$\text{R.M.S.} = \sqrt{\frac{x_1^2 + x_2^2 + \cdots + x_N^2}{N}}$$

and in a frequency distribution, by $\sqrt{\Sigma x^2 f_x / \Sigma f_x}$.

ROOT (Plant). In seed plants, the root is generally the first part of the plant to emerge from the germinating seed. The functions of the root are primarily anchorage of the plant, absorption of water and mineral salts in solution, and conduction of these to the stem, and also storage of food. Anchorage is obtained by the much-branched, far-reaching root system, which penetrates deeply into the ground and resists such forces as wind acting on the top of the plant. Commonly, one thinks of the root as the part of a plant found in the ground. While this is true in the majority of cases, in some plants the roots are found in the air.

Upon breaking through the seed coats of the germinating seed, the young roots turn downward and soon put out an abundance of minute hairs. These serve the twofold purpose of attaching the root firmly in the soil and of absorbing moisture and nutrients from the soil. The root continues to grow into the soil, elongating and branching. See Fig. 1.

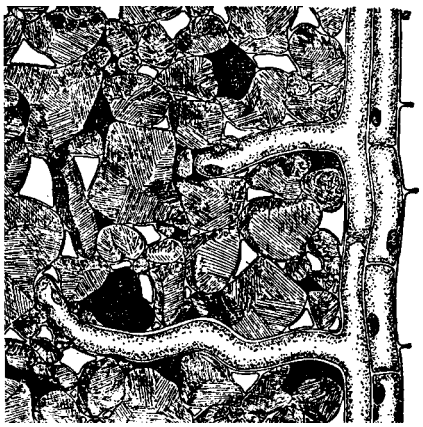

Fig. 1. Root hairs penetrating the soil. Note the tiny rock particles, the bits of humus, the films of water, and the air spaces.

Externally there are certain characteristics that distinguish a root from a stem, even when the latter grows underground. The root bears no leaves on its surface and is not separable into nodes and internodes, as is the case in the stem. The apex of the root is covered by a protective structure called the root-cap, a distinctive feature never found in stems. Just back of the tip, the surface of the root is usually provided with root hairs. Branching in roots is quite distinct from that in stems, the branch-roots, appearing at irregular intervals; frequently these branchroots are borne in longitudinal rows, a fact that is correlated with their origin. Branch-roots develop from the pericycle, a tissue deep in the root, and not from the sub-epidermal tissue as do stem branches.

Several types of root systems are recognized. See Fig. 2. In many plants, the first formed, or primary, root continues to grow downward to form a long root, which penetrates deep into the ground. Branchroots arising from this are commonly much shorter, and of smaller diameter. Such a root is called a tap root, and the entire root system in such cases is known as a tap-root system. Familiar examples are found in the dandelion, and in

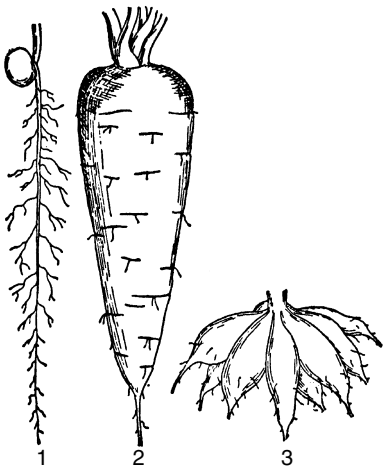

Fig. 2. Different kinds of roots: (1) fibrous tap root of pea; (2) fleshy tap root of carrot; (3) fleshy foscicled roots of dahlia.

oak trees. Monocotyledonous plants rarely show this form of branching. In them and in many other plants, the primary root soon loses its individuality, the secondary roots becoming larger, and forming an extensive root system, in which no single root is distinguished from the others by its larger size and more obvious downward growth. Such a system is called a fibrous root system, and the individual roots are known as fibrous roots. Wheat has such a root system. In many plants, the roots become important places of storage of foods, the roots often being conspicuously enlarged because of this storage. Such roots are called fleshy roots. Their existence is of great value to man, since many of them become important crop plants, as, for example, carrots, parsnips, turnips and beets. In many plants, several roots are swollen with food so that a group or fascicle of storage roots is formed, as in the *Dahlia*.

In many plants, especially in the tropics, the roots are formed in the air. Such aerial roots are often quite different from ordinary roots, being much coarser, less branched and lacking root hairs. In aerial roots the outer portion is frequently modified to a spongy tissue capable of absorbing moisture rapidly and retaining it tenaciously. See Fig. 3. This tissue, the velamen, is particularly well- developed in epiphytic orchids. Other plants have aerial roots which extend either downward from the branches, or from the lower part of the stem. Such roots are called, respectively, prop roots or brace roots. The terms are often used interchangeably. These roots soon penetrate the surface of the ground and become like ordinary roots. The Banyan tree shows the downward-growing prop roots particularly well, while in the Screw-Pine and in Corn plants, brace roots are well-developed. See Fig. 4. In many tropical plants, especially in those of large trees, the roots radiate out over the surface of the ground. Often these roots are conspicuously developed vertically, forming thin plates of considerable depth, but only a few inches thick; they are called buttress roots.

Fig. 3. A type of modified roots–aerial roots of poison ivy (*Rhus toxicodendron*.)

In parasitic plants the roots may be curiously modified or replaced by absorptive organs which penetrate the tissues of the host plant until they reach the conducting system, from which they obtain their nutrient

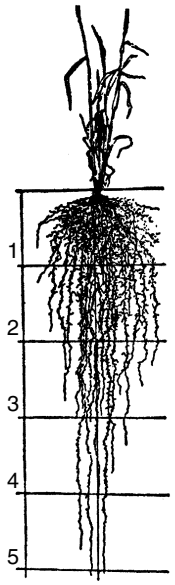

Fig. 4. Root system of wheat plant at blossoming time. Figures at left indicate depth in feet. (*Weaver.*)

supply. In some plants, roots are entirely lacking, their functions being taken over entirely by other parts of the plant. In the saprophytic Orchid, *Corallorrhiza*, for example, the much-branched coarse underground stem, or rhizome, functions as a root; in the Bladderworts, *Utricularia*, floating in water, roots are entirely unnecessary and nonexistent. In the Spanish Moss, *Tillandsia*, growing epiphytically in tropical and subtropical America, roots are entirely lacking, absorption occurring over the surface of the plant.

Commonly, the extent of a root system is very much underestimated. See Fig. 5. Only when the entire plant is removed from the soil by careful and extensive digging is the great spread of the entire root system seen. Then it is found that the roots may penetrate the soil to a depth much greater than was supposed. In common Red Clover, for example, the roots may go downward to a depth of 8 or 9 feet, while in alfalfa depths of 15–20 feet or more are found. The lateral spread of roots is also often very great. In the common Squash the lateral roots may extend outward 10–15 feet, while other roots of the same plane penetrate the soil to depths of 4–6 feet, forming a very extensive system. The nature of the soil, and especially the amount of oxygen present in it, are important factors in determining the amount of branching and the extent of the root system. In general, porous well-aerated soil favors extensive branching.

Roots do not seek water, as popularly supposed from the fact that they seem to grow toward water. This tendency is explained by the fact that roots respond very definitely to certain external factors, such as gravity. Most roots react positively to gravity, that is, are positively geotropic, growing directly downward into the soil. If a young plant is placed so that its root is horizontal, in a short time it will be found that this root has changed its direction of growth and is growing downward

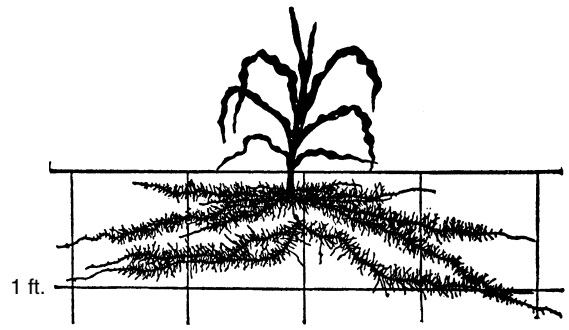

Fig. 5. Root system of Iowa Silver Mine corn 36 days old. (*Weaver.*)

again. Many roots are also affected by light, from which they turn away, being negatively phototropic. Temperature also affects roots, so that a root encountering a region having a temperature more favorable for its growth will increase more rapidly than other roots. Entirely like this is the response of roots to favorable moisture conditions, which lead to greater growth of the roots extending in that direction. It is such phenomena that lead to the statement that roots seek water. Often they do seem to seek water, especially when they penetrate joints in sewer pipes, sometimes at distances of 30–60 feet or more from the stem of the plant, and form great masses of much branched roots, which may completely clog the sewer pipe, and become a source of great inconvenience and expense. Other factors such as the nature of the soil and its contained minerals, also influence the growth of roots.

The internal structure of the root is quite constant and distinct from that of the stem. In the tip of the root an apical meristem, or zone of dividing cells is found. The cells of this region are more or less cubical in shape, thin-walled, and contain a dense protoplasm and a relatively very large nucleus.

Over the apical end of the root, and covering the actively dividing cells is the root cap. This is a mass of loosely aggregated cells arising in various ways. In some plants the cells of the root cap are formed from the meristem cells in general. In dicotyledonous plants there is frequently a special layer of cells, called the calyptrogen, covering the apical surface of the root. These cells divide and form cells that become the root cap. However formed, the root cap is continuously renewed throughout the life of the root, forming a protective cover over the tip. The outer and consequently older cells of this cap are loosely arranged. Their walls become considerably modified to form a mucilaginous mass, which greatly reduces the friction of the elongating root against the soil particles. This mucilaginous mass is often very conspicuous in the brace roots of corn.

Just back from the apical meristem of the root is the zone of elongation. In this region the cells show very characteristic changes. The most obvious of these is the increase in length that occurs in most of the cells. At the same time there appears in each cell a conspicuous central vacuole which enlarges greatly, the cytoplasm being pushed out to a thin peripheral layer in which is found the nucleus. In roots this elongation region is much larger than is the corresponding region in the stem, a fact presumably correlated with the denser medium through which it grows. Usually it is less than a centimeter long.

As the root continues elongating the cells gradually change to form a third zone not sharply set off from the second. In this, the zone of maturation, the cells gradually assume their final form. Externally the most conspicuous feature of this zone is the presence of the root hairs. A root hair is a slender outgrowth of a cell of the epidermis, or outermost single layer of cells. In size they vary from 0.1 to 10 millimeters long, with a diameter averaging about 0.01 millimeter; the number of them formed on the root surface varies from 200 to 400 or more, so that they cause a tremendous increase in the surface of the root. The life of a root hair is not long, being commonly only a few days, after which it disappears. Usually the wall of a root hair is very thin and modified externally to a pectic substance, which sticks closely to the soil particles and absorbs water readily therefrom. Within the wall is a thin peripheral layer of actively streaming cytoplasm. The central part of the hair is occupied by an evident vacuole, which is continuous with that in the basal portion of the cell from which the hair protrudes.

As the root grows older and the cells composing it mature, a very definite structural pattern appears. See Fig. 6. The outer portion, or cortex, is composed almost entirely of parenchyma cells, which are of irregular shape, loosely aggregated, and serve mainly for storage of materials.

The innermost layer of cortical cells is very distinct, forming the endodermis. In this layer, the walls of certain cells become thickened and lignified; other cells, called passage cells, retain their thin walls and permit free flow of water to the xylem. In Monocots the walls are all thickened.

Within the endodermis is the stele (see Fig. 7), or central cylinder. The first cells to differentiate in this region are the water-conducting xylem elements, which arise in discrete groups. The number of these groups is usually constant for any given species of plant, cross-sections through the root at this stage showing a number of isolated groups of cells surrounded by unmodified cells. Between these groups of cells and somewhat farther

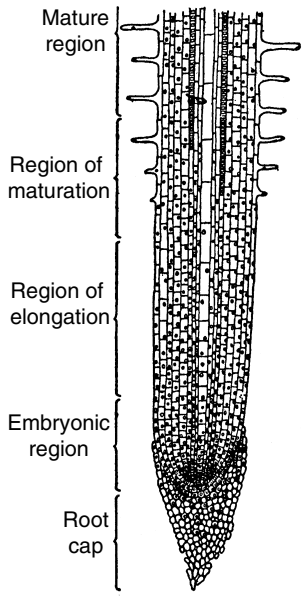

Fig. 6. Longitudinal section of onion root showing the regions of development.

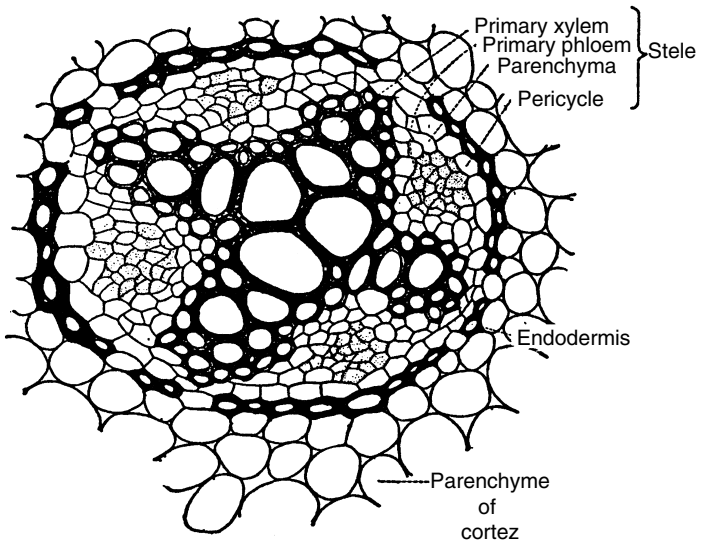

Fig. 7. A cross section of the stele of a young root of the buttercup (*Ranunculus acris*.)

from the center of the root other groups of cells become evident as the root grows older. These are the phloem cells. While the walls of xylem cells soon become thickened by the formation of ligno-cellulose against the primary wall, those of the phloem cells remain constantly thin. With continued growth of the root, the cells of the central portion gradually become changed into additional xylem cells, so that finally, in most roots, no unmodified cells remain in the center; that is, characteristically the root does not contain pith cells. Remaining outside the phloem and xylem cells are many only slightly changed cells, which form the pericycle. This is the region from which branch roots originate, and also the region which by the division of its cells forms the cork cambium which produces the cork in the outer bark of tree roots after the first few months of growth. The root therefore contains the following tissues, derived entirely from the modification of the cells originally resulting from the divisions of the apical meristem. (1) A central cylinder of alternate masses of xylem and phloem cells, surrounded by a sheath of slightly modified cells called the pericycle, these composing the central cylinder. (2) Outside this is the endodermis, with its cells showing characteristic thickenings of the walls. (3) Around the endodermis is the cortex, surrounded by (4) the outermost layer, the epidermis. All these tissues are collectively known as primary tissues.

With further growth of the root, secondary tissues appear. These are formed from a special group of cells known as cambium cells. Cambium cells first appear in the region inside the phloem patches, appearing in cross-sections of the root as crescent-like patches which gradually extend radially until they unite to form a continuous sheath around the xylem. By their divisions new cells are formed, both inside and outside the cambium band. Those inside gradually develop into secondary xylem cells, while those outside become secondary phloem cells. Continued development of the cambium band causes the primarily phloem cells and all other cells formed externally to be pushed outward and gradually crushed. Since growth often occurs periodically in the root, especially in regions having alternations of favorable and unfavorable seasons, annual rings are found in roots as in stems. As root enlargement occurs, the pericycle cells become meristematic and by their divisions form a mass of periderm cells around the central cylinder.

The functions of the root are primarily anchorage of the plant, absorption of water and mineral salts in solution, and conduction of these to the stem, and also storage of food. Anchorage is obtained by the much-branched far-reaching root system, which penetrates deeply into the ground and resists such forces as wind acting on the top of the plant.

The water of the soil, together with substances in solution, is taken into the plant largely through the portion of the root covered by root hairs. The outer wall of the latter soaks up water readily. The wall of the cell is permeable, permitting water to pass through easily. The outer surface of the cytoplasm of the cell is also a membrane, which is semipermeable, that is, readily permits certain substances such as mineral salts in solution to pass through, but does not allow organic substances to pass. A similar condition exists in the membrane of the cytoplasm that separates it from the cell sap in the vacuole. This cell sap has a high concentration of organic solutes dissolved in it, so that it has an osmotic pressure of 4 to 10 atmospheres, which is much greater than that of the soil solution. Since these two solutions are separated by a semipermeable membrane, it is but natural that water molecules should pass more freely into the cell than out, causing water to move from the soil into the plant. Once in the root hair, the water increases the turgor of the latter. This water then passes into the cortical cells and through them to the xylem. There it enters the vessels and moves up through the root into the stem. See also **Ascent of Sap**.

ROPE. A structure comprised usually of from three to six strands of fibrous material, twisted in such fashion that the twist of the rope offsets the twist in the strands, thus making it possible for the strands to hold together. Until about 1850, nearly all fiber rope was hemp (*Cannabis sativa*), a soft fiber cultivated since ancient times. Currently, well over 90% of the cordage used is made up of hard fibers, notably abaca and agave. Some of the physical characteristics of both hard and soft fibers are given under **Bast Fibers**.

Twine is small rope, usually composed of two or more threads. Yarn is also termed *thread*. A strand is defined as two or more yarns or threads twisted together, with the twist in a direction opposite to that of the threads. In commercial twine, the twist is usually right-handed. Cord is defined as small commercial twine, comprised of two or more threads. The standard packaging of rope is 1,200 feet (equals 200 fathoms) and is termed a coil. Rope is also packaged in half-coils.

Several synthetic fibers are used as well for the manufacture of rope, but usually have a cost disadvantage as compared with the natural fibers. Among the commonly used synthetics are nylon and Dacron, Glass, Saran, and polyethylene synthetics also have been used in rope manufacture.

Natural fibers, such as manila and sisal, will lose strength when exposed to dry air over long periods, but this strength can be regained through reconditioning, provided the exposure temperature was not excessive. Exposure to air in excess of 250 °F (121 °C) can cause a strength reduction of from 10 to 20%. Above 300 °F (149 °C), manila and sisal fibers begin to char. Nylon can withstand higher temperatures, but in addition to cost, has the disadvantageous characteristic of stretching appreciably when loaded. Glass fibers are incombustible, withstanding high temperatures, but do lose strength beyond a temperature of 400 °F (204 °C). They are considered serviceable, however, up to about 1,000 °F (538 °C). Objections are poor flexing and abrasion properties, particularly when wet. Saran fibers are serviceable up to about 170 °F (77 °C), rapidly losing strength

at higher temperatures. The melting point is 340 °F (171 °C). High-tenacity polyethylene is essentially unaffected by temperature changes below 220 °F (104 °C) and the monofilaments, if containing no plasticizer, will remain flexible down to about −100 °F (−73.3 °C). A disadvantage of polyethylene is its slippery characteristic, making it difficult to use with capstans or winches.

ROPE CLOUD. See **Clouds and Cloud Formation**.

ROSACEAE. See **Rose Family**.

ROSAT (Roentgen Satellite). The X-ray observatory ROSAT was operated in a near-earth orbit from 1 June 1990 through February 1999. ROSAT stands for Roentgen satellite, in honor of Wilhelm Conrad Roentgen, who discovered the X-rays in Würzburg in 1895 and won the first Nobel Prize in Physics in 1901. The general aim of the project was to explore the whole X-ray sky with unprecedented sensitivity, angular resolution and coverage. See Fig. 1.

Fig. 1. The ROSAT Satellite. (*Max Planck Institute, MPE.*) http://heasarc.gsfc.nasa.gov/docs/rosat/gallery/rosat_sat.html.

The ROSAT project began in 1975 with a successful proposal of the Max Planck Institute for Extraterrestrial Physics (MPE) in response of an announcement of opportunity for large projects of the German Ministry for Research and Technology. The basic technology, high resolution Wolter optics and imaging proportional counter (PSPC) was developed at MPE in the 1970s and tested by means of high altitude rocket flights. In the early 1980s the project was internationalized: NASA agreed to provide the launch with the Space Shuttle and a focal plane instrument. The UK contributed a small EUV telescope and financial support. After the Challenger catastrophe in 1986, NASA offered a launch with a Delta rocket, which took place on 1 June 1990. Table 1 summarizes the division of tasks between Germany and its partners.

The X-ray telescope on ROSAT had three image detectors, which were sitting on a carousel. Two of them were position-sensitive proportional counters (PSPC), providing colored (energy resolved) images with

20 arc sec resolution over a 2 degrees field of view. The third detector was a multichannel plate detector (high resolution imager, HRI), delivering black and white images of high angular resolution (5 arc sec) over a field of view of about 0.5^0. See Fig. 2.

ROSAT saw first light two weeks after launch on 17 June 1990. After six weeks of calibrations and instrument verifications, ROSAT performed half-a-year all-sky survey, the first ever done with an imaging X-ray telescope, leading to the discovery of 80,000 X-ray sources. Thereafter, the satellite was used in a pointed mode for more than seven years. This program was completely open for guest observers. In total, 9,000 fields in the sky have been studied, with an average observation time of three hours. The longest pointing, the ROSAT Deep Survey, lasted two weeks. In total, a few thousand scientists from 26 countries have used ROSAT data, and more than 4,500 scientific publications have been written by them until September 2000. The ROSAT archives will be a precious astrophysical database for many years to come.

The first X-ray picture of the **moon** ever taken was obtained by ROSAT in 1990. It shows the sunlit side glowing in X-rays from the solar corona that are reflected at the lunar surface. The lunar disk casts a shadow on the "X-ray sky background." ROSAT discovered **comets** as a new class of X-ray sources. Comets are cold objects ("dirty snowballs"), and therefore, it was a great surprise when Comet Hyakutake turned out to be a bright X-ray source. The total number of comets detected with ROSAT is a dozen. The data suggest that the X-rays are due to the transitions of excited carbon, nitrogen and oxygen atoms which are produced by charge exchange reactions between solar wind ions (e.g., C^{5+}, C^{6+}, O^{6+}, O^{7+}) and water molecules in the cometary coma.

ROSAT has given many new results in stellar astronomy, both on the coronal emission of cool **stars** and on the emission from shock heated gas in the strong stellar winds of hot and massive stars. A surprising results of the ROSAT All Sky Survey was the detection of many young stars (T Tauri Stars) far outside the known star-forming regions. They either have been ejected from their birthplace with high velocities or have been born in cloudlets which are not visible any more. ROSAT also discovered X-ray emission from **Brown Dwarves**. The ROSAT survey revealed many fewer **White Dwarves** than predicted. The reason is a pollution of the White Dwarf atmospheres by heavy elements that absorb soft X-rays very effectively.

In the beginning of the ROSAT mission a number of objects were discovered emitting extremely soft X-ray rays. They are very bright and show temperatures of a few hundred thousand Kelvin. It turned out that these sources are species that had been predicted to exist, but which had

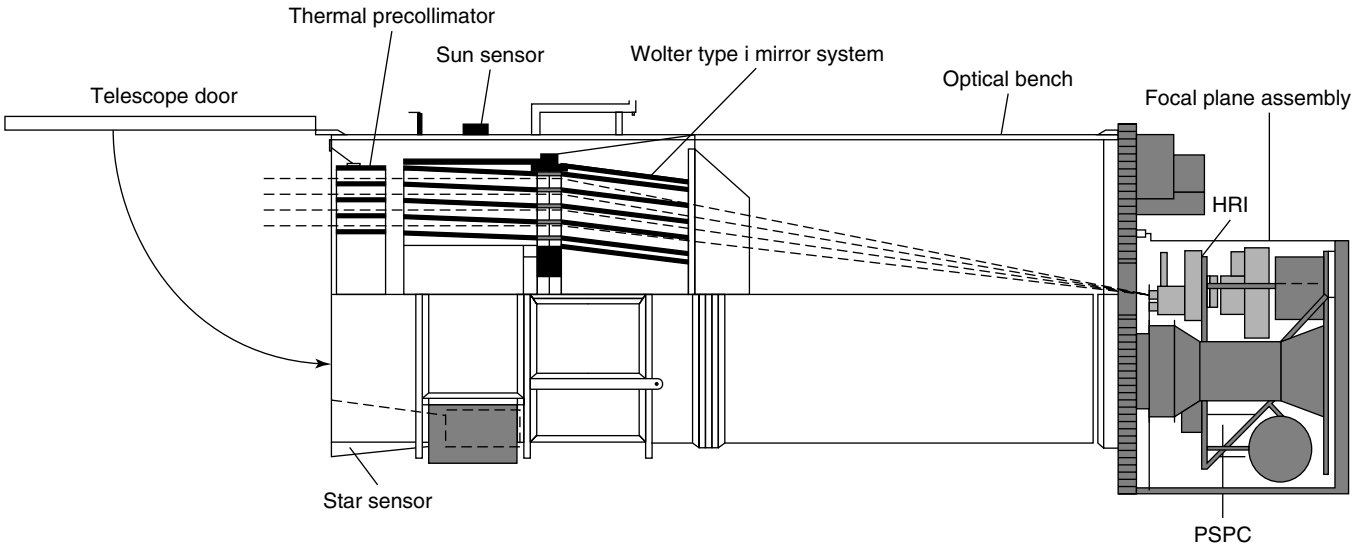

Fig. 2. Diagram of the ROSAT X-ray Telescope (the Wide Field Camera is not shown). X-rays would enter from the left and were focussed by the Wolter Type 1 mirror. The ROSAT mirror consisted of four nested parabola/hyperbola pairs. The double reflection is required for focusing in grazing-incidence optics of this type. The incident X-rays were focussed on the instruments carried by the focal plane assembly. (*Max Planck Institute, MPE.*) http://heasarc.gsfc.nasa.gov/docs/rosat/gallery/rosat_diagram.html.

not been found before ROSAT. They are White Dwarves in binary systems, accreting matter from their companion at a rate just sufficient to sustain steady nuclear burning on the surface of the White Dwarf. This provides the unique opportunity to directly observe a thermonuclear reactor, which is usually deeply buried in the interior of a star.

The famous **Supernova 1987A** was the ROSAT First Light Target on June 16, 1990, but it was too faint at that time. It was first discovered in soft X-rays with ROSAT in 1992 and is steadily becoming brighter since*. In total, some 200 **supernova remnants** (SNR) have been found with ROSAT. In the Vela, SNR protrusions were found at the periphery of the shell type source; they are thought to be produced by fragments of the exploding star. ASCA observations revealed that they have different chemical compositions. A new SNR was found in the Vela complex which must be very young (~680 years), since it shows gamma ray emission from radioactive ^{44}Titanium (lifetime 90 years) detected subsequently by the Compton Gamma ray observatory. See also **Compton Gamma-Ray Observatory (CGRO)**.

With ROSAT 34 **radio pulsars** were detected in X-rays showing an X-ray luminosity proportional to the rotational energy loss, suggesting that their X-ray emission is produced by high energy electrons accelerated in the pulsar magnetosphere. Four of these radio pulsars, including the Vela pulsar, exhibit an additional thermal spectrum corresponding to a temperature of ~1 MioK, which is interpreted as the thermal radiation from the photosphere of the **neutron star**. A few point sources discovered near the centers of young Supernova remnants also show very soft X-ray emissions, which must be attributed to photospheric emissions. The importance of these observations lies in the fact that the surfaces of these tiny stars (radius 10 km) have now become visible! Future X-ray spectroscopy should allow to measure their enormous gravity as well as their radii which contains important information on the physical properties of matter at supranuclear densities.

The ROSAT survey of the **Andromeda Nebula** yielded 500 X-ray sources. As in the Milky Way, the brightest of them are young supernova remnants or binary systems with neutron stars or black holes accreting matter from their companion. These bright source populations have been studied with ROSAT in many **galaxies**. In addition, the hot interstellar medium, which is heated by supernova explosions, has been investigated.

A small fraction of all galaxies have an **active galactic nucleus** (AGN) emitting huge amounts of energy in all spectral bands. Quasars represent the most powerful AGN. The irradiation is variable, indicating that it is emitted from a small region, generally not more than a few light weeks or months across. AGN often show jets, originating in their core. It is generally believed that the central engine is a supermassive black hole, swallowing matter at a high rate. The famous quasar 3 C 273* contains a black hole of $\sim 10^9$ M_o accreting one earth mass per second.

Because of their large luminosity AGN can be detected at large distances or redshifts. In the ROSAT deep survey about 1000 (!) sources per square degree in the sky were detected, mostly quasars and other classes of AGN. These observations showed that the X-ray sky background is at least to 80% produced by these faint sources, thus solving one of the oldest puzzles in X-ray astronomy.

ROSAT observations have shown that the hot plasma ($\sim 10^8$ K), a typical **cluster of galaxies**, has a mass which is a few times larger than the total mass of all visible galaxies. The X-ray data also allow to determine the total gravitational mass of the cluster which turns out to be a few times larger than visible in X-rays and in optical light. The physical nature of the missing "dark matter" is still unknown. Many clusters show double structures, indicating the merging of two clusters or complicated inner structures. This must be due to earlier merging or interactive processes. Thus, one "sees" how these large structures evolve in the universe. However, the evolution of the cluster population with redshift is smaller than expected in a high density universe. Actually, the matter density inferred from cluster evolution is only about 30% of the "critical density" which is necessary to close the universe.

ROSE CHAFER *(Insecta, Coleptera)*. Of the family *Scarabacidae*, this insect is particularly damaging to grape. The gray or fawn-colored, slender beetles, with long legs, consume both leaves and blossoms of grape. They are quite damaging to newly set grapes. The beetles are found in largest numbers during the first few weeks after bloom. The insect is also damaging to cherry (it eats the ripe fruit) and rose (it eats the leaves). Poultry also can be poisoned by eating rose chafers. Other plants attacked include apple, cabbage, clover, corn, garden beans, and peppers, as well as bush berries, such as blackberry, raspberry, and strawberry. Cultivation is the best protection. This should be practiced in May and June at the time when the insect is in the pupal stage. Relatively few rose chafers are found in areas where crops that require cultivation, such as corn and potato, are raised. See Fig. 1.

Fig. 1. Rose chafer. (*USDA*.)

ROSE CURVE. A higher plane curve of trochoidal type (see **Cyclic Curve**). Its equation in polar coordinates can be found from the general equation of the cyclic curve if one sets $a = (R - r)$, $n\theta = R\phi/2r$, and $k = 2a$. The result is $r = k \sin n\theta$. If n is an odd integer, there are n leaves, and if n is even, $2n$ leaves. Substitution of $\cos n\theta$ for $\sin n\theta$ rotates the curves by 45°, so that one leaf lies on the positive OX-axis. The origin in each case is a multiple point, since nodes occur and there are n tangents. These curves are also sometimes called *trifolium, quadrifolium*, etc. See Fig. 1. (See also **Folium of Descartes**; and **Lemniscate of Bernoulli**, which are similar in appearance to the rose curves.)

See **Curve (Higher Plane)**.

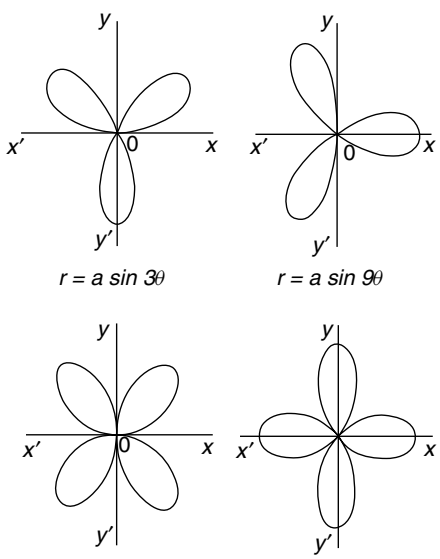

Fig. 1. Rose curves.

ROSE FAMILY. Included in this family (*Rosaceae*) are some 2,000 species of plants, a few of which are of tremendous value to man. Most of them are perennial plants, either trees or shrubs or herbs. Nearly all have alternate leaves, either simple or compound, with stipules present. The flowers are of many forms, and grow in racemes or cymes. Frequently the receptacle is more or less hollowed and often forms a part of the mature fruit. The flowers are commonly perfect and have their parts in multiples of five. The fruit may be either dry or fleshy, and in many species is an aggregate of many individual fruits. The flowers are usually conspicuous and insect pollinated. The most important economic members are found in three of the five or more suborders. One of these, the *Pomoideae*, has the carpels often united together and fused with the inner wall of the receptacle, which becomes fleshy; such a fruit is called a pome. In this subfamily are found the apple, pear, and quince.

Rosoideae, a second subfamily of *Rosaceae*, is large, containing many genera and species. Here the fruit is one-seeded and indehiscent, with usually many carpels borne on an enlarged central stalk or carpophore. In some genera, the floral axis encloses the carpels in the mature fruit. Shrubs or herbs with simple or compound leaves and various inflorescences comprise the group. Several are important plants extensively cultivated.

Drupoideae, the third major subfamily of *Rosaceae*, contains genera of considerable commercial importance. Members of this subfamily are trees or shrubs with simple leaves, and the fruit, a drupe, is usually one-seeded, the ovary wall or pericarp being differentiated into a fleshy outer portion, the exocarp and mesocarp, and an inner endocarp which is very hard or stony. In these plants, the bark contains a gum that frequently exudes in masses. The leaves, bark, and seeds are bitter due to the presence of a glucoside amygdalin, which, in the presence of an enzyme emulsin, produces prussic acid. The important economic members are the peach, the apricot, and related species, the plums and prunes, and the cherries. The almond is also a member of this subfamily.

Apple Tree (*Pyrus Malus*)

A medium-size tree, usually less than 40 feet (12 meters) in height. The wood of the tree is red, hard, and dense and sometimes is used for making tool handles. The flowers are borne on short lateral branches known as spurs, and are pink and pleasantly fragrant. They are self-sterile and insect-pollinated, particularly by the honeybee. The fruit is a pome, the fleshy part of which is regarded as modified stem tissue, the receptacle.

When unripe, the fruit contains much malic acid and starch. On ripening, the amount of malic acid decreases, while much of the starch changes to sugar. At the same time, characteristic aromas and flavors develop. When ripe a change occurs in the middle lamella of the cell wall, the substance dissolving away in part so that the cells become more or less separate. On further ripening, the flesh in certain varieties becomes mealy and loses most of its taste. Each of the five carpels that form the parchmentlike core of the apple contains two seeds.

The taxonomy of the commercial apple is obscured by centuries of selection and breeding experimentation and thus it is difficult to assign the numerous varieties to certain species. Just one example of the variation among the numerous types is shape, ranging from oblate to spherical and from conical to ovoid. See Fig. 1.

Champion specimens of apple trees in the United States are described, along with other trees of the rose family, in Table 1.

Propagation of the apple tree may be accomplished by seed planting, but with doubtful success since the new plant will usually bear small undesirable fruits. To perpetuate desirable strains, therefore, grafting or budding is usually practiced. Many people top-graft old apple trees; frequently a single tree may have a dozen or more varieties grafted thereon.

Temperature is a major factor limiting areas of apple production. The trees require a sufficient period of cold to induce dormancy. Without the cold period apples do not flower and fruit properly. Thus, although the trees will grow in semitropical-to-tropical climates, they will not set fruit satisfactorily and generally will not be vigorous. Conditions damaging to apples include long, hot summers and spring frost injury. The trees do not tolerate high humidity and excessive moisture very well. A temperature of less than 45 °F (7.2 °C) for at least 900 to 1000 hours (39 to 42 days) is needed to break dormancy. When the trees are not exposed to sufficient cold for the proper length of time, the leaf buds will not open in the spring. The flower buds require less cold than the leaf buds. When leaves do not appear shortly after blossoming, the fruit set will be small or none at all. Temperature requirements vary considerably with the particular variety of fruit.

Although apples can be produced in many temperate regions, there are usually some shortcomings in any region. On the average, Washington State has a near-ideal climate for many apple varieties, but periodically the crop will be severely damaged by spring freeze conditions. In Michigan and New York, problems include cold injury in winter and spring, plus high humidity and moisture during summer.

Fig. 1. The apple is a fruit of many variations. There are over 20 leading varieties (see Table 2), with a range of colors and shapes. One botanist estimates that over a thousand varieties of apple have been known, the majority of which have not been candidates for commercialization. (*USDA*.)

The ranking of leading varieties of apples produced in the United States is shown in Table 2. Apples are usually grouped into summer and late-fall varieties.

Apples are used in several ways. Many are eaten raw; others used as sauce or made into pies and tarts. The high pectin content causes them to be much used in the making of jelly. Large quantities of apples, particularly cull fruit, are ground up and the juice pressed out to produce cider. Fermentation causes cider to acquire a considerable percentage of alcohol, it then being known as hard cider. By the action of acetic acid bacteria, cider may be changed to vinegar. From the crushed pulp, called pomace, remaining after the juice is expressed, commercial pectin is obtained.

Controlled-Atmosphere Storage. The use of controlled-atmosphere storage (CA) for apples has been increasing steadily since the early 1970s, when less than one-third of fresh-stored apples were stored by this method, compared with well over half of the fresh-stored apples as of the early 1980s. Apples in CA storage ripen, respire, and soften much more slowly than those in regular cold storage. Experience has shown that the storage life of the McIntosh variety can be doubled by CA. CA storage, a process first developed in England (Kidd and West) and further engineered at Cornell University (Smock), dates back to the early 1940s. Storage costs of the CA method are about twice those of traditional cold storage, a factor that has slowed its use to some extent, but increasing use reflects the outstanding advantages gained from it. Basically, in CA, the oxygen and carbon dioxide content of the atmosphere are adjusted in accordance with the requirements of the fruit. Oxygen level is usually reduced from the 20.9% content of oxygen in normal air to 2–3%, whereas the normal 0.03% carbon dioxide of air is increased in the process to a range of 1–8%, the exact values of oxygen and carbon dioxide depending upon variety of fruit stored and the storage temperature used. Generally, the temperature is held above 29 °F (−1.7 °C) and below 32 °F (0 °C). The relative humidity is usually maintained somewhat in excess of 90%. Packing of the fruit in closed spaces is done carefully to ensure good air circulation throughout the fruit. Initially, the fruit is quickly chilled. Varieties that respond well to CA include Delicious, McIntosh, Rome Beauty, Jonathan, Stayman, and Newton Pippin, with somewhat poorer results with Golden Delicious.

Productivity. Apple production has undergone a number of changes during the present century and particularly since World War II. The number of orchards has been markedly reduced, the remaining orchards and new orchards have been much larger, and, during the first half of the century, yields of apples per unit area of ground required have increased three- to four-fold. Over the last several years, the trend has been to high-density plantings. Trees are much smaller than the apple tree that for many years was considered standard. The trend has been to semidwarf and dwarf trees. The smaller trees have a number of advantages, including their better utilization of sunshine and consequent production of higher-quality fruit. Smaller trees usually produce earlier than the standard trees. Even though the dwarf tree produces less fruit per tree, the number of trees per area can be substantially increased, so that yields per acre (hectare) are increased. The smaller trees, however, require greater care than the standard sizes if maximum production is to be achieved. A dwarf tree is expected to develop not taller than about 6 to 8 feet (1.8 to 2.4 meters); a semidwarf tree will be from 10 to 12 feet (3 to 3.6 meters) tall; a standard tree will average some 20 feet (6 meters) in height. The ultimate size of the tree is determined by the rootstock and by the soil richness, as well as the cultural practices (pruning, etc.) used by the orchardist.

Cultural Practices. Seeds of the tree rarely improve upon the parent and thus seedlings are chiefly used to produce stocks for grafting or budding. Standard trees are produced by planting seeds, by growing the seedling for 2 years, and by grafting the desired variety on them. Dwarfing rootstocks must be propagated vegetatively by rooting the shoots of specific rootstocks in stoolbeds. Dwarfing rootstocks have been studied extensively in Europe since about 1912, such studies commencing considerably earlier than in the United States. Quite early in this century, the East Malling Research station in Kent, England cataloged a series of rootstocks, ranging from very dwarf to near standard-size trees. Most of the common dwarfing rootstocks so developed carry the designation M (standing for Malling) and a number.

The rootstock with the greatest dwarfing effect in common use is the M9. Trees on this rootstock rarely grow larger than 8 feet (2.4 meters) in height. The M9, however, has a poor root system that requires good soil and frequent irrigation, and the trees on this rootstock must be staked or grown beside a trellis. Free-standing trees grown on M9 rootstock without support are frequently toppled over by heavy weight of fruit and by high winds. The next most dwarfing rootstock is M26. Trees on this rootstock are somewhat larger and the root system is stronger, but these trees also require staking. The M7 and M106 rootstocks produce semi-dwarf trees. These trees generally do not require staking, but the M7 rootstock still may be pushed over by heavy winds. M2 and M111 rootstocks produce more vigorous semi-dwarf trees and their root systems are less sensitive to diseases. Trees on M106, M2, and M111 rootstocks are relatively large and require a more laborious training method during early years.

Trees may be dwarfed by the *interstem method*. They usually require grafting twice. First, a piece of dwarfing rootstock is grafted onto a large root system of a semi-dwarf rootstock. The variety is then grafted on the top of the stem-piece, which becomes a so-called interstem. The length of the interstem determines the degree of dwarfing. Such trees are produced to

Note: Other varieties include Baldwin, Ben Davis, Empire, Grimes, Idared, Lodi, Macoun, Milton, and Wealthy.

take advantage of the larger root and the dwarfing effect of the interstem. It requires 1 year longer to produce double-grafted trees. See Fig. 2.

Ultra-dwarf trees, sometimes referred to as meadow orchards, are being pioneered in England and Israel.

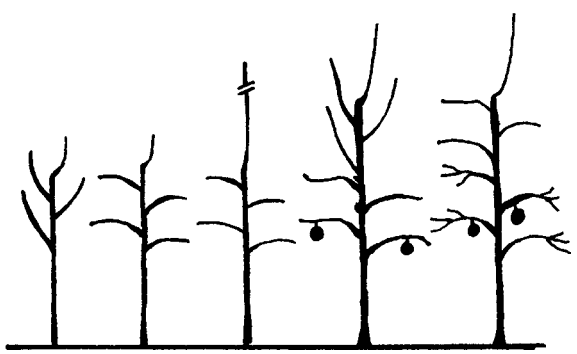

Fig. 2. Development of a dwarf apple tree. (*After Faust.*)

Almond Tree (*Prunus amygdalus*)

The almond is related to peach and stone fruits and is a medium-size tree with pale pink or white flowers, probably native to western Asia and northern Africa. The fruit, a drupe, has the seed or kernel enclosed within a reticulated endocarp. There are two kinds of almond, bitter and sweet. Bitter almonds, used for flavoring, contain some hydrocyanic acid (HCN). The sweet almond is used as a dessert and for confections and yields almond oil.

There are numerous references to the almond in the Old Testament, suggesting that the crop has long been familiar in the countries of the

Near East. Almost invariably, these references concern the esteem with which almonds were held, and their value as gifts. Gradually, plantings of the crop moved westward to the Mediterranean region and, for many years, Italy and Spain, were the two major and rival producers of almonds. There are reports of almonds being brought from Europe to the United States as early as 1840 for planting along the eastern coast. Climate and soil conditions were not favorable to the almond and, consequently, production in the United States had to await experimental plantings in California. In the 1870s, research and cross-breeding developed basic stock that resulted in the Nonpareil, NePlus, and other varieties which currently are popular in the West Coast almond industry.

Nutritional Aspects. The dry almond has a water content of 4.7% and a relatively high food energy content of 598 calories per 100 grams. Protein content is 18.6%; fat, 54.2%; and carbohydrate, 19.5%. Like most nuts, the almond is high in glutamic acid.

Almond flowers are self-incompatible and thus two or more compatible varieties must be selected for a planting to ensure pollination. In California, the Nonpareil variety, a consistent and heavy producer, accounts for about 55% of all plantings. Frequently, NePlus variety will be planted in rows with Nonpareil, for a total of 50 to 90 trees per acre (124 to 222 trees per hectare). The NePlus plantings will average about 7.5% of the total. To ensure a good crop, the grower usually will have honeybees brought in by a commercial beekeeper during the bloom period. Under favorable conditions, a well-managed orchard will yield approximately 1 ton (2000 pounds) of nut meats per acre (2240 kilograms per hectare). In recent years, a number of varieties have been introduced. Davey, Karpareil, Merced, and Thompson, for example, are also good pollinators for Nonpareil, and some authorities consider that these also produce a superior kernel.

Almonds are the first crop to bloom in spring. In California, this occurs in late February. From that point, the orchards must be virtually frost-free, rains should be at a minimum, and the days sufficiently warm (55–60 °F; 12.8–15.6 °C) to ensure full pollination by the bees. By mid-March, the trees are leafed out and small, fuzzy, gray-green nuts will be observed. As the weather warms, the crop matures rapidly. In early July, the hulls begin to split open, slightly exposing the shell within. The kernels then start to dry, the split widens, and the nuts are soon ready for harvest.

Almond Flavorings. Some food processors find it more convenient to use almond flavoring rather than almonds per se in various products. Bitter almond oil is a principal source of almond flavorings.

Bitter almond oil is obtained by cold expressing the fixed oils from previously ground bitter almond (*Prunus amygdalus*), apricot (*P. armeniaca*), and peach (*P. persica*). The kernels of these fruits contain the glucoside amygdalin, which when hydrolyzed by enzymes, will yield benzaldehyde and hydrogen cyanide. Bitter almond oil for use as a flavoring must be distilled to render it fully free of hydrogen cyanide (HCN; prussic acid). After pressing, the ground kernels are mixed with water to complete the aforementioned enzymatic hydrolysis. The mixture is then steam distilled to yield from 0.5% to 0.7% essential oil. Oil intended for food use is further treated to remove HCN by precipitation as an insoluble calcium ferrocyanide. The oil is used in both nonalcoholic and alcoholic beverages, in ice creams, candies, baked goods, gelatins and puddings, chewing gums, and maraschino cherries. Levels of usage in these products range from about 30 parts per million up to about 340 parts per million. Most countries generally regard the oil safe (GRAS) if it is free from prussic acid.

Apricot Tree (*Prunus armeniaca*)

The apricot is a stone fruit (drupe) and ranks fifth in terms of total worldwide deciduous fruit production. Of the genus *Prunus*, the apricot is *Prunus armeniaca*. This genus also includes almond, cherry, nectarine, peach, and plum. A drupe is a fleshy, one-seeded fruit that does not split open of itself, and with the seed enclosed in a stony endocarp, which is called a *pit*. As with other members of *Prunus*, the apricot tree has simple, alternate, serrate leaves. In the case of the apricot, they are ovate to round-ovate, abruptly short-pointed, closely serrated (toothed), thin, bright green, smooth above and below (usually), with stout stalks. See Fig. 3. Flowers are white, solitary, with no or very short stalks (peduncles) appearing from lateral buds of last year's growth or sometimes on short year-old spurs before the leaves appear. The fruit is short-stalked, somewhat flattened, nearly smooth when ripe mostly yellow, and overlaid more or less with red. The stone is flat and smooth, ridged on one edge. The tree is small, round-topped, with reddish bark. The eating quality of tree-ripened fruit rates high, but unlike most other stone fruits, is not widely available in the fresh market.

Fig. 3. Apricot (*Prunus armeniaca*). (*USDA*.)

Background. Although the name of the species would indicate that its origin may have been Armenia, there is much more evidence that the apricot is native to China, as is the case of the peach and nectarine. A very early Chinese record (the Shan-hai-king) makes reference to a *sing* (believed to be apricot) in China as early as 2205 B.C. Field plant researchers also have found apricots growing wild in some of the mountain ranges of China. Pling recorded that the apricot reached Italy by about 100 B.C. No records have been found, however, that associate knowledge of the apricot with the period of the Greeks. There is not full agreement regarding the importation of apricot into England. Some authorities place the date at 1524; others say that the fruit was brought to England about 1620 by an armed privateer. The earliest mention of the fruit in North America is 1720, records indicating that the fruits were being grown in Virginia at that time. By 1835, 17 varieties of apricot were listed in British horticultural catalogs. By 1866, in North America, 26 varieties were listed by Downing. In 1879, the American Pomological Society recorded only 11 varieties. As with so many other fruits (and vegetables), the Spanish missionaries were responsible for introducing the apricot into southern California. A fine orchard of apricot trees was reported in Santa Clara, California as early as 1792.

Apricot trees are adapted to a variety of soils and climatic conditions, but the growing site must be relatively frost-free for the trees to produce fruit. The most frost-free sites are near large bodies of water, on the tops or sides of hills, or near the base of high hills or mountains. In the valleys, there is little air movement and the coldest air settles in the lowest places where damaging temperatures occur more frequently and for longer periods than on sites with good air drainage.

Apricot trees grow best in deep, fertile, well-drained soil, but they grow well in light, sandy soil when adequately fertilized and watered. Growers must avoid poorly drained soil, as well as sites where tomato, cotton, or brambles have grown because these crops harbor the *Verticillium* wilt fungus that causes "black heart" of apricot.

Apricot trees are vigorous and, unlike peach trees, are long-lived and hardy. They may grow to very large size, but it is desirable not to allow the trees to become larger than economical harvesting permits. Generally, apricot trees require less space than peaches and most plums. Planting distances range from 22 feet (6.6 meters) or somewhat less to 24 feet (7.2 meters and somewhat over). Planting density of all deciduous fruit trees has been the object of discussion of growers for many years.

Although a number of new varieties and cultivars of apricot have been introduced in recent years, the varietal situation applying to apricots is considerably simpler than is the case of peaches, for which thousands of varieties have been listed and hundreds of varieties have appeared during the last several decades.

Apricots are not commonly stored in commercial quantities, although they keep well for 1, 2, and 3 weeks within a temperature range of 31–32 °F (−0.6–0 °C). Fruit picked when firm enough to ship or store has about the same maturity as that commonly used for canning and lacks the character and full flavor of tree-ripened fruit. Apricots stored at 40–45 °F (4.4–7.2 °C) have less flavor and a more mealy texture after ripening than fruit stored at temperatures within the first-mentioned range. Relative humidity required is about 90%. After storage apricots will ripen at temperatures between 65 and 75 °F (18.3 and 23.9 °C).

Blackberry and Dewberry (*Rubus*)

These berries, as well as raspberry, are of the genus *Rubus* in the larger family *Rosaceae*. In these species, the fruit is an aggregate of many drupelets, which cling closely to the axis in the blackberries and dewberries, but slip free therefrom in the raspberries. An erect habit distinguishes blackberries from the prostate dewberries. All have a perennial root system and annual or biennial stems. Propagation is mainly by suckers and root cuttings. The fruits frequently are consumed fresh near their place of origin, but they are also cultivated on a commercial scale for shipment to distant markets and for processing.

The blackberry in one or another of its many varieties is native in most of the temperate parts of the northern hemisphere — in fact, brambleberries, of which blackberries are a part, inhabit almost the whole globe with exceptions of dry desert regions. The blackberries of North America fall into 5 major groups: (1) *Erect or nearly-erect bush*, such as the Early Harvest and Eldorado, which are found along the Atlantic Coast from Florida to Canada and westward to the prairie states; (2) *eastern trailing blackberries*, which inhabit about the same range; (3) the *southeastern trailing blackberries*, such as the Manatee and Advance, which range along the Atlantic and Gulf coasts from Delaware to Texas; (4) the *trailing blackberries*, from which the loganberry is derived, which occur on the Pacific Coast from southern California northward to Canada; and (5) the *semi-trailing evergreen* Black Diamond and Himalaya varieties found in Oregon, Washington and California, which were naturalized from European importations (Darrow, 1937). Possibly of more convenience, is the simpler classification in which erect blackberries (See Fig. 4) are referred to as blackberries and the trailing blackberries are called dewberries (Hedrick, 1948).

A variety or cultivar also may be described as being thorny or thornless.

Propagation. Erect blackberry plants can be propagated from root suckers or root cuttings. The latter method yields the greatest number of new plants. Trailing blackberries and some semitrailing varieties are propagated by burying the tips of the canes. These take root and form new plants. Thornless Evergreen and Thornless Logan varieties must be propagated by tipping, as the other methods give rise to thorny plants.

Pollination. Some self-unfruitful varieties of blackberries require cross-pollination. Other varieties, even though self-fruitful, may benefit from the pollen-distributing visits of insects. The flowers of blackberries are very attractive to honeybees, the primary pollinators, and small plantings are usually pollinated adequately by them. Control chemicals should be scheduled to avoid injury to pollinating insects.

Cherry Tree (*Prunus cerasus*)

Cherry trees are relatively small-fruited trees of medium size, indigenous to Europe. The principal cherries of commerce are (1) *Prunus avium* L. the sweet cherry; (2) *P. cervasus* L., the sour or tart cherry. Occasionally, the sour cherry hybridizes with unreduced pollen of sweet cherry to produce *Duke cherries*[1] (*P. gondouinii* Poit & Turp.). Other essentially nonfood species of cherry include *P. mahaleb*, of European origin and used as propagating stock; *P. mazzard*, also used as rootstock; *P. pennsylvanica*, the pin, wild red, or bird cherry; *P. bessey* and *P. pumilla*, both classified as sand or dwarf cherries; and *P. serotina*, the wild black cherry, highly valued for its wood in quality cabinet and furniture making. Some of the wild cherries can be used for making jellies, jams, wines, and cordials.

[1] Duke cherries are tetraploid and intermediate between the parent species. Some of these are very similar to sour cherries in fruit characteristics, but have an upright growth habit.

Fig. 4. Close-up of fruit of trailing variety of blackberry. (*USDA*.)

Botanically, cherries are more closely related to plums than to peaches or apricots of the *Prunus* genus. Some borderline *Prunus* species are difficult to classify definitely into one or the other group. Cherries generally differ from plums in that leaves emerging from buds are folded lengthwise, in contrast to being rolled in plums. Also, in cherries, the stone is more globular, the fruit and stone are smaller, and the flowers occur in corymbose (short, broad, more-or-less flat-topped inflorecence) rather than the umbelliferous (having a common point of attachment) clusters.

Cherry trees can become large trees, but in orchard practice relatively low-growing types are used and trees are trained low and wide by pruning. An example of a record sour cherry tree (not orchard-trained) is that selected by the "American Forests" and located in Calhoun County, Michigan. The tree is 9.9 feet (3 meters) in circumference at a height of 4.5 feet (1.4 meters); 68 feet (20.4 meters) high; with a spread of 75 feet (22.5 meters).

When fully hardened, sweet cherry trees are hardier than peaches, but more tender than most apple varieties. Cherry bark is somewhat like that of birch, but it is predominantly red or black. The leaves are oblong-ovate to obovate, large, and soft, with double teeth. Flowers are white, about 1 inch (2.5 centimeters) across, and come out with the leaves; they are in clusters. The cherry fruit is globular or oblong, long-stemmed, and white or deep red to black when ripe. See Fig. 5. These characteristics vary considerably with variety and type. Sweet cherry trees require cross-pollination from other varieties to set fruit.

Cherry trees are in the group of deciduous tree fruits that require a winter dormant period for proper development and fruit production. Thus, they are limited to temperature regions having sufficient winter cold to break the natural rest period. In their distribution northward in the Northern Hemisphere, they are limited by the duration and intensity of winter cold. If the trees are not exposed to sufficient cold, the buds do not open properly in the spring. For best growth, cherry trees require ample moisture in the soil of their root zone throughout the growing season. Since the trees

Fig. 5. Sweet cherry (*Prunus avium*) ripening in a Michigan orchard. (*USDA.*)

develop large leaf areas, the total water requirement is relatively high. A minimum of 30 inches (75 centimeters) of precipitation or a combination of precipitation and irrigation must be made available. Several champion cherry trees in the United States are listed in Table 1.

Background. The first recorded mention of cherry is contained in Greek literature. Theophrastus in his "History of Plants" described the cherry as early as 300 B.C., and indicated that by then the fruit had been cultivated for a number of centuries. Early Chinese and Egyptian literature makes no mention of the fruit. Pliny suggested that Lucullus introduced the cherry to Italy in 65 B.C. Historical research in recent years, however, indicates that the cherry had been known in Italy at a much earlier date. Early herbalists and historians paid little attention to describing the different varieties of cherry or in giving them names. Gerarde, in 1596, wrote: "The Ancient herbalists have set down 4 kinds of cherry trees: (1) the first is great and wild; (2) the second is tame or of the garden; (3) the third hath sour fruit; and (4) the fourth is that which is called in Latin *Chamaecerasus*, or the dwarfe cherry tree. The later writers have found divers sorts more, some bringing forth great fruit, others lesser; some with white fruit, some with blacke, others of the colour of black blud, varying infinitely according to the climate and country where they are grown."

The cherry was one of the first fruits planted in the fields cleared and enriched by the American pioneers. From Canada to Florida, the colonists, although having different skills, were forced to turn to cultivation of the soil. Possibly, the French settlers were the first to plant cherries in Nova Scotia, Cape Breton, Prince Edward Island and in the early settlements on the Saint Lawrence River. Settlers in New England brought trees from England. A memorandum of the Massachusetts Company of March 16, 1629 stated: "Stones of all sorts of fruits, as peaches, plums, filberts, cherries, pear, apple, quince, kernells were to be sent to New England." For a long time after introduction in New York, the cherry in common with other fruits was grown as a species. Varieties and budded or grafted trees were probably unknown. The first nursery for cherry and several other fruit trees was established at Flushing, Long Island, New York in 1730.

The cherry quickly spread in Colonial days to the South and to the Franciscan missions in California. However, modern fruit growing on the Pacific Coast began in Oregon. Until 1847, the few cultivated fruits to be found in Oregon were seedlings, mostly grown by people associated with the Hudson Bay Fur Company. In 1847, Henderson Lewelling crossed the plains from Henry County, Iowa with a choice selection of grafted fruit trees. These he transported in boxes of soil, which he hauled in a wagon drawn by oxen. In this traveling nursery, Lewelling brought to Oregon cherries of the Bigarreau, English Morello, and probably several other types. The label of one of the cherries was lost and it was renamed the Royal Ann. Actually it was the Napoleon, which had been cultivated for more than 3 centuries. Later the work of a relative, Seth Lewelling, stimulated others to breed cherries, and their work included the well-known Lambert variety.

Varieties. *Sweet Cherries.* In most cherry-producing regions, sweet-cherry varieties are not as dependable as sour ones. They are more subject to difficulty in establishing the trees, and are subject to frost damage, cracking of fruit, brown rot, and loss of fruit from birds.

Sour or Tart Cherries. These varieties are also sometimes called *pie cherries or red cherries*. Sour cherries are separated into two distinct groups based on the color of the fruit juice: (1) the Amarelle or Kentish group, with colorless juice; and (2) the Morello or Griotte group, with reddish juice and usually dark-red fruit. In addition, a subspecies classification is sometimes given to the Marasca group, which is used for distilled or brined products. Further classification into Montmorency, Morello, Brusseler, and Vladimir groups has been suggested.

About 270 named cultivars (varieties) of sour cherries were described as early as 1914 by Hedrick. By 1950, only 12 more varieties had been added and, by 1970 only 5 additional varieties. Ten of the 17 varieties added since 1914 are mutations of Montmorency.

Numerous strains or mutations of Montmorency have been selected for productiveness, season of fruit maturity, or disease resistance. The fruits of these are similar to the Montmorency. Only three cultivars are of economic importance: (1) Montmorency; (2) English Morello; and (3) Early Richmond.

Duke Varieties of Cherries. Unless there is a known demand, these cherries are seldom grown on a large scale. The Duke varieties are neither sweet nor sour, but a blend of both. Most people find them too sour for eating fresh, but many prefer them for canning, freezing, and pie making.

Peach Tree *(Prunus persica)*

Native to China, peach trees are small and usually not very long-lived. They can be considered semi-hardy and, due to their habit of producing flowers very early in the growing season, before leaves appear, are frequently severely damaged by late heavy frosts. The calyx tube of the flower surrounds the pistil, but is not adnate thereto. The ovary is one-celled, but frequently contains two ovules when young, only one of them developing. Peach fruits are of two types. In one, the fleshy mesocarp slips readily from the stony endocarp. These are termed *freestone peaches*. In the other type, the two layers are closely adherent, giving *clingstone fruits*. Peach fruits are quite perishable when mature.

Clingstone and Freestone Types. Generally, the freestone-type peaches are sold on the fresh market, while clingstone peaches are usually processed. There are also some varieties that qualify as *semi-freestone* peaches. With all types there are varieties that have white flesh and others with yellow flesh. Generally, in North America, peaches with yellow flesh are in greatest demand.

Exemplary of the innovative thinking that goes into fruit breeding research is a study being made of freestone varieties at the Russell Research Center (Athens, Georgia). One scientist has observed that recognition of the relative levels of enzymes in freestone peaches compared with those of clingstone peaches may be helpful in improving the freestone peach. The freestone peach, as viewed by consumers is somewhat "ragged" when it comes out of the can, softening more than the clingstone peach. This softening problem is related to the "melting" characteristics of peach flesh. Freestones are characterized by a melting-type of flesh, while clingstones are frequently nonmelting. This characteristic tends to make the freestone quite difficult to process. Firming up the freestone would be very helpful to processors.

Scientists have found that the difference in texture may be due to more degradation of pectin in freestone than in clingstone fruit. Polygalacturonase is the enzyme involved in pectin degradation. In examining six varieties each of freestone and clingstone peaches, it was found that, at the unripe stage, all varieties of both types had low levels of water-soluble pectin and virtually no polygalacturonase activity. But in ripe freestone peaches there were high levels of soluble pectin and both endo- and exo-polygalacturonase. In the clingstone peach, only exo-polygalacturonase is present. The scientists found that endo-polygalacturonase is much more effective in degrading pectin than the exo-polygalacturonase. Thus, the conclusion — if pectin is the critical component in peach softening, the difference in enzyme composition accounts for the difference in softening characteristics. Further research, based upon this fundamental observation, may lead to later practical assistance to the processor.

Varieties. The selection of the variety of peach to plant is probably the most important decision a grower must make in developing a new orchard, or in replanting an old orchard. The selection process is not simplified by the large number of new varieties introduced each year. These emanate from a number of research teams that constantly are seeking improvements in the fruit for better quality, better resistance to diseases, insect, and environmental factors, and better shipping qualities, as well as making varieties available for different harvesting dates, among numerous other objectives. In a 50-year period of research, records indicate that some 700 new varieties of peaches have been introduced. Most of these varieties already have become obsolete.

The number of varieties introduced may seem large, but many are special-purpose varieties for adaptation by only one or a few of the several peach-growing regions. For example, the chilling requirement of a variety to break the rest period of its buds narrowly limits the area to which the variety may be adapted, particularly as regards the southern states. Florida requires very low-chilling varieties. In the North, winter hardiness of fruit buds is a limiting factor. Fruits of some varieties tend to develop enlarged sutures or elongated tips when grown in a warm climate. In the North where it is adapted, the same variety may produce perfectly round fruit. Maximum red color of fruit is developed when the temperatures just preceding maturity are cool. Thus, many varieties are not successfully grown in warm climates, such as California, because they lack sufficient exterior red color. Other varieties having adequate color for warm climates develop too much red color and are too dark in a cool climate, such as Michigan. Fruit of some varieties develops too much astringency when grown in the cool climates of western Oregon or Washington, where varieties with low astringency are needed. Resistance to bacterial leaf spot is important in varieties grown in Texas and the Southeast. It is less important elsewhere, such as California. Peach brown rot and leaf curl are diseases which also limit distribution (Weinberger).

Because of this constantly changing situation, specific varieties are not described here. The *Elberta*, although still a significant variety, has been taking on the role of a classic, with new varieties frequently compared against it.

Pear Tree *(Pyrus communis)*

Of Eurasian origin, the pear tree differs in several ways from the apple. See Fig. 6. Usually it is a taller tree, with a tendency to more upright growth. In contrast to the rough leaves of the apple, those of the pear are smooth and glossy. The wood is quite dense and sometimes used in the same manner as apple wood. The flowers are white. The fruit is more juicy and sweeter than is the apple, and the flesh especially when green contains an abundance of stone cells. Pears are used almost entirely as edible fruit, eaten either fresh or canned. The alligator pear (avocado) is not related to the true pear. Champion specimens of pear trees in the United States are described in Table 1.

Early cultivation of the pear probably predates recorded history by several centuries. Charred remains of the fruit have been found in the prehistoric lake dwellings of Switzerland. It is recorded that pears were cultivated in Greece at the time of Homer (850 B.C.), who referred to pears being grown in the garden of Alcinous and called them a "gift of the gods." Evidence shows that the Roman conquerors carried pears with them to the temperature parts of the Old World. Pliny, in his *Natural History*, names 41 varieties of pear. Thousands of varieties of pear are known. There were over 700 varieties in the Horticultural Society's garden in England as early as 1842. In 1866, T.W. Field of England cataloged 850 varieties of which he indicated 683 were of European origin. Pear seeds were mentioned in a communication between the Massachusetts Company and American colonists as early as 1629. It is believed that the first pear tree in the United States was planted near Salem, Massachusetts in about 1630. This became known as the Endicott pear tree. Pear trees did very well in the eastern Colonial settlements. As with so many other fruits and vegetables, the pear was originally introduced into southern California by the padres for planting in their mission gardens. The first evidence of commercial pear sales in the West was during the period of the Gold Rush. However, commercial pear production in California did not commence until about 1914.

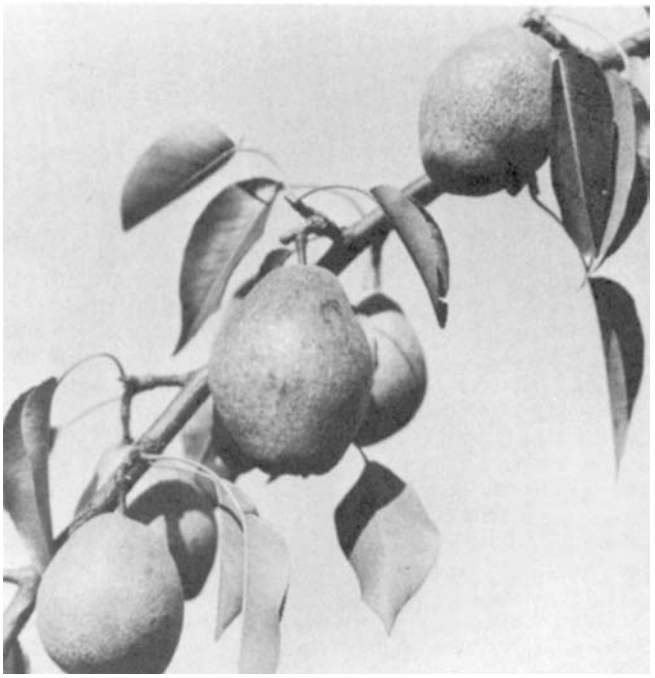

Fig. 6. Pear (*Pyrus communis*). (*USDA*.)

Varieties. More than 3000 varieties of pear are known in North America, but fewer than a dozen are of commercial importance.

Plum Tree *(Prunus avium)*

Of several different species, these small to medium trees have been cultivated since before the Christian era. The flesh of the fruit surrounds a hard pit in which there is a seed. There are more than 2000 varieties of plum, of which relatively few are of commercial importance. See Fig. 7. Champion specimens in the United States are listed in Table 1.

In a classic book, "The Plums of New York," Hedrick (1919) observed that, of all the stone fruits, plums furnish the greatest diversity of kinds. The trees are diverse in structure, some of the plums being shrublike plants with slender branches, others true trees with stout trunks and sturdy branches; some species having thin, delicate leaves and others coarse, heavy foliage.

In generalizing on the important plum trees of commerce, the trees are deciduous with simple and alternate oval leaves, veined, dull green to pale-green, serrated at the edges. The tree may be upright, spreading, drooping, or round-topped, depending largely upon climate, soil, and cultural handling. The bark of some varieties is birch-smooth, while that of other varieties is locust-rough. Flowers are white and generally appear with the leaves. The fruit is longer than broad, somewhat compressed, but may be smooth or roughened, with a groove or suture on the ventral side.

Nomenclature. At one time, the words "plum" and "prune" were used as synonyms for the fruits of hundreds of varieties comprising some 15 different species. A distinction in meaning evolved gradually. Botanically, all prunes are plums. In current usage, particularly in North America, *prune* signifies a variety that can be and is normally dried *without the removal of the pit*. The word refers to both the fruit in its fresh state and to the dried product. *Plum* designates a variety grown primarily for uses other than drying — mainly for fresh consumption, but also for canning, freezing, crushing, and jam- and jelly-making. Most plum varieties will ferment when dried with the pit. If they are dried after removal of the pit, the product is called 'dried plum' and not 'prune.' The *fresh prune*, which is grown extensively in the Pacific Northwest of the United States, does not fit into either category. Varieties of this prune are equally well suited and have been utilized in substantial volume for fresh use, canning, and drying. A more recent trend is to call these plums by the name "purple plum."

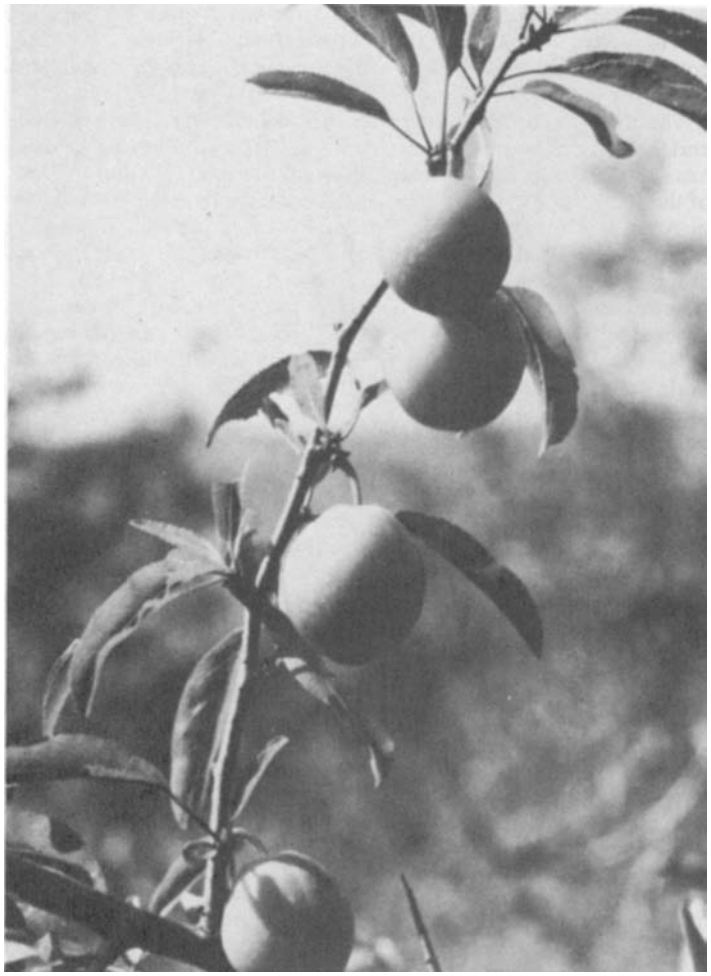

Fig. 7. Plum (*Prunus domestica*). (*USDA*.)

Species and Varieties. The two principal species of commercial plums are (1) *Prunus domestica*, also known as the European plum, varieties of which tend to be purple-to-black; and (2) *P. salicina*, also known as the Japanese plum, the varieties of which tend to be yellow-to-crimson.

Cultural Factors. Plums are propagated by budding on seedlings in the nursery, in a method similar to peach propagation. Peach rootstock does best in light, sandy, well-drained soils. It is sensitive to wet soil. About 50% or more of Italian prune trees in some regions are on peach rootstocks (in Idaho and foothill areas of California). Myrobalan rootstock is adaptable to a wide variety of soils and degrees of moisture, and its seedlings are compatible with a wide variety of Japanese — and European-type plums. Myrobalan is hardy, with deep roots, but is not particularly vigorous. Plums are sometimes budded on apricot where nematodes are a problem, or where there is soil of high alkalinity. Almond as a rootstock is best suited to warm, dry soils. Most Japanese plum varieties can be topworked on European varieties, producing durable trees.

Fresh Plums. Most of the fresh market plums grown in California are of the Japanese type. Tree growth habits vary considerably in character among the Japanese varieties, ranging from low and spreading to upright. Leaves are of medium size, pointed, and free from hair on the lower surface, a characteristic that distinguishes them from the European type. European plum trees are characteristically large, vigorous growers with large, thick leaves that are dark green above and pale green beneath. Fruit of the Japanese varieties is large and usually heart-shaped. It often has a pronounced apex, and is bright-red or yellow in skin color. The flesh is juicy and firm, either red or yellow. Most European plums marketed in fresh form belong to the Imperatice group, which are blue in color. The fruit is medium sized with firm flesh and thick skin.

Plums can be grown in most of the fruit production areas of California. Adequate growth can be attained on a fairly wide range of soil types. However, ample, good-quality irrigation water is required to produce commercially acceptable crops. For proper leaf and bud development, Japanese varieties require 700 to 1000 hours of winter chilling (temperatures below 45 °F; 7.2 °C). European varieties require 800 to 1000 hours of winter chilling. Japanese plums bloom in late February and March and are more susceptible to frost injury than European plums, which bloom in March and April.

Commercial plum production is reported in 30 California counties, extending from Butte in the north to Riverside in the south. The major production areas are concentrated in a few counties — Tulare, Fresno, Kern, and Placer. There has been a major shift in the geographical location of the California plum industry during the past 30 years. Plantings have declined substantially in the Sierra Nevada foothills region, but this trend has been offset by plantings in the lower San Joaquin Valley. Many varieties of plums have been developed in California during the over 100 years since introduction. New varieties have resulted from systematic breeding to develop superior hybrids, chance seedlings, and bud mutants. Characteristics, such as time of bloom and maturity, fruit size, color, eating quality, and intercompatibility with pollenizer trees determine which varieties are selected for commercial production.

Quince Tree *(Cydonia oblonga)*

A small, rather shrubby tree, the quince is much less important commercially than the pear or apple. The fruit is large, more or less hairy during growth, and hard and yellow at maturity. Each carpel contains several seeds invested with a mucilaginous pulp. It is not edible in the fresh state and thus does not qualify as a dessert fruit, although some varieties grown in the Near East are reputed to be delicious when consumed raw. The quince, like the persimmon and pomegranate, has an illustrious historical past and was greatly esteemed by ancient cultures, but it has fallen out of favor in the modern marketplace. For many years, the quince has been regarded in North America as a secondary fruit and used mainly as a raw material for jellies and preserves — and in recent years it has become increasingly difficult to find these products in the marketplace. There are only a few of what might be called fruit orchards in production in the United States today (in New York State). The literature, both from an agro-economics and scientific research standpoint, on the quince is extremely limited and generally of old vintage.

Believed to have originated in central and eastern Asia, the quince has been cultivated for over 2000 years. The quince is a small tree, usually not over 10 to 15 feet (3 to 4.5 meters) in height. The trunk is erect; the branches are crooked. Pink or white solitary flowers appear in spring. The tree has ovate leaves, tapering at one end and fruits resembling a large, yellow apple. In making flavoring substances, both the fruits and seeds can be used. Among flavorings made are a decoction (5%), an infusion (15% from seeds), and a fluid extract. For marmalades, jellies and preserves, the hard, acid flesh of unripe fruits, harvested in October, is preferred. A quince-seed mucilage is yielded by the seeds of ripe fruits and this can be used as a thickening agent in lieu of tragacanth gum. Quince flavoring is used on occasion in non-alcoholic beverages, ice creams, ices, and baked goods.

Raspberry *(Rubus)*

The raspberry is closely associated with the blackberry and dewberry. In these species, the fruit is an aggregate of many drupelets, which slip freely from the axis in the raspberry, but which cling close in the blackberries and dewberries. From a botanical standpoint, this quality of the raspberry separating from its receptacle is the primary difference between these species of berries.

Generally, the raspberries are perennial plants with either erect, procumbent or trailing stems; mostly armed with fine, slender, more-or-less stiff bristles and variously-shaped prickles; with stems or canes of most shrubby species of the temperate region biennial and reaching their full size the first year. In the second year, short lateral branches appear which bear flowers and fruits. After flowering and fruiting, the 2-year-old canes die and are replaced. The canes are either circular in cross section, or angled, or angled and furrowed. In some species, the tips of the canes bend over, touch the soil, strike root, and thus give rise to new plants.

The leaves are alternate, either simple, lobed or pinnately or palmately or pedately (with laterial division cleft) compound, mostly deciduous but in some species wintergreen or evergreen. Stalks of the leaflets resemble the canes. Stipules are always present at the base of the leaf stems. Flowers are always stalked and borne either solitary or in racemes or panicles. They are mostly bisexual, with both stamens and pistils. Flowers are white, rose, or pink. In the fruit, the pistils are transformed into small, more-or-less juicy and coherent drupelets. The ripe fruits are usually red, yellow or black, rarely green.

Raspberries grow best in cool climates. In the United States, they are not well adapted south of Virginia, Tennessee, or Missouri. Nor are they well adapted to areas in the Plains States or Mountain States where summers are hot and dry and winters are severe.

There is little evidence of formal cultivation of the raspberry in ancient times. The red raspberry did not draw the attention of Europeans until the 16th century. However, Hedrick (1925) observes that no doubt the raspberry crept into fields and was more or less cultivated from the very beginnings of agriculture in regions where it grows wild. Greek and Roman agricultural writers who lived prior to the Christian era do not mention the raspberry, although they have much to say about the tree fruits and grapes. Pliny, at the beginning of the Christian era, mentioned wild raspberries as coming from Mount Ida. The first well-documented reference to cultivated raspberries dates back to 1548 when Turner, the English herbalist, observed that they "growe in certayne gardines in Englande." Lawson in 1618 mentioned raspberries and currants growing along the border of gardens. In 1629, Parkinson discussed the "rapis berry" as useful for sickness, and mentioned several ways to use the berries and leaves for alleviating a number of human ills. The Horticultural Society of London listed 23 "sorts" of raspberries in the Catalogue published in 1826.

Hedrick, in referring to the culture of the red raspberry in North America observed that not until agriculture was well advanced with little land in waste could there have been a need for cultivated raspberries. Wherever its culture could have succeeded the native plant runs riot in waste places. It is one of the first plants to follow forest fires, to creep into newly cleared lands and become a weed in fence corners and neglected fields. Hedrick also mentioned that early explorers and settlers on the Atlantic seaboard often mentioned black raspberry as one of the delectable wild fruits of the country. It was found from New England to the Carolinas in the borders of woods, as a fringe about fields, around the stumps that dotted clearings, and came uninvited into the gardens.

It appears that the serious start toward domestication of the black raspberry started in 1850 by finding better methods of propagation. The red raspberry is propagated by suckers. The black raspberry throws no suckers and first was propagated laboriously by division. Bending the canes to the soil and covering them so that the tips will take root was later adopted from nature as the best means of manual culture.

Varieties and Culture. There are three main types of raspberries — red, black, and purple. They differ in several ways in addition to the color of the fruit. *Red raspberries* have erect canes. They are grown most extensively in the western states. *Black raspberries (blackcaps)* have arched canes that root at the tips. They are grown mostly in the eastern half of the United States and in Oregon. See Fig. 8. *Purple raspberries* are hybrids of red raspberries and blackcaps. They have the same growth characteristics as blackcaps and are propagated in the same way. They are grown extensively only in western New York State, although they are adapted to about the same regions as that for blackcaps. Some raspberries have yellow fruit; these *yellow raspberries* are variations of red raspberries and, except for fruit color, have all the characteristics of red raspberries. They are usually limited to home gardens.

Fig. 8. Black raspberry (*genus Rubus*). (*USDA*.)

Fig. 9. A ripening cluster of strawberries. (*USDA*.)

Strawberry *(Fragaria)*

The strawberry is a perennial herb of several species. The fruit is an enlarged, fleshy receptacle with numerous seeds embedded at the surface. What appear to be seeds to the casual observer are, in actuality, achenes. The seed is contained within a thin, dry ovary wall. See Fig. 9. The strawberry plant grows from a central stem called a crown whose terminal is a growing point. From this growing point, leaves, flowerbuds, and runners develop. Runners are branches from the main stem. Branch crowns may develop following rapid runner development. Buds in the axils of the leaves produce flower clusters when temperatures are cool and days are relatively short. Different varieties produce clusters with many flowers, while others produce clusters with few flowers. Some varieties produce clusters that branch close to the crown, while others branch far out on the stem. Clusters with many flowers may produce a large number of berries, but the berries may be small. Natural propagation of the plant is by runners which form mainly after the blooming season. Shape is variable. See Fig. 10.

The strawberry is among the most widely adapted of fruit crops. Varieties have been selected that can be grown in at least the higher elevations in

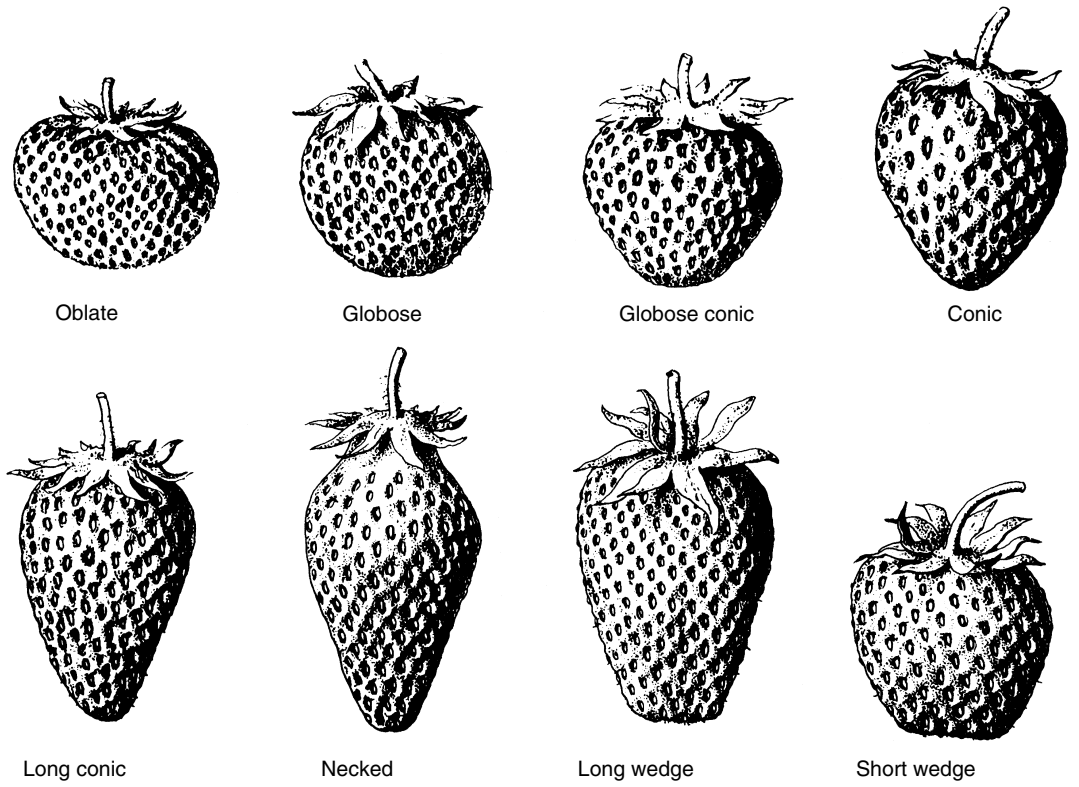

Fig. 10. Range of shapes of strawberries. (*USDA*.)

the tropical regions, and others are grown in northern latitudes where very severe winter conditions prevail. Although the strawberry can be grown as far north as most fruits, it is not truly hardy in the sense that the plant parts can withstand very low temperatures. As grown in cold climates, the vital plant parts are at or below ground level during the winter. Thus, they are protected by snow or other cover. Without such protection, the plants are very susceptible to winter killing. In commercial production, the practice of heavy mulching with straw or similar materials is followed in cold regions to ensure protection if there is little or no snow cover.

In the United States, varieties for the most southern latitudes differ in their growth response from those adapted to severe winters. The principal fruiting in the most southerly regions occurs during the winter and early spring months. Varieties adapted there must grow, flower, and fruit during the relatively short, cool days of winter.

Background. In the days of the Romans and Greeks, all plants of the genus *Arbutus* were included along with strawberry in one classification. The strawberry was first distinguished by Pliny, who called it *fragum*, a tribute to the sweet taste of the fruit. The present genus name *Fragaria* is Latin, although some botanists believe the name may have stemmed from *fragrans* (fragrant). The French *fresas* (*frayses* and modern *fraises*) and the Spanish *fresa* apparently came from the same source and the names definitely refer to the sweet odor of the fruit.

The unimproved or wild strawberry is native to many regions of the world. There are numerous varieties. As early as the 14th Century, it was reported that at least 1200 plants of small-fruited, indigenous European species were cultivated in the Royal Gardens at Louvre, France. At this time, the strawberry was commonly a part of French home gardens, a practice that commenced in England in the 15th century. The early American colonists were delighted to find *Fragaria virginiana* growing along the Atlantic coast and north to New England and west to the Rocky Mountains. American Indians in New England called this berry the "wuttahinmeash" and mixed it with meal in bread making. Roger Williams (1643) referred to the strawberry as the wonder of all fruits growing naturally in these parts. From observations of the colonists, it appeared that the Indians probably had cultivated the strawberry for several centuries prior to the colonial period.

A species, *F. chiloensis*, native to the south coastal region of Chile and the Cordillera of the Andes of South America, as well as the beaches and coastal mountains of western North America and the mountains of Hawaii, was taken to France from Chile by Captain Frezier in 1712. Records show that the species reached England by 1727. The original Chilean plants apparently were large-fruited selections that had been cultivated by the aborigines since before the arrival of the Spaniards. Some of these berries are still cultivated. Because only female plants were carried to Europe by Frezier, there was little effect of their introduction for about a century. Natural hybridization with *F. virginiana*, already in European gardens, occurred. As pointed out by Hedrick (1948), the rapid improvement that occurred can be regarded as one of the most remarkable phenomena recorded in pomology.

Varieties. The cultivated strawberry in America is a fruit that originated by hybridization from the wild species of eastern North America and the wild species of South America. The berries have a unique, tangy taste. They are highly valued as dessert fruit and are rich in vitamin C. Among the most important varieties, based upon total tonnage of fruit marketed, are the Tioga, Northwest, Shasta, Midway, Surecrop, Fresno, Blakemore, Florida Ninety, Pocahontas, Tennessee Beauty, Catskill, Albritton, Dabreak, Sparkle, Headliner, Raritan, Siletz, Hood, and Rodinson. Several other varieties are grown successfully. New varieties of strawberries appear from time to time.

The two general classes of strawberries are: (1) everbearers; and (2) one-crop varieties, sometimes called "June bearers." Everbearers produce fruit during spring, summer, and fall. The once-crop varieties produce fruit only in late spring and early summer.

Minor Fruits of the Rose Family

Medlar Tree (Mespilus germanica). A small tree or large shrub, the medlar is found in southern Europe and is native to that region. However, it is found in the United States, particularly in parts of New York State. In the wild state, the tree has thorns which cultivated trees do not bear. The fruit is tart and is used in making preserves. Flowers are large, solitary, and white. Frost assists in the ripening of the fruit and improves the flavor.

Hawthorn Tree (Crataegus). Of the same family (*Malaceae*), the hawthorn bears a fruit somewhat resembling a miniature apple. Over a thousand species of hawthorn have been described. The hawthorn is the hedgerow tree in northern Europe. The name means hedgethorn. The

common species is *C. monogyna*. The common hedgerow hawthorn has attained a height of almost 50 feet (15 meters) and, in some cases, a girth of nearly 10 feet (3 meters). The trees are admired for the beauty of their foliage and can assume large proportions when permitted to develop as single trees. Champion specimens in the United States are listed in Table 1.

Crab Apple Tree (Pyrus angustifolia, etc.). There are approximately 15 species of these relatively small trees, found in the Temperate Zone of the Northern Hemisphere. Crab apples were valued in the Middle Ages for their juice, serving much as vinegar does in modern cooking. The trees are valued today for their flowers and foliage in gardens. Because they are considerably hardier and adaptable to poor soil, they can make fitting substitutes for cherry trees. Champion crab apple trees in the United States, as selected by American Forests are described in Table 1.

Shadbush or Serviceberry (Amelanchier). Usually small shrubs of value for coloring and foliage in gardens, but as indicated by the accompanying table, can become large trees. In England, the plant is known as the juneberry or snowy mespilus. Flowers are white and star-shaped. Usually in June, bunches of berries somewhat like black currants appear. Autumnal colors are soft red, orange, and brown. Champion serviceberry trees in the United States, as selected by The American Forests, are described in Table 1.

ROSEMARY. See **Spices**.

ROSIN. See **Resins (Natural)**.

ROSSBY NUMBER. A dimensionless number relating the ratio of inertial to Coriolis forces for a given flow of a rotating fluid.

Explicitly, the Rossby number is

$$\mathrm{Ro} = \frac{U}{fL},$$

where U is the velocity scale, f is the Coriolis parameter, and L is the horizontal length scale. This number plays a fundamental role in defining the regime of large-scale geophysical fluid dynamics. Large-scale flows are defined as those that are significantly influenced by the earth's rotation and with sufficiently large L for Ro to be order one or less (e.g., flows with sufficiently small Rossby number are in geostrophic balance). See also **Coriolis Parameter**.

AMS

ROSSBY PARAMETER. The northward variation of the Coriolis parameter, arising from the sphericity of the earth.

In spherical coordinates,

$$\beta = \frac{1}{a}\frac{d}{d\phi}(2\Omega \sin\phi) = \frac{2\Omega\cos\phi}{a},$$

where Ω is the angular speed of the earth, ϕ the latitude, a the mean radius of the earth, and β the Rossby parameter. The Rossby parameter, usually treated as a constant, is of importance dynamically in producing Rossby waves.

See also **Barotropic Instability**; **Beta-Plane**; **Coriolis Parameter**; and **Rossby Wave**.

ROSSBY WAVE. A wave on a uniform current in a two-dimensional nondivergent fluid system, rotating with varying angular speed about the local vertical (beta plane).

This is a special case of a barotropic disturbance, conserving absolute vorticity. Applied to atmospheric flow, it takes into account the variability of the Coriolis parameter while assuming the motion to be two-dimensional. The wave speed c is given by

$$c = \overline{u} - \frac{\beta}{K^2},$$

where u is the mean westerly flow, β is the Rossby parameter, and $K^2 = k^2 + l^2$, the total wavenumber squared. (This formula is known as the Rossby formula, long-wave formula, or planetary-wave formula.) A stationary Rossby wave is thus of the order of the distance between the large-scale semipermanent troughs and ridges in the middle troposphere. The Rossby wave moves westward relative to the current, in effect slowing the eastward movement of long-wave components relative to the short-wave components in a barotropic flow. This effect is important in a numerical forecast with a barotropic model, but attempts to apply the formula to actual contour patterns considered as waves have less dynamic justification and correspondingly less success.

See also **Barotropic**; **Barotropic Disturbance**; **Barotropic Model**; **Coriolis Parameter**; and **Long Wave**.

ROSSI X-RAY TIMING EXPLORER (RXTE). The Rossi X-ray Timing Explorer is a large X-ray space telescope capable of making observations over a large range of the X-ray spectral region (2–200 kiloelectron Volts (keV)) with unprecedented high time resolution (as little as one microsecond between readings). Its All Sky Monitor (ASM) collects a continuous daily record of hundreds of X-ray sources in the sky, searching for transients and recording slow variations in X-ray brightness. Its more sensitive Proportional Counting Array (PCA) and High Energy X-Ray Timing Explorer (HEXTE) instruments make in-depth observations of the X-ray variability of sources in our galaxy and of distant galaxies. Scientists compete for time on these instruments to schedule studies of well-known objects or to quickly observe transients uncovered by the ASM.

Compared to the night sky that is visible to the naked eye, the X-ray sky is incredibly dynamic: X-ray sources wink into being, reaching surprising brightness before gradually fading over weeks or months. Bright, persistent, but highly variable X-ray sources shine where there is only a faint optical counterpart. Even distant giant galaxies have tremendous X-ray output that can vary on short time scales (days) to the longest time scales yet observed. Scientists now understand that most cosmic X-rays are produced near the surfaces of white dwarfs and neutron stars and near the event horizons of black holes. White dwarfs, neutron stars and black holes are often collectively referred to as *compact objects*. Each is an end point of the stellar life cycle, during which a normal star like the Sun eventually sheds its outer, lighter layers, leaving behind a dense core that has collapsed due to its own gravity. These exotic objects are described by very extreme physics: matter compressed to unimaginable densities where even space and time behave very differently than expected. It is impossible to reach these conditions in any laboratory on Earth; the Rossi Explorer was designed to peer carefully at these objects to test the physics of extremes.

Compact objects often reside in a binary star system, in which X-ray source and a normal hydrogen-burning star like our Sun orbit each other. Gas is stripped off the normal star and usually forms a disk of material around the neutron star before eventually crashing onto its surface. This disk is referred to as an accretion disk. The Rossi Explorer has made great strides in the understanding of neutron stars in binary star systems. During X-ray outbursts of several such systems, Rossi has detected very rapid time and spectral variability. While the signal detected is not strictly periodic there is a strong preferred frequency in the X-ray output, often referred to as *quasiperiodic*. The rapid spectral changes and these high frequency quasi-periodic oscillations (QPOs) are actually probes of the inner accretion disk: this is the only window into the behavior of space and time near compact objects. Often, two distinct high frequency QPOs are observed in the same source. While both slowly adjust their frequency as the outburst progresses, the difference in their frequencies typically remains constant. The frequency difference between these twin peaks is believed to reveal the otherwise masked neutron star spin period. See also **Binary Stars**.

As the number of neutron stars with known spin periods increases, scientists can place new constraints on the mass, radius, and equation of state of neutron stars. Already, some theoretical equations of state for matter at neutron star densities are all but ruled out by RXTE observations. Watching the frequencies of QPOs change with time has produced the first evidence of some predictions of Einstein's theory of General Relativity in the strong field regime. The fact that there appears to be a "speed limit" for

QPOs is taken as evidence for the innermost stable orbit around neutron stars. Other scientists have found evidence of Lense-Thirring precession (or frame dragging) around neutron stars and black holes in the behavior of kHz QPOs. See also **Neutron Stars**.

The Rossi Explorer has discovered dozens of new transients, peered intensely at numerous outbursts in over 30 systems, and detected many orbital and long term periods in systems where the period was not previously known. Also in the Rossi collection is the youngest known pulsar (about 700 years old) and the closest known microquasar, a stellar-sized black hole emitting jets of high-speed particles from its poles about 40,000 light years from Earth. Intensive study of one microquasar has uncovered an intricate interplay between the accretion disk of matter swirling into the event horizon of the black hole and the intense jets sometimes seen from these sources. When an instability disrupts the disk, a portion of the material is accelerated and ejected as a relativistically expanding cloud, causing an outburst that is seen in the radio and infrared regions of the spectrum. See also **Pulsar**.

Active Galactic Nuclei (AGN) are the extremely energetic central engines of distant galaxies. Intensive monitoring of AGNs over a wide range of time scales has revealed a surprising similarity between the characteristics of rapid brightness flickering in AGN and the much smaller X-ray binaries found in Earth's galaxy. Some scientists interpret the result as evidence that material falling into a black hole follows a simple scaling law: the flickering properties are proportional to the absolute brightness (and therefore the mass) of the black hole. If that is true, then the RXTE observations mean this rule applies over a very wide range of masses (from single black holes in our galaxy with masses a few times the mass of the Sun up to galactic cores, estimated to contain a few million times the mass of the Sun). The masses of black holes in X-ray binaries can be accurately determined from the orbital motion of the two stars. Using the black hole flickering scaling rule, scientists can now estimate the total mass of the supermassive black holes in the cores of active galaxies from a measurement of their flickering properties. See also **Galaxy**.

The ASM has amassed a collection of long-term light curves that give scientists important insight on the dynamics of these objects at the longest time scales. Many X-ray binaries show a periodicity much longer than the orbital period of the two stars. This superorbital period is thought to be the precession of the disk of material around the compact object. Much like a spinning toy top wobbles as it moves across a table, the saucer-shaped accretion disk may slowly change its plane of orientation with time, effectively casting a shadow and blocking some of the X-rays that are headed toward Earth. Other systems show random long term variations thought to be caused by an instability in the accretion disk which can disrupt the flow of matter onto the compact object. The ASM is finding that many X-ray binary systems have long term light curves that can not be classified as simply periodic or random. Perhaps both disk instabilities and precession are at work in such systems.

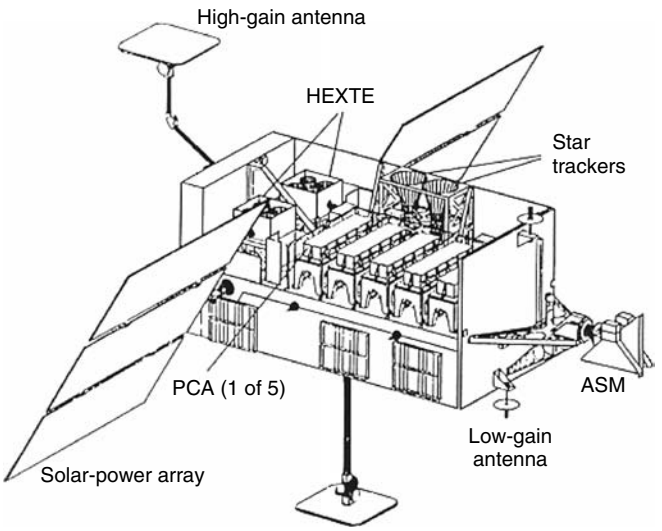

Fig. 1. Rossi X-ray Timing Explorer (GSFC/NASA). Diagram location: http://rxte.gsfc.nasa.gov/Images/xte/xte_spacecraft.gif.

The Rossi Explorer was launched by NASA aboard a Delta II rocket from Cape Canaveral, Florida, on December 30, 1995. The PCA was built by NASA Goddard Space Flight Center; the HEXTE was built by the University of California, San Diego; and the ASM was built by the Massachusetts Institute of Technology. See Fig. 1. The Rossi Explorer maintains a low-earth circular orbit at an altitude of 580 kilometers, corresponding to an orbital period of about 90 minutes, with an inclination of 23 degrees. NASA Goddard operates the satellite and manages the Rossi Explorer data archive. This X-ray mission is named in honor of Professor Bruno Rossi (1905–1993), an authority of cosmic rays whose experimental techniques at the Los Alamos Laboratory and at MIT gave birth to the field of X-ray astronomy. See also **X-Ray Astronomy**.

ROSS, RONALD (1857–1932). Ross was a British doctor who elucidated the role of the mosquito in the transmission of malaria. The son of a military officer, Ross was born in Nepal but was sent back to England in 1865 for his education. His father determined on his medical career, Ross himself feeling more drawn towards literature and art. He received his medical training at St Bartholomew's Hospital Medical School in London, and after a brief period as a ship's surgeon, joined the Indian Medical Service (IMS) in 1881. During his first furlough in England in 1888–1889, he took a Diploma of Public Health (DPH) and married Rosa Bloxam, by whom he had four children. In his next stint in India, Ross became interested in malaria, the parasite of which had been discovered in 1880 by C. L. A. Laveran. Ross was unable to find it in the blood smears of malaria patients, but during his next furlough in London (1894–1895), Patrick Manson showed him how to recognize the Plasmodium and told him of his (Manson's) belief that the disease is transmitted by mosquitoes. Ross returned to India determined to prove Manson's 'Grand Induction', and after two frustrating years, on 20 August 1897, he found the pigmented parasite in the stomach wall of a brown, dappled-winged mosquito (now known to be a species of Anopheles). Manson was able to help Ross obtain research leave in Calcutta from his IMS duties. Ross there showed that the parasite develops within the mosquito and worked out its transmission cycle in bird malaria. For this research, Ross received the 1902 Nobel Prize for Medicine or Physiology. See also **Malaria**; and **Manson, Patrick (1844–1922)**.

Ross retired from the IMS in 1899 and was appointed to a lectureship at the newly founded Liverpool School of Tropical Medicine. He advised on aspects of malaria prevention in many parts of the world, beginning with an expedition to Sierra Leone in 1899. He later went to Mauritius, Greece and other malarious countries. Ross always emphasized the crucial role of mosquito control, which he initially believed could be done easily and at little cost. He also developed mathematical models to help interpret the epidemiology of the disease. His ideas were elaborated most fully in *The Prevention of Malaria* (1910). Ross's *Memoirs* (1923) contain a full account of his career until then, including his bitter priority dispute with the Italian parasitologist Battista Grassi over the discovery of the malaria transmission cycle. Ross moved to London in 1912, where eventually a Ross Institute (now part of the London School of Hygiene and Tropical Medicine) was created in his honour. He also wrote novels, poems and mathematical works. See also **Grassi, Giovanni Battista (1854–1925)**.

Ross seemed to thrive on controversy, and he never tired of reiterating the importance of his own work on malaria. At the same time, he could be generous in support of other scientists whom he believed had been unfairly treated, and he campaigned for greater financial rewards for scientific workers. He edited the journal *Science Progress* for many years.

ROTAMETER. See **Flow Measurement**.

ROTATION AXIS. A symmetry element possessed by certain crystals, whereby the crystal can be brought into a physically equivalent position by rotation about an axis which can be onefold, twofold, threefold, fourfold, or sixfold, according to whether the crystal can be brought into self-coincidence by the operations of rotation through 360, 180, 120, 90, or 60 degrees about the rotation axis. See also **Mineralogy**.

ROTATION (Dynamics). A body is said to rotate when all of its particles move in circles about a common axis with a common angular velocity. This motion may be either free or constrained, as illustrated, respectively, by the earth turning on its axis, and by a flywheel or a pendulum.

If one twirls an umbrella about its handle, it tends to open. This is because the centrifugal forces exert torques tending to throw the stays outward on their pivots. Through any point of a rigid body there are at least three lines, mutually perpendicular, about which the body would rotate without any such centrifugal torque. It may be shown that the moment of inertia of the body with respect to any one of these lines is either a maximum or a minimum as regards all lines through the given point. They are called principal axes. In general there is only one line about which a free body will rotate permanently; it is the principal axis of greatest moment of inertia through the center of mass. A body constrained to rotate about an arbitrary axis will, when released, tend to change its motion so as to rotate about this permanent axis, but the adjustment is complicated by precession, so that the body may "wobble" like a badly thrown discus.

If a free body, at rest, is given a sudden push along some line not through the center of mass, it begins to rotate about some other line beyond the center of mass and perpendicular to the applied force. This line is the axis of instantaneous rotation. It is only a temporary axis, the rotation being at once transferred to an axis through the center of mass. The line mutually perpendicular to the instantaneous axis and to the line of the force passes through the center of mass, and its intersections with the other two lines are conjugate points, having the same relation as the center of oscillation and the center of suspension of a rigid pendulum. If the push is given in line with the center of mass, the axis of instantaneous rotation is at infinity, and the motion is then one of pure translation.

A torque applied so as to tend to change the axis about which a body is rotating results in the peculiar behavior known as precession. The angular momentum of a rotating body is the product of its angular velocity by its moment of inertia about the axis of rotation. The kinetic energy associated with rotational motion is equal, in absolute units, to $\frac{1}{2}$ the product of the moment of inertia by the square of the angular velocity — a formula analogous to that for kinetic energy of linear motion.

ROTATION (Earth). See **Earth**.

ROTATION-REFLECTION AXIS. A symmetry element possessed by certain crystals, whereby the crystal is brought into self-coincidence by combined rotation and reflection in a plane perpendicular to the axis of rotation. Rotation-reflection axes may be onefold, twofold, threefold, fourfold, or sixfold, according to whether the rotation which, with the reflection, brings the crystal into self-coincidence is through an angle of 360, 180, 120, 90, or 60 degrees.

ROTATORIA *(Rotifera)*. The wheel animalcules, minute animals with a circlet of cilia at one end of the body, whose movements in some species give the appearance of rotation to the entire disk. They live in water, even in the small quantities found in matted vegetation and temporary pools, and are adapted to withstand long dry periods in such situations. The group is a phylum of minor importance. See Fig. 1.

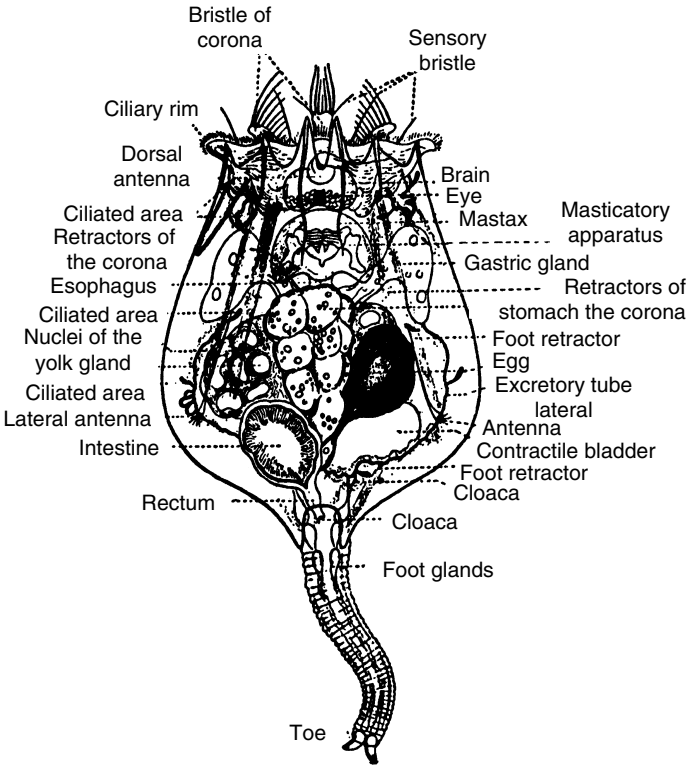

Fig. 1. Sectional diagram of a rotifer. (*Wesenburg-Lund*.)

Although rotifers are minute their bodies are complex in structure. The body wall consists of an external cuticle and a syncytial ectodermal layer which bounds the internal cavity. There are no muscle layers but bands of muscle are present. The alimentary tract (digestive system) is tubular and includes a pharynx with an elaborate grinding apparatus, known as the mastax, an expanded stomach, with a ciliated (cilia) lining, and a short intestine. Near the anus is an expanded cloaca, which receives the ducts of the excretory and reproductive systems. The essential unit of the excretory system is the flame cell, like that of flatworms. The pair of ducts bearing these cells empty into a contractile vesicle or bladder. Reproduction in this phylum is complex, owing to the frequent occurrence of parthenogenesis and to the adjustment of the life cycle to fluctuating environmental conditions.

Some authorities regard the rotifers as a phylum and others associate with them two other forms of animals, making each of the three groups a class in the phylum *Rotifera*, also named *Trochelminthes*.

ROTIFERS. See **Rotatoria**.

ROUNDING. The process of approximating to a number by omitting certain of the end digits, replacing by zeros if necessary, and adjusting the last digit retained so that the resulting approximation is as near as possible to the original number. If the last digit is increased by unity the number is said to be rounded up; if decreased by unity it is rounded down. Thus, if the number 0.04645 were to be rounded to three significant Figures, it would be rounded up to 0.0465, since the digit dropped is 5 (or greater).

ROUNDWORMS. See **Nematodes**.

ROUS, FRANCIS PEYTON (1879–1970). Francis Rous was an American pathologist who demonstrated that cancer tumors could be caused by viruses.

Francis Peyton Rous was born in Baltimore, Maryland in 1879. He studied medicine at Johns Hopkins University, under Sir William Osler, and graduated MD in 1905. Rather than pursuing a career in clinical medicine he switched to the study of pathology, and accepted a post at the University of Michigan working as assistant to A. S. Warthin.

In 1909 Simon Flexner, the then Director of the Rockefeller Institute for Medical Research in New York, persuaded Rous to join the staff of the Institute, and there he spent the rest of his working life. He began research on the problem of cancer, although his friends advised him not to study this complex disease. In 1910 and 1911 Rous published a number of papers in which he suggested that tumors occurring in chickens had been induced by a virus, and that the cancer could be transplanted from one chicken to another. This became known as the *Rous sarcoma virus*. In the following three years his research with J. B. Murphy appeared to establish that a virus could cause cancer. This concept caused great controversy; at the time it was widely held that cancers were not infectious. Disheartened by this skeptical reception of his work, Rous turned his attention to other medical problems. See also **Cancer and Oncology**; **Flexner, Simon (1863–1964)**; and **Oncogenic Viruses**.

During World War I, Rous in collaboration with Joseph Turner and Oswald Robertson worked on the problem of blood transfusion. They searched in vain for viable substitutes for blood, but Rous and Turner perfected a method for preserving and storing human blood cells using a weak solution of gelatin — the Rous–Turner solution. Robertson then implemented this method of preservation while serving overseas in Belgium with the British Army, thereby establishing the first ever blood bank. This research on blood inspired Rous to examine in more detail the role of the liver and gallbladder in the blood cycle.

In 1934 Rous returned to cancer research following the discovery by R. E. Shope of the cancer-causing papilloma virus in cottontail rabbits. This supported Rous' findings made two decades earlier. His subsequent research led to greater understanding of the mysteries of cancer, and in light of new discoveries in molecular biology his concept of the viral origin of cancer was finally recognized as a milestone in medicine, rather than a curiosity or anomaly. As a symbol of this change in 1966, at the age of 86, Rous was awarded the Nobel Prize for Medicine or Physiology, which he shared with Charles Brenton Huggins. See also **Papillomaviruses**.

After his retirement he continued to work at the Rockefeller Institute. Away from his laboratory Rous was a keen naturalist and author; as an undergraduate he wrote a regular 'Flower of the Month' column for a Baltimore newspaper, and for 46 years he was editor of the *Journal of Experimental Medicine*. He died of abdominal cancer in February 1970.

CLAIRE E. J. HERRICK, London, UK

ROUTINE (Computer System). A set of coded instructions arranged in proper sequence to direct a computer to perform a desired operation or sequence of operations. A subdivision of a program consisting of two or more instructions that are functionally related; therefore, a program.

Diagnostic Routine. A routine used to locate a malfunction in a computer, or to aid in locating mistakes in a computer program. Thus, in general, any routine specifically designed to aid in debugging or trouble-shooting.

Executive Routine. A routine that controls loading and relocation of routines and in some cases makes use of instructions not available to the general programmer. Effectively, an executive routine is part of the machine itself. Synonymous with monitor routine; supervisory routine and supervisory program.

Heuristic Routine. A routine by which the computer attacks a problem not by a direct algorithmic procedure, but by a trial and error approach frequently associated with the act of learning.

Interpretive Routine. A routine that decodes and immediately executes instructions written as pseudocodes. This is contrasted with a compiler that decodes the pseudocodes into a machine language routine to be executed at a later time. The essential characteristic of an interpretive routine is that a particular pseudocode operation must be decoded each time it is executed. Synonymous with interpretive code.

Service Routine. A broad class of routines which are provided at a particular installation for the purpose of assisting in maintenance and operation of the computer as well as the preparation of programs as opposed to routines for the actual solution of production problems. This class includes monitoring or supervisory routines, assemblers, compilers, diagnostics for computer malfunctions, simulation of peripheral equipment, general diagnostics and input data. The distinguishing quality of service routines is that they are generally tailored so as to meet the servicing needs at a particular installation, independent of any specific production type routine requiring such services.

Tracing Routine. A diagnostic routine used to provide a time history of one or more machine registers and controls during the execution of the object routine. A complete tracing routine would reveal the status of all registers and locations affected by each instruction, each time the instruction is executed. Since such a trace is prohibitive in machine time, traces that provide information only following the execution of certain types of instruction, are more frequently used. Furthermore, a tracing routine may be under control of the processor, or may be called in by means of a trapping feature.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ROUX, PIERRE PAUL ÉMILE (1853–1933). Pierre Roux was a French medical bacteriologist, key experimenter in the development of Pasteur's rabies treatment, discoverer of the diphtheria exotoxin, and director of the Institut Pasteur 1904–1933.

Raised by his widowed mother in Confolens, France, Émile Roux began his medical studies in the 1870s at Clermont-Ferrand, where he took a post as laboratory assistant to Émile Duclaux, then chemistry professor in the Faculty of Sciences. He continued his clinical studies in Paris. Before finishing his thesis there, he was asked by Duclaux to help him develop a course in bacteriology at the Sorbonne. It was also Duclaux who later introduced Roux to Pasteur, at the time that Pasteur was embarking on his campaign against microbial diseases. Pasteur himself did not have a medical degree, and as he was hoping to begin experiments on living animals, he needed an assistant who was at least experienced in administering injections. Roux, on Duclaux's recommendation, began working with Pasteur in 1878. See also **Pasteur, Louis (1822–1895)**.

Roux became one of Louis Pasteur's leading collaborators and made key technical contributions to many of Pasteur's famous successes, including the vaccines against anthrax and chicken cholera, and the treatment for rabies.

In 1888 he began, with Alexandre Yersin, his research on diphtheria. Together they identified the toxin produced by the bacillus and its role in producing the symptoms of the disease. This was the first demonstration of a bacterial exotoxin. Later Roux, with Louis Martin, used the toxin to develop antidiphtheria serum, which was used to treat diphtheric children in 1894. See also **Yersin, Alexandre (1863–1943)**.

Though privately he found himself in conflict with Pasteur over issues of technique and ethics, he was unwavering in his loyalty to the Institut Pasteur. In 1904, following the death of his old friend Émile Duclaux, he became director of the Institut Pasteur, a post he held until his own death in 1933.

SUZANNE BOARD, Toronto, Ontario, Canada

ROUX, WILHELM (1850–1924). Wilhelm Roux was a German anatomist who did fundamental work in experimental embryology, for which he coined the concept of developmental mechanics (Entwick-elungsmechanik).

Roux, who came from a Huguenot family, was the son of a fencing teacher at the University of Jena. From 1873 he studied medicine in Jena, Strasbourg and Berlin. Among his teachers were Ernst Haeckel, Gustav Schwalbe, Friedrich Daniel Recklinghausen and Rudolf Virchow. He graduated in 1877 and then went to Breslau in 1879. Here he was given the position of unsalaried lecturer (Privatdozentur) before being promoted to Associate Professor in 1880 and then Director of the newly founded Institute for Developmental History and Developmental Mechanics in

1889. He also held a chair of anatomy in Innsbruck from 1889 on, and in 1895 became Director of the Anatomical Institute of the University of Halle, a position he held until his death from a stroke in 1924. See also **Haeckel, Ernst Heinrich Philipp August (1834–1919)**; and **Virchow, Rudolf Carl (1821–1902)**.

It was Schwalbe in Jena who put Roux on the track of morphological investigations. In his 1878 dissertation on the branching of blood vessels, "Die Verzweigung der Blutgefäe," he showed how the flow and pressure of blood helped to form blood vessels. Early fame derived from his "Der Kampf der Teile im Organismus" of 1881, where he extended Darwin's natural selection into the field of intercellular relations and the formative processes of bodily organs. This included a concept of 'functional adaptation', which was intended to explain a process that he thought to be essentially guided by nutritional and functional stimuli. After that Roux started to investigate the causal relations in embryogenesis which led him to the formulation of his program of developmental mechanics (Entwickelungsmechanik). The pursuit of this program included the invention of an experimental technology designed to study early formative processes of organisms in relation to cell division. Roux's mechanistic concept was one of mosaic development where cleavage went along with an uneven distribution of germinal qualities onto the developing organs. However, he admitted that regenerative processes in embryonic development did occur that were not in agreement with his ontological conception of the process. The development and popularity of his program was enhanced by controversies Roux engaged in, most notably with the physiologist Eduard Pflüger. With the latter Roux engaged in a debate as to whether the development of a longitudinal axis in amphibians was governed by external mechanic factors (gravity) or by internal processes. Roux also founded two monograph series dedicated to developmental mechanics and the *Archiv für Entwickelungsmechanik*, which continued to appear until 1996.

ROWAN TREE. See **Ash Trees**.

ROWLAND, FRANK SHERWOOD (1927–). An American who won the Nobel Prize for chemistry along with Paul Crutzen and Mario Molina in 1995 for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone.

ROXEL PROCESS. A process for increasing the flame resistance of cotton by chemically modifying the fiber, i.e., by applying a formulation consisting of tetrakis(hydroxymethyl)phosphonium chloride (THPC), triethylolamine, and urea in aqueous solution. These substances cross-link with the hydroxyl groups of the cellulose to form an efficient and durable protective medium. This process is used in the manufacture of blankets, curtains, bed linen, and the industrial safety garments.

ROYAL ANTELOPE. See **Antelope**.

ROYAL JELLY. The food given by worker honeybees to the young larvae during the first 3 days of their existence and to the larvae of queens until they are fully developed. It is a thick white liquid formed in the stomach of the worker by partial digestion of honey and pollen, and is apparently a highly concentrated food. Queen cells are supplied with the material in excess of the needs of the larvae. If conditions within the colony deprive queen larvae of this abundance they fail to become as large, and in some cases they may even develop as intermediate forms between queen and worker. Such individuals may, however, have the instincts of queens and so may mate and lay fertile eggs. The change from royal jelly to a less concentrated food in the case of worker larvae apparently is responsible for the development of worker bees, since both queens and workers may develop from identical eggs. See also **Honey**.

RSA CRYPTOSYSTEM. See **Encryption**.

RUBBER CHEMICALS. Rubber chemicals are materials that are added in minor amounts to rubber formulations in order to improve their properties and make them commercially useful. Raw rubber polymer has very limited practical applications because of tackiness, flow, and other undesirable features. Rubber chemicals are added to assist processing, promote cross-linking, and provide longevity to the part in service. Vulcanizing adjacent polymer chains together by cross-links prevents flow, increases strength, and provides recovery from deformation. The most widely used method of cross-linking polymer chains is by heating with elemental sulfur (vulcanization). Accelerators speed up the reaction of sulfur with polymer to improve the economics of manufacture and prevent degradation that would otherwise occur upon prolonged heating. Peptizers and process aids assist flow during the mixing and shaping operations. Antidegradants protect the part in service from heat, oxygen, ozone, and repeated flexing. Other rubber chemicals function as blowing agents, adhesion promoters, and activators or retarders which modify the onset of cross-linking.

Accelerators and antidegradants are the two main types of rubber chemicals. Alkyl mercaptans are used as polymerization regulators. Organic rubber processing chemicals include: benzothiazoles, sulfenamides, dithiocarbamates, thiurams, substituted p-phenylenediamines, other amines, phenols, and phosphites. In addition to the materials listed above, other organic materials find a minor portion of their use in rubber processing, such as waxes and fatty acids. Also, the rubber industry uses modest amounts of inorganic compounds, notably elemental sulfur, zinc oxide, magnesium oxide, and sodium bicarbonate.

Accelerators of Vulcanization

Vulcanization was first reported in 1839 with the discovery that heating natural rubber with sulfur and basic lead carbonate produced an improvement in physical properties. In 1906, aniline was the first organic compound found to have the ability to accelerate the reaction of sulfur with natural rubber. Various derivatives of aniline were soon developed which were less toxic and possessed increased acceleration activity. See also **Rubber (Natural)**.

Mercaptobenzothiazoles. These compounds form the basis for the largest-volume organic accelerators. 2-Mercaptobenzothiazole (MBT) is prepared by heating aniline, carbon disulfide, and sulfur in an autoclave at elevated temperature and pressure. Tars from the reaction can be removed by taking the crude MBT up in water by making the sodium salt, clarifying the solution, and then precipitating pure MBT with acid. MBT can be oxidized to the disulfide (MBTS) or it can react with zinc oxide to form the zinc salt (ZMBT). MBTS is the largest-volume of the three benzothiazole accelerators. ZMBT is too fast-curing for most dry rubber compounds and is used mainly in latex applications.

Sulfenamides. Sulfenamides are often produced by oxidizing an equimolar mixture of MBT and an aliphatic amine. Alternatively, the *N*-chloroamine can react with the sodium salt of MBT. One sulfenamide, OTOS, uses a thiocarbamyl functionality in place of the benzothiazole group. Sulfenamides do not become active accelerators until the sulfur–nitrogen bond thermally dissociates, providing delayed action before cross-linking occurs. Delayed action is useful in applications which require lengthy processing operations such as joining many layers together to make a tire. Sulfenamides are the primary accelerator used in building tires, making them the largest-volume of all accelerator classes.

Dithiocarbamates. These compounds are prepared by the reaction of dialkyl amines with carbon disulfide in the presence of sodium hydroxide. For use as rubber accelerators, the sodium salts initially prepared are converted to water-insoluble zinc or other metal salts. Dithiocarbamates provide the most rapid cross-linking and, together with the related thiurams, are known as ultra-accelerators. Various metals are used to achieve specific properties. Copper provides low compression set for O-rings and gaskets based on synthetic rubbers. Selenium and tellurium provide good aging and high modulus. Heavy metals such as cadmium and lead do not migrate and have been used in polymer blends although they are being replaced by bismuth. Sodium and piperidine are exceptionally fast-curing and are used in latex operations. Zinc is most frequently used.

Thiuram Sulfides. These compounds, are an important class of accelerator. Thiurams are produced by the oxidation of sodium dithiocarbamates. The di- and polysulfides can donate one or more atoms of sulfur from their molecular structure for vulcanization. The use of these compounds at relatively high levels with little or no elemental sulfur provides articles with improved heat resistance. Producers have introduced ultra-accelerators based on longer-chain and branched-chain amines that are less volatile and less toxic. This development is also motivated by a desire to minimize airborne nitrosamines.

Guanidines. Guanidines were one of the first aniline derivatives used as accelerators. They are formed by reaction of two moles of an aromatic amine with one mole of cyanogen chloride. Diphenylguanidine (DPG) has enjoyed a resurgence in demand as an activator for sulfenamides and a co-accelerator in tire tread compounds which employ silica fillers for low rolling resistance. Guanidines alone show too little activity to be extensively used as primary accelerators.

Thioureas. Thioureas are typically made from primary amines and carbon disulfide. The amine can be ethylamine, butylamine, ethylenediamine, or aniline. The last produces diphenylthiourea which is commonly known as thiocarbanilide. Thioureas are often used as accelerators for polychloroprene (Neoprene) or other rubbers that contain chlorine as reactive cross-linking sites.

Xanthates. These compounds are relatively fast accelerators which are used at low temperature because most examples decompose without cross-linking at higher temperature. Xanthates are produced by reaction of equimolar amounts of alcohol and carbon disulfide in the presence of caustic. The sodium salt is then converted to the zinc compound or oxidized to the disulfide. See also **Xanthates**.

Dithiophosphates. These compounds are made by reaction of an alcohol with phosphorus pentasulfide, then neutralization of the dithiophosphoric acid with a metal oxide. Like xanthates, dithiophosphates contain no nitrogen and do not generate nitrosamines during vulcanization. Dithiophosphates find use as high temperature accelerators for the sulfur vulcanization of ethylene–propylene–diene (EPDM) terpolymers.

Aldehyde-Amines. There is a long history of use of the reaction products of aldehydes and amines. Most such reactions yield a dark-colored liquid mixture containing many different structures. Hexamethylenetetramine (Hexa) is a notable exception, giving an adamantane-type structure with nitrogen atoms replacing carbon at the bridgeheads. Hexa reverts to formaldehyde and ammonia in the presence of water, and is a scorchy accelerator sometimes used in adhesion systems. At one time, aldehyde–amines were used in making hard rubber (ebonite), but this use of rubber has largely been replaced by plastics. Aldehyde–amines find use as accelerators for thiadiazole cures of halogenated polymers.

Health and Safety Factors. To minimize exposure to potentially toxic materials, powders are generally offered with an antidusting agent applied. Many chemicals, including accelerators, can cause skin irritation in sensitive individuals. The availability of pellets, prills, and polymer-encapsulated master batches to minimize worker exposure to chemicals is a service offered by several suppliers. Nitrosamine levels in rubber articles for use by infants are regulated in several countries. Manufacturers of these articles have developed nitrosamine-free compounds. However, great care must be taken in manufacturing and packaging to prevent recontamination of the articles with nitrosamines which are ubiquitous in the environment.

Cross-Linking Agents

Sulfur. The most widely used and economical cross-linking agent is sulfur. It provides rubber articles with high strength and excellent resistance to failure when flexed. Improved resistance to heat can be obtained by reducing the amount of sulfur and increasing the amount of accelerator. This change provides a greater proportion of monosulfide cross-links, which have higher thermal stability than di- and polysulfide cross-links. For optimum dispersion of small amounts of sulfur, some suppliers offer sulfur preblended with magnesium carbonate or in polymeric master batch forms.

In natural rubber compounds, insoluble sulfur is used for adhesion to brass-coated wire, a necessary component in steel-belted radial tires. The adhesion of rubber to the brass-plated steel cord during vulcanization improves with high sulfur levels (~3.5%).

MBSS, DPTH, and the thiuram disulfides are examples. Morpholine disulfide and caprolactam disulfide can also donate one atom of sulfur from their molecular structure for cross-linking purposes. Monosulfide cross-links provide better thermal stability than the sulfur–sulfur bonds in di- and polysulfide cross-links, which predominate when elemental sulfur is used.

Peroxy Compounds. Peroxides give carbon–carbon cross-links, which provide rubber articles with the maximum resistance to heat, oxygen, and compression set. Resistance to compression set is important in applications such as gaskets and O-rings, which must maintain a seal by recovering their initial dimensions after deformation. Peroxides are beneficial in polymer blends or fully saturated polymers that cannot be cross-linked by other methods. Dialkyl peroxides are the principal type of peroxide used in the rubber industry.

Coagents are often used with peroxides to increase the state of cure. Some coagents, such as polybutadiene or multifunctional methacrylates, are used at high levels to form polymer grafts or interpenetrating networks. Other coagents such as triallyl cyanurate, triallyl trimellitate, and *meta*-phenylene bismaleimide are used at low levels to reduce the tendency of the polymer to degrade by chain scission.

The use of peroxides requires special handling precautions and compounding considerations. Compounds containing peroxides must be protected against exposure to air (oxygen) during the high temperature cross-linking process or chain scission and a tacky surface result. Peroxides are oxidizing materials and should be stored away from other rubber chemicals and kept away from heat sources. See also **Peroxides And Peroxide Compounds (Inorganic)**; **Peroxides And Peroxide Compounds (Organic)**.

Multifunctional Hydroxy, Mercapto, and Amino Compounds. These are used to cross-link halogenated polymers. Depending on the lability of the halogen, the cross-linking agents can be capped to reduce reactivity or used in combination with accelerators to increase the rate of reaction. Benzoyl capping is common with hydroxy and mercapto compounds; forming the carbamate by reaction with one equivalent of carbon dioxide is used with diamines.

Quinone dioximes, alkylphenol disulfides, and phenol–formaldehyde reaction products are used to cross-link halobutyl rubbers. In some cases, nonhalogenated butyl rubber can be cross-linked by these materials if there is some other source of halogen in the formulation. Alkylphenol disulfides are used in halobutyl innerliners for tires. Methylol phenol–formaldehyde resins are used for heat resistance in tire curing bladders. Bisphenols, accelerated by phosphonium salts, are used to cross-link fluorocarbon rubbers. 2,5-Dimercapto-1,3,4-thiadiazole derivatives, accelerated by amines, are used to cross-link chlorinated polyethylene. Polyisobutylene containing brominated *para*-methylstyrene cure functionality can be cross-linked in polymer blends with dimercapto-1,3,4-thiadiazole derivatives accelerated with thiuram disulfides. Trithiocyanuric acid is suggested for use in polyacrylates containing a chlorine cure site and in epichlorohydrin rubbers.

Diamine curatives were the first cross-linking agents for fluorocarbon rubbers. They are corrosive to mild steel molds and have been replaced in many applications by the bisphenol or other more recent cure systems. Nevertheless, some diamines are still used for food-contact applications of fluorocarbon rubbers and in zinc-free cures of halobutyl rubbers for

pharmaceutical stoppers. Methylene dianiline and triethylene tetramine are cross-linking agents for ethylene–acrylic elastomers.

Activators and Retarders

Zinc oxide is a common activator in rubber formulations. It reacts during vulcanization with most accelerators to form the highly active zinc salt. A preceding reaction with stearic acid forms the hydrocarbon-soluble zinc stearate and liberates water before the onset of cross-linking.

For increased solubility to prevent bloom, shorter-chain carboxylic acids or zinc carboxylates can be substituted. The use of chain-branched carboxylic acids reduces the tendency for the formulations to lose sulfur cross-links or revert upon prolonged heating. Translucent articles such as crepe soles can use a zinc carboxylate or employ zinc carbonate as a transparent zinc oxide.

Magnesium oxide is a typical acid scavenger for chlorinated rubbers. Compounds containing zinc oxide or magnesium oxide may tend to swell upon immersion in water. These inorganic salts have some water solubility and osmotic pressure causes the vulcanizates to imbibe water to equalize pressure. As such, vulcanizates tend to swell more in fresh (distilled) water than in salt water. To minimize water swell, insoluble salts such as lead oxides can be substituted. Because of the health concerns associated with lead, there is much rubber industry interest in other acid acceptors, such as synthetic hydrotalcite.

Retarders were originally arenecarboxylic acids. These acidic materials not only delay the onset of cross-linking but also slow the cross-linking reaction itself. The acidic retarders do not function well in black-filled compounds because of the high pH of furnace blacks. Modern retarders are designed to scavenge the most reactive accelerator precursors and are known as prevulcanization inhibitors. This technique delays the onset of cure without affecting the speed of the main cross-linking reaction.

Processing Agents

Natural rubber must be reduced in viscosity in order to obtain workable compounds. Many different chemical peptizers have been employed over the years for this purpose, including arenemercaptans, arenesulfonic acids, pentachlorothiophenol [CAS: 133-49-3] or its zinc salt, and dithiobisbenzanilide [CAS: 135-57-9] or its zinc salt. Dithiobisbenzanilide with an activator and clay diluent is the preferred peptizing agent for natural and synthetic rubbers. The viscosity of natural rubber and synthetic polyisoprene can be reduced by mechanical shear alone, but using a peptizer makes the viscosity reduction during mixing less sensitive to variations in time and temperature, providing uniformity in viscosity from batch to batch.

Processing aids also assist flow but do so by physical rather than chemical means. Processing aids may be separated into two general categories: external and internal. External processing aids have a polar functionality at one end of the molecule and a long-chain, oleophilic tail. These materials tend to migrate to surfaces where the polar head becomes adsorbed and the oleophilic tail allows the hydrocarbon polymer to slide along the coated surface with less effort. The surface can be either the metal walls of the processing equipment or the filler particles introduced into the rubber matrix. Internal processing aids such as oils or waxes increase melt flow. They reduce the viscosity of the rubber matrix by allowing polymer chains to slide past one another with greater ease. Many high performance processing aids are proprietary mixtures of materials with both internal and external functions.

Homogenizing agents are higher molecular weight versions of external processing aids. They are useful in polymer blends to reduce the domain size of the dispersed polymer phase. Homogenizing agents can be particularly useful in blending polymers having dissimilar solubility parameters.

Vulcanized vegetable oils are processing aids that flow under shear but not under heat. They are made by heating unsaturated soybean or rapeseed oil with either sulfur monochloride, S_2Cl_2, or elemental sulfur. The products cross-linked with S_2Cl_2 are white powders. They are used as a main component of erasers to allow greater ability to lift a pencil mark without smearing (noodling). The sulfur-vulcanized products are dark brown solids, used in soft roll compounds to help hold in liquid plasticizers and assist the grinding of the rubber-covered roller to concentricity.

Other processing aids are tackifiers or antitack agents. Tackifiers are resinous products which help a multilayered article stick together before it is vulcanized. Tackifiers may be aliphatic or aromatic materials derived from coal, petroleum, or renewable sources. A variety of additives are used to keep unvulcanized sheets of rubber from sticking together and can be applied by dusting, dipping, or spraying.

Other Rubber Chemicals

Blowing agents are used to create cellular products and have been reviewed. Closed-cell sponge is used for minimal water absorption in applications such as wet suits or automotive weather-strip.

Adhesion promoters are used to bond rubber to brass-plated steel cord in radial tires or conveyor belting. A gradual decrease in stiffness from steel to rubber is desired.

Dispersing agents such as sodium salts of polymerized alkylarenesulfonates [CAS: 9084-06-4] or [CAS: 8061-51-6] are surface-active agents which only weakly reduce the surface tension. Wetting agents such as sodium lauryl sulfate [CAS: 151-21-3] more strongly reduce surface tension. Dispersing agents are used when a large quantity of surface area must be treated with surfactant without the mixture entrapping bubbles; wetting agents are used to adjust the amount of fabric penetration or the flow of the latex mixture. Thickeners are used to prevent the settling of additives and can be organic polyelectrolytes or inorganic smectites [CAS: 12199-37-0]. Colloidal stabilizers such as casein are also used but are falling into disfavor because of the desire to avoid protein which can cause anaphylactic shock in sensitive individuals. Various antifoams prevent air entrapment and preservatives help avoid growth of microbes that could create slime or odors.

Flame retardants such as α-alumina trihydrate [CAS: 14762-49-3] can be added to latex-based foamed carpet backing; a combination of antimony oxide [CAS: 1309-64-4] and chlorinated paraffins is used in dry rubber.

Organofunctional silanes are used to promote polymer-to-filler bonding with clay or silica fillers. Vinyl silanes are used in peroxide-cured wire insulation to promote stronger bonding with calcined clay fillers. Mercapto silanes are used to treat kaolin clay in sulfur-cured compounds.

Consumer articles often use colorants, reodorants, or finishing agents. Carbon black provides the best technological properties for industrial applications, so most rubber articles are black. Red iron oxide or other inorganic pigments are used to color mineral-filled articles. Organic coloring materials provide brighter colors, although special compounding or processing may be required to maintain the color. Reodorants can be used to provide a more pleasing aroma for consumer articles. Finishing agents can be applied for a more attractive surface appearance. See also **Carbon Black**.

RUBBER, NATURAL. [CAS: 9003-31-0]. *Natural rubber* is the name applied to the polymer *cis*-1,4-polyisoprene obtained chiefly from the

latex of the *Hevea brasiliensis* tree.[1] Natural rubber is a vital, strategic, and irreplaceable raw material used in enormous quantities by the commercial, medical, transportation, and defense industries. At least 40,000 different products and over 400 medical devices contain natural rubber. Primarily due to its molecular structure and high molecular weight (>1 million g/mol), natural rubber has excellent performance properties, such as elasticity, resilience, heat dispersion, abrasion resistance and cold-malleability, which cannot easily be mimicked by artificially produced polymers derived from petroleum.

The rubber tree grows best in a warm, damp, uniform climate, with temperatures remaining in the 24–28 °C (75-82 °F) range year-round, humidity above 70%, and a well-distributed rainfall of 1800–2000 mm/yr (71-79 inches) falling on well-drained soils. It is usually limited to areas extending 15° on either side of the equator, where it can survive up to an altitude of 300 meters (984 feet). The average rubber trees stand about 40–50 feet (12–15 meters) high. Originally, the tree grew wild in the Amazon valley, and in 1876 Sir Henry Wickham collected some 70,000 seeds at the request of the India office and brought them to Royal Botanic Gardens at Kew, in England. About 2000 of the seeds were successfully cultivated into plants, some of which were sent to Peradeniya in Sri Lanka and to Malaysia via the Singapore Botanical Gardens. Later shipments were sent to Indonesia, and by 1880 *Hevea* seedlings were widely distributed in Southeast Asia.

The rubber tree quickly flourished in Malaysia, where large areas of jungle were cut down and planted with rubber trees. Henry Ridley, who was appointed Director of the Singapore Botanical Gardens in 1888, did perhaps more than anyone else to encourage the planting of rubber, and in the 1890s devised modern methods of tapping that resulted in the economic harvesting of the rubber crop. Further development, by John Parkins, of the coagulation process in which dilute acid was added to the latex also helped to develop the economic viability of the plantation industry.

Rubber comes from the tree as a milky white fluid, which is a colloidal suspension of rubber in a liquid consisting mostly of water. The tree is tapped by well-trained workers, who use a sharp-edged tool, and the cutting action goes at an angle of 30° from top left to bottom right. It is important that the rubber latex-bearing cells be cut, but that the blade not wound the inner cambium layer, as this would harm the tree. A cup is hung below the cut to collect the white, milklike latex, which contains about 35% rubber, the remainder being water, protein, resins, organic materials, and other plant substances.

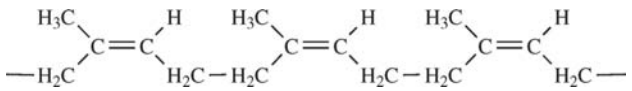
The yield of the *Hevea* tree can be increased by applying chemicals to the bark. These include 2-chloroethylphosphonic acid, which supplies small quantities of ethylene gas. This type of chemical is applied in a high-viscosity liquid form, usually mixed with palm oil or other diluent. The function of it is to stabilize the latex so that it continues to flow for a longer time and thus increases rubber yield. Because of the higher rubber yield per tapping operation, the cost of tapping labor is reduced. When stimulants are used, the tree is given a longer rest period between tappings to avoid diseases that would eventually kill it. See also **Plant Growth Modification and Regulation**.

Rubber is one of the most important materials on earth, an essential component for countless industries, technologies and machines. It has captured the fancy of nations — Japan's attack on Pearl Harbor gave the empire control over 90% of the world's natural rubber supply — and tycoons — Thomas Edison performed some 17,000 rubber breeding experiments in his last years and Henry Ford created a massive, doomed plantation in South America named Fordlandia. While synthetic rubber is a multi-billion dollar industry, countless applications still demand the real thing, and virtually all the world's natural rubber comes from plantations in Southeast Asia.

Properties of Natural Rubber

Chemically, natural rubber or *cis*-polyisoprene, has a broad molecular-weight distribution, ranging from several million to about one hundred thousand.

[1] It is alleged that English scientist Joseph Priestly observed that the material could be used for rubbing out lead pencil marks and thus gave the material the name rubber. ("Introduction to the Theory of Perspective," Joseph Priestly, 1835.)



Natural rubber is soluble in practically all aromatic and aliphatic hydrocarbons and particularly in halogenated hydrocarbons. When cements and solvent adhesives are made using natural rubber, methylethylketone (MEK) frequently is used to reduce viscosity. Although MEK is not a solvent, it tends to disperse large molecular particles, resulting in lower-viscosity dilution. Crude rubber is decomposed by heat and can be cyclized at 250 °C. It can easily be hydrogenized and reacts readily with halogens. The stress-strain properties of natural rubber are the best of all the elastomeric polymers. In vulcanized films made by the latex process, the tensile strength may exceed 6000 pounds per square inch (41 mPa), and ultimate elongation is as high as 700% or more.

Natural rubber is readily attacked by oxygen. Copper and manganese, if present in amounts greater than the specified 0.001%, greatly accelerate oxidation. There are, however, naturally occurring antioxidants in natural rubber that help preserve it until vulcanization. All vulcanized natural-rubber products contain added antioxidants to ensure satisfactory life.

Rubber burns quite readily and generates more than 10,000 cal/g. The specific gravity of rubber is 0.934, a property utilized in concentrating natural-rubber latex by the centrifuge process. The serum, which is mostly water and has a specific gravity of about 1.0, tends to separate readily from the rubber. The liquid concentrated latex is used in making foam rubber, dipped goods, adhesives, and carpet backing for nonwoven carpets. An industry has developed around this application, which involves spreading foamed latex onto the underside of carpeting, making an integral carpet-foam system.

Crystallization. Raw natural rubber may freeze or crystallize during transit or prolonged storage, particularly at subzero temperatures. The rubber then becomes hard, inelastic, and usually much paler in color. This phenomenon is reversible and must be differentiated from storage hardening. The rate of crystallization is temperature-dependent and is most rapid at −26 °C (−14.8 °F). Once at this temperature, natural rubber attains its maximum crystallinity within hours, and this maximum is no more than 30% of the total rubber.

During crystallization, rubber molecules associate into a crystal array. As the storage temperature is increased, thermal motion of the molecules restricts crystallization until, at temperatures above 20 °C (68 °F), the rate is near zero. Observed melting temperatures of natural rubber depend markedly on the temperature at which crystallization occurs. Figure 1 shows a general trend in which the higher crystallization temperatures result in higher crystal melting temperatures. The wide range of melting temperatures exhibited by rubber crystallized at low temperature is a reflection of a polycrystalline texture that contains a large number of small crystals. The generally accepted crystal melting temperature of natural rubber is 30 °C (86 °F). Crystals with high melting temperature are fewer and larger than those formed at lower temperatures and take a relatively long time to form.

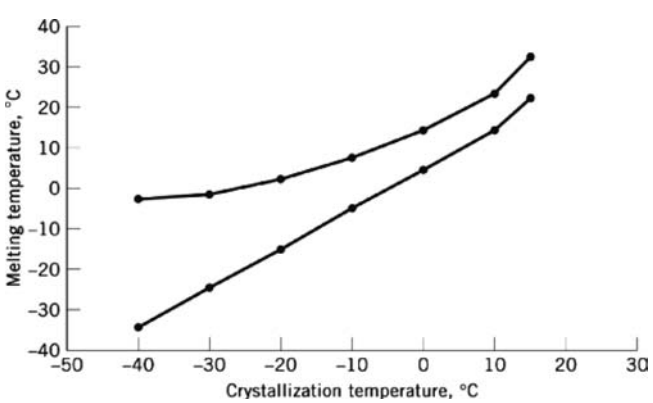


Fig. 1. Relation between crystallization temperature and melting temperature for natural rubber.

Frozen rubber is normally thawed by storing in a hot room at 40–50 °C (104-122 °F). Because rubber is a relatively poor thermal conductor, melting is governed by the slow conduction of heat through the bale. As the rubber melts, distinct regions of thawed and frozen rubber become apparent and a sharp boundary can be distinguished between the two. Palletized frozen rubber can take a considerable time to thaw; in a hot room at 50 °C (122 °F) it takes about two weeks for the center of the pallet to reach 30 °C (86 °F). Dismantling frozen pallets and thawing bales singly or in well-spaced stacks obviously helps, but this can be a costly operation. Methods of dealing with frozen rubber vary from factory to factory, and consumer experience determines conditions appropriate to particular needs or limitations.

Storage Hardening. Storage hardening is a slow, irreversible increase in the Mooney viscosity of natural rubber that occurs during storage and transport; an increase of some 30 Mooney units is typical for nonviscosity stabilized grades. Hardening is thought to result from the interaction between the nonisoprenic groups, such as aldehydes, present on the rubber molecule to form cross-links, and as the rubber hardens, the extent of long-chain branching and gel increases. Storage hardening is also accelerated by high temperature and low humidity.

Many mechanisms of storage hardening are proposed and all have been reviewed. One of the most favored is the bimolecular aldol reaction between rubber aldehyde groups. Nevertheless, the involvement of rubber-bound epoxide groups has also been postulated in cross-link formation, though this was later refuted. The hardening mechanism is certainly catalyzed by the presence of amino acids in the latex; however, the question of what constitutes a definitive mechanism for storage hardening has yet to be resolved.

Nevertheless, storage hardening can be effectively inhibited by the addition of a reagent such as hydroxylamine, which produces an oxime via a condensation reaction and thus blocks the cross-linking process. For viscosity-stabilized grades (CV) produced in this way, the viscosity increase during transit and storage is negligible.

Cure Characteristics. Methods of natural rubber production and raw material properties vary from factory to factory and area to area. Consequently, the cure characteristics of natural rubber can vary, even within a particular grade. Factors such as maturation, method and pH of coagulation, preservatives, dry rubber content and viscosity-stabilizing agents, eg, hydroxylamine-neutral sulfate, influence the cure characteristics of natural rubber. Therefore the consistency of cure for different grades of rubber is determined from compounds mixed to the ACS1 formulation. The ACS1 formulation is as follows: natural rubber, 100; stearic acid, 0.5; zinc oxide, 6.0; sulfur, 3.5; and 2-mercaptobenzothiazole (MBT), 0.5.

Plasticity Retention Index. The oxidation behavior of natural rubber may affect both the processing characteristics and final vulcanizate performance, and the plasticity retention index (PRI) test can be used to give an indication of both. Natural antioxidants present in natural rubber give some protection and a measure of the efficacy of protection is given by PRI. $PRI\% = P_{30}/P_o \times 100$, where P_0 is the initial Wallace plasticity and P_{30} is the plasticity after aging in an oven at 140 °C (284 °F) for 30 min. During mastication, rubber with high values of PRI tends to break down less rapidly than rubber with a low value; normally there is little significant difference between rubbers with a PRI above a value of 60%. PRI can also be correlated with the aging performance of natural rubber vulcanizates. For example, raw rubber with a large PRI value gives better high temperature aging resistance, even in a formulation containing two parts of *p*-phenylenediamine antioxidant.

Chemistry and Technology

Natural rubber as obtained from *Hevea brasiliensis* is *cis*-1,4-polyisoprene with small amounts of nonrubber produced by the tree. Although the double-bond structure is useful for chemical modification purposes, it does not benefit natural rubber's heat resistance. Natural rubber is relatively unstable compared to the more modern almost fully saturated elastomers, such as EPDM rubber. In terms of physical properties, the strain crystallizing nature of natural rubber gives it high tensile and tear strengths, and it exhibits both low heat buildup and low rolling resistance. These latter two features make it especially attractive for tire manufacture. However, unless modified, it shows extensive swelling in oils, is relatively permeable to gases, and is not generally suitable for damping applications. In the majority of applications, natural rubber is used in blends and, until fairly recently, remarkably little was known about the distribution of cross-links in such blends. Modern techniques have been adapted to look into this subject, with a consequent improvement in properties brought about by achieving a better balance of cross-links in the blend. In latex applications, a large proportion of the industry has moved out to the Far East, for example to Malaysia, if only because it is logical to ship the final product to the end user country rather than the latex, which contains 40% water. In general terms, the proportion of natural rubber in the total rubber market is slowly increasing, partly because it is technically necessary in tires for radial sidewalls, low rolling resistance, and low temperature behavior, and partly because the rubber industry is moving to the Far East, where the bulk of natural rubber is grown and is more easily available.

Compounding and Vulcanization. Crude rubber in the raw state has few applications with the exception of crepe soles for shoes. To make commercial rubber products, the material must be mixed with a variety of chemicals and vulcanized into desirable end shapes. Charles Goodyear discovered in 1839 that adding sulfur to rubber and heating the mixture greatly enhances the physical properties of rubber. The material no longer becomes tacky in warm weather and in cold weather it does not become brittle. The material is much tougher, and the quality of products made this way results in service for a much longer period of time. In addition to sulfur, which crosslinks the large rubber molecules and makes it a giant organic molecule, zinc oxide, organic accelerators, antioxidants, reinforcing pigments, and other processing aids are used in compounding rubber for useful vulcanized products.

The function of the antioxidant is to improve service life of the product against such well-known degrading agents as oxygen, light, and nitroso compounds. One theory is that the antioxidant selectively reacts with the degrader, slowing down its reaction with the rubber molecule, which would result in scission and eventually poorer physical properties. During recent years, considerably aggravated by air pollution, degradation of vulcanized rubber by small quantities of ozone (a few parts per million) in the air has become a serious problem. Ozone has little noticeable effect on unstretched rubber, but even under slight stretch it causes cracks in the surface, which grow perpendicularly to the direction of extension. Hundreds of different antioxidants and antiozonants are employed, amine and phenol complexes being the basis of most. See also **Antioxidant**.

Accelerators act as catalysts of vulcanization, but, unlike most catalysts, they undergo chemical change during the reaction. Benzothiazyl disulfide is one of the oldest types, dating back to 1925, but it still accounts for the greatest use in the industry today. Besides the thiazole types, other popular accelerators are sulfenamides, aryl guanidines, dithiocarbames (extremely fast accelerators used mostly in latex compounds), and thiurams (also very fast and often used as a secondary accelerator to hasten the vulcanization rate). Accelerators also contribute to improved ageing properties of the end product. See also **Rubber Chemicals**.

Stearic acid is an activator of vulcanization, as is zinc oxide, both reacting to form zinc stearate, which enhances the activity of the organic accelerators. Zinc stearate is impractical to add directly to the rubber because its slippery, lubricating nature makes it difficult to mix in the batch.

With an accelerated system, a simple network structure with dialkenyl mono- and disulfide crosslinks and conjugated triene units as main-chain modifications is obtained:

With an unaccelerated sulfur-natural-rubber system, the poor crosslinking efficiency results in sulfur being incorporated into the rubber network as long polysulfide crosslinks, cyclic monosulfides, and vicinal crosslinks, which are very close together and act physically as a single cross-link. See Fig. 2.

It is theorized that between the complex network structure of the unaccelerated system and the simpler network structure of the accelerated system, structures made up of the two models represent natural-rubber vulcanizates made at various times and temperatures of cures, with different reactant concentrations, and showing the effects of other variants.

At any given degree of crosslinking, the tensile strength is highest with polysulfide bonds. High elongation at break is obtained by

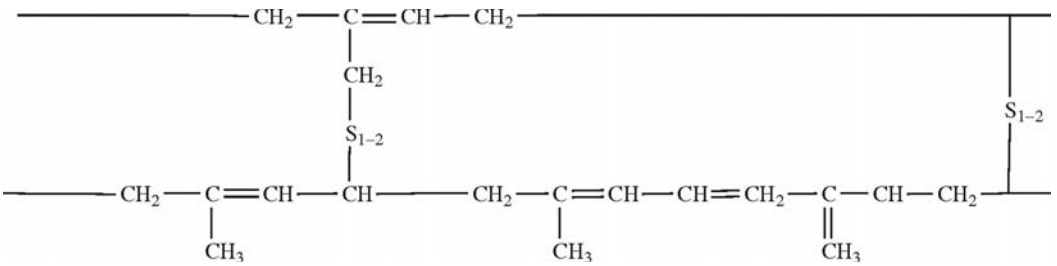

Fig. 2. Accelerated system.

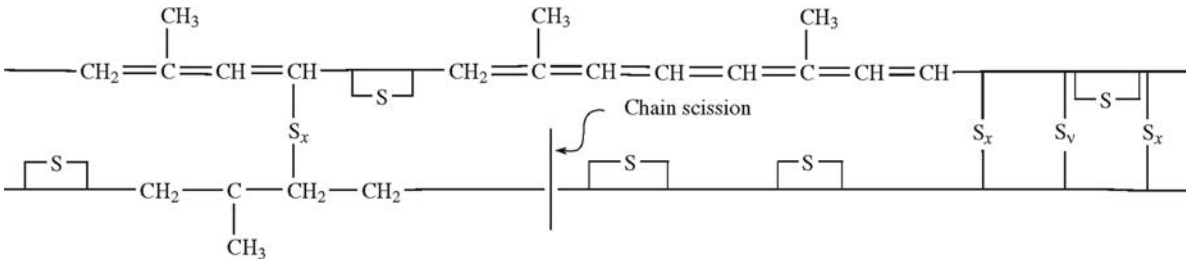

Fig. 2. Unaccelerated system.

TABLE 1. PROPERTIES OF CARBON BLACK-FILLED NATURAL RUBBER VULCANIZATES WITH VARIOUS CURE SYSTEMS[a]

[e] Plus dicumyl peroxide, 2.5 parts; Flectol H, 2 parts.
[f] Plus Novor 950, 6.7 parts; Caloxol, 5 parts; zinc 2-methyldithiocarbamate, 2 parts; zinc 2-mercaptobenzimidazole, 2 parts; 2,2,4-trimethyl-1,2-dihydroquinoline (polymerized), 2 parts.
[g] IRHD = International Rubber Hardness Degrees (ISO 48).
[h] To convert MPa to psi, multiply by 145.
[i] A measure of rebound resilience (BS903: Pt. A8: 1990, Method A).
[j] HBU = heat buildup, a measure of temperature rise and resistance to fatigue (ISO 4663/3).

slightly decreasing the crosslinking action. If lower elongation is required, slightly excessive crosslinking is used, usually accompanied by higher tensile strength. Vulcanization of rubber decreases its solubility in solvents, and this property frequently is used as a qualitative measure of cure.

Vulcanization by sulfur accounts for practically all the commercial products. Basically, a high sulfur, low accelerator (2.5 parts phr of sulfur and 0.5 part of sulfenamide) system results in a mainly polysulfidic cross-linked rubber that has a high tensile strength and exhibits good dynamic performance, but has relatively poor aging characteristics, even with an antidegradant present (Table 1). On the other hand, an efficient vulcanizing (EV) system based on low sulfur and high accelerator levels (see Table 1) leads to a mainly monosulfidic cross-linked network with consequent improvement in compression set and aging characteristics, but less good tensile and tear properties and inferior dynamic performance. Between them there are a multitude of semi-EV systems that fall between the high sulfur–low accelerator and low sulfur–high accelerator recipes and give a compromise in properties, as indicated in Table 1. For maximum heat resistance, as distinct from oxidative aging, there are also the Peroxide and Novor systems. The peroxide vulcanizing agents, eg, dicumyl peroxide [CAS: 80-43-3], give direct carbon–carbon cross-links for extreme thermal stability. However, such systems have little or no scorch safety, unless

a free-radical trap is incorporated, and they tend to require very long cure times. For example, about six times the half-life of the peroxide is needed to ensure complete decomposition; otherwise, aging performance is reduced. Further, *p*-phenylenediamine-type antioxidants are to be avoided, as they reduce efficiency of the cure. The virtue of peroxide vulcanization of natural rubber lies in improved heat resistance and good aging, creep, and compression set. In general, however, the vulcanizates suffer from poor low temperature crystallization performance compared to a conventional sulfur cure, and also have inferior tensile and tear properties. Urethane cross-linking systems, eg, Novor 950 (see Table 1) are also extremely heat resistant, but exhibit inferior tensile and dynamic properties compared to conventional sulfur-cured vulcanizates. One added virtue is that they can be used in conjunction with sulfur systems to produce an excellent compromise according to the ratios used.

Ultrahigh-frequency (UHF) energy may be used for preheating and precuring rubber compounds for continuous vulcanization (CV) of rubber, containing carbon black, for such applications as weather stripping, tubing, hose, and, in some instances, tire tread compounds. See also **Rubber Compounding**.

Carbon black is the major reinforcing pigment used, not only for natural rubber, but for practically all the synthetic rubbers. As much as 40–50 parts by weight, based upon 100 parts of rubber, is used in all tire-tread compounds. Carbon black greatly increases tensile strength at low elongations (modulus) and results in longer-wearing tires. Colloidal silica contributes some reinforcing properties to rubber, but not to the same degree as carbon black. See also **Carbon Black**.

In summary, there are a range of vulcanizing systems which can be used for natural rubber, and the choice is dependent on the combination of properties required. No single one offers ideal, all-around properties combined with good heat resistance. The end user has to be selective, according to the properties required for the final application. Certain properties such as oil resistance and gas permeability have been omitted from Table 1, because in regard to these properties natural rubber is substantially inferior to synthetic rubbers such as acrylonitrile rubber and halobutyl rubber.

Protective Systems. The principal category of protective agents is the staining antidegradants, which protect against oxygen, ozone, and flex-cracking. By far the most effective are the *p*-phenylenediamines. The second category is staining antioxidants with antiflex cracking capability only. Examples of these are diphenylamine–acetone condensates and naphthylamine derivatives. They are good antiflex cracking agents, but not as effective as the *p*-phenylenediamines. The condensates are good as general-purpose antidegradants and are used in tire compounds. The third type is made up of the low staining amine antioxidants. These impart good protection against heat and oxygen, and the *p*-phenylenediamine is also effective as a metal deactivator. All stain less than most of the other amine antioxidants. Among nonstaining antioxidants, the least staining and discoloration is given by the phenolic antioxidants, such as the phenol-alkanes, hindered phenols, and hydroquinones. These give reasonably good antioxidant protection, but some are susceptible to pinking on exposure to light. For nonstaining protection against ozone attack under static conditions, waxes are used. The type of wax is determined by the service condition involved and the temperature. Traces of certain metals such as copper, manganese, and iron act as catalysts in the oxidation of natural rubber vulcanizates. Many amines and some phenolics are effective inhibitors of metal-catalyzed oxidation. See also **Waxes**.

Modified Forms of Natural Rubber. Because of the limitations in the properties of natural rubber itself, many workers, even before synthetic rubber was produced, attempted to change its structure to broaden its use into new applications. Several of these were only scientific curiosities such as, for example, hydrogenated natural rubber and ethyl *N*-phenylcarbamoylazoformate (ENPCAF) modified natural rubber. However, these led the way to more practical materials such as chlorinated natural rubber for chemical- and heat-resistant paints and coatings, and cyclized natural rubber for shoe solings, hard moldings, and industrial rollers. Although these have virtually disappeared, poly(methyl methacrylate)-grafted natural rubber, superior processing natural rubber, and epoxidized natural rubber are available. The first of these, poly(methyl methacrylate)-grafted rubber (MG rubber), is made by the polymerization of vinyl monomers with the rubber to produce a material of increased modulus or hardness according to the percentage of grafting. The overall result is a modified natural rubber, which is a hard flexible material combining high rigidity with complete recovery from impact. MG rubber is used for hard impact-resisting rigid articles and as an adhesive. The latter use is because it contains within its molecular structure both polar poly(methyl methacrylate) and nonpolar polyisoprene components and these make it an attractive material for bonding unlike surfaces, eg, natural rubber with poly(vinyl chloride) (PVC). The second modified form of natural rubber readily available is superior processing rubber. This group consists of intimate mixtures of cross-linked and uncross-linked materials prepared by blending vulcanized latex with diluted field latex in proportion to percentage of vulcanized phase required. There are generally five grades available, as shown in Table 2.

The third and newest modified natural rubber available is epoxidized natural rubber (ENR). This modification was actually discovered as early as 1922, although the elimination of ring opening and side reactions to give a purely epoxidized material took another 50 years or so to achieve. The resulting polymer is a new material, with properties totally different from natural rubber, as indicated in Table 3.

Thermoplastic Natural Rubber. Natural rubber thermoplastic materials are based on blends of natural rubber and polypropylene. Basically, there are two types: those with a low natural rubber content, which are really only rubber toughened forms of polypropylene, and the softer grades with high natural rubber content, which are truly classed as thermoplastic elastomers. The latter have high strength and good recovery properties, better aging than conventional natural rubber vulcanizates, and excellent ozone resistance. These materials all have to be processed on thermoplastic machinery, and 180 °C (356 °F) is regarded as the minimum melt temperature.

The hard (low natural rubber content) grades are best regarded as rubber-modified polypropylenes. Their main attribute is impact resistance, especially at low temperatures, for any given stiffness, as shown in Table 4.

The more important grades of thermoplastic natural rubber, which fall into the olefinic class of thermoplastic elastomers, are prepared with the natural rubber phase partially cross-linked during blending, a process known as dynamic vulcanization. The hardness of the soft blends is controlled by the natural rubber content, and typical properties of those of 50–90 hardness (Shore A) are shown in Table 5.

The good strength properties of the natural rubber thermoplastic blends may relate to the natural rubber phase undergoing strain-induced crystallization, as there is a distinct upturn in the stress–strain curve of the natural rubber blend which is not seen with other olefinic thermoplastic elastomers. It may be noted too that the natural rubber blend exhibits good recovery properties with compression set values of the softer materials not too dissimilar to that of a conventional high sulfur vulcanizate (see Table 1). Thermoplastic natural rubber, when correctly compounded, has excellent aging characteristics, as shown in Table 5, and ozone resistance is also high. Even the softest grades with the highest natural rubber content exhibit no cracking after exposure to 100 pphm ozone for 7 d at 40 °C and 20% strain. Its recyclability is demonstrated in Table 6 where the retention of tensile strength and modulus is shown after reprocessing five times.

These thermoplastic natural rubber elastomers have a place in the modern world, where recycling has become so important, and when excessive heat is not found in service. Thus, footwear, glazing seals, sports goods, hose, domestic products, and a whole range of automotive products have already been identified for such use. It must be noted, however, that tires are not a potential market for these materials, because of the high temperatures which result from emergency braking.

Natural Rubber-Rubber Blends. The majority of natural rubber is used in blends with other elastomers. This has been common practice for many years, and most of the formulations employed by the manufacturers of rubber products have been derived empirically. It was not until 1988 that there was a method of measuring cross-link density in blends. Using a swollen-state nmr spectroscopy technique, it has been found possible to not only measure cross-link density in natural rubber itself, but also in the individual phases of vulcanized blends. This technique has enabled studies to be made of a range of natural rubber–synthetic rubber blends and, as was expected to be the case, has also shown a total imbalance of cross-link density in incompatible blends such as natural rubber and nitrile rubber. However, the ability to measure individual cross-link densities in such a blend and effectively confirm that the natural rubber phase is under-cross-linked enables changes to be made to redress the imbalance. Thus, by careful selection of suitable curatives, which are likely to be more soluble in the natural rubber phase, a much more even distribution of cross-links between the two polymers has been achieved, with the resulting improvement in physical properties such as tensile strength. The technique is being applied to other natural rubber–synthetic rubber blends, and it seems likely that improvements will even be made in blends of natural rubber with EPDM. This will be of immense benefit, because a combination of the virtues of these two polymers, the strength and resilience of natural rubber and the oxidation resistance of EPDM, will provide a material much sought-after by the manufacturing industry.

Uses of Natural Rubber

Thousands of flexible products requiring top performance characteristics are made of natural rubber, e.g., huge earthmover tires, truck tires, tires for large aircraft, bridge supports, and surgeons' gloves. The treads of most passenger car tires in the United States consist mainly of styrenebutadiene synthetic rubber because of lower cost and lower temperature buildup during use.

The use of natural rubber in passenger car tires has increased in recent years due to the industry going from bias to radial types which, in North America, now account for 75% of the total. Higher degree of tack or cohesive bonding during the building of the radial tire, as compared with that of styrene-butadiene rubber, is largely responsible for this.

Because of its excellent high- and low-temperature properties, many products used in the arctic and tropical areas of the world are made from natural rubber. However, it is not suitable for applications where there is contact with naphtha, e.g., gasoline hoses, because the solvent swells the material. Almost all elastic bands are made from natural rubber. Because of its excellent tack properties, the material is used in solvent and latex form as the base for adhesives.

The use of natural rubber in latex products covers items such as gloves, condoms, balloons, catheters and other dipped goods, latex thread, foam and carpet backing, and rubberized coir and hair. In total, latex goods consume about 11% of world rubber production. Thereafter, there are four categories: footwear, nonautomotive engineering, belting and hose, and nontire automotive applications, which consume 1.5–4% each. Footwear is self-explanatory, with the market for athletic shoes, especially those made in the Far East, tending to keep natural rubber in this market. Nonautomotive engineering applications cover the use of natural rubber in civil engineering products such as bridge bearings, off-shore oil field equipment, and the growing market for rubber–metal-laminated bearings to protect buildings against earthquakes. This relatively new application was born out of the early work on metal-laminated natural rubber bearings for bridges, which later spawned the use of natural rubber bearings to protect buildings against ground-borne vibrations, eg, from the London Underground. This in turn developed in the 1980s into natural rubber bearings to protect buildings against earthquakes, a technique fast developing around the world in earthquake-prone areas, notably Japan, New Zealand, Italy, and the state of California in the United States. Another significant use of natural rubber is in belting and hose, where natural rubber's high strength, resilience, and fatigue performance still help to maintain its use as a premium rubber for these applications.

With the dependence of synthetic rubber on petroleum, natural rubber, which is produced by solar energy, may look increasingly attractive over the years ahead.

Processing Raw Materials

Dry Rubber. All commercial grades of dry rubber arise from the organization of tapping and tappers and from the methods of coagulation and processing. Rubber production is generally managed in three ways:

1. The tapper can be a smallholder with 2–20 ha who will sell the crop, either in latex or semiprocessed form.
2. The tapper can be an employee of a self-contained estate or plantation of several thousand hectares with the whole operation of dry rubber production managed by the estate.
3. The tapper can be part of a government-sponsored cooperative and will deliver the crop to central manufacturing stations.

The first cultivated rubber trees produced 500 kg/ha of rubber and selective breeding over the years has resulted in yields during the mid-1990s as high as 3000 kg/ha. However, average yields in the principal producing countries can vary from 400–1200 kg/ha. In Malaysia the smallholder sector produces about 850 kg/ha, whereas the estate plantations can produce about 1200 kg/ha.

Latex and Its Collection. The latex from the *Hevea brasiliensis* tree is a colloidal dispersion consisting of nonrubber substances and rubber particles in an aqueous serum phase. The rubber hydrocarbon constitutes 30–45% of the whole latex; the nonrubber substances account for 3–5%. Rubber particles vary in size from 0.15–3μ and contain 90–95% natural rubber, ie, cis-1,4-polyisoprene, with a molecular weight distribution of 10^5–10^7 g/mol. The shape of the molecular weight distribution curve, which varies from a skewed unimodal to a bimodal distribution, and the molecular weight of natural rubber is determined by clone. In natural rubber, latex coagulation takes place under acid conditions at about pH 5. Coagulation can either be induced by the deliberate addition of acid or occurs naturally in the tapping cup by reaction with acids produced by bacterial action, ie, autocoagulation.

Rubber latex is formed and stored in rings of latex vessels found in the soft bark region of the tree, which lies between the inner cambium tissue and the outer hard bark layers. The physiological role of latex in the rubber tree is undetermined, however, the mechanism of production and methods of tapping are well understood. Latex is collected from the rubber tree by tapping once every two or three days. A tree is tapped by carefully cutting into the trunk with a special knife that removes a thin slice of bark and severs the latex vessels without affecting the normal sap circulatory system. The cut is made at an angle of 25–30° halfway around the circumference of the trunk, and at the lowest point a short metal spout is inserted, from which the latex flows into cups and is collected four to five hours later. It is also possible to apply a stimulant such as Ethephon, the active ingredient of which is 2-chloroethanephosphonic acid; the latter releases ethylene gas to increase the time during which latex flows and thus increase yield with a reduced tapping frequency. Unless the latex is to be processed immediately, a small amount of preservative, eg, ammonia, is added to prevent premature coagulation before the latex is brought to a factory or smallholder processing center. Rubber collected in this manner is known as field latex.

Latex continues to drip after the initial collection and coagulates naturally in the cup to form cup lump. Coagulum which forms as a film of latex on the tapped cut, called tree lace, or from latex that has dripped onto the ground, called earth scrap, is collected the next day along with the cup lump. Some smallholders may not collect the latex at all, but allow it to coagulate in the cup and collect it as cup lump. All these methods produce rubber known as field coagulum.

Smoked Sheet. For making ribbed smoked sheet, the field latex is immediately mixed with dilute formic acid in long horizontal tanks. Because fresh latex is somewhat protected by a protein surface layer, it does not coagulate or gel immediately on addition of the acid. Within a few hours, however, the rubber particles in the latex gel form a spongy mass which is then run through a series of smooth metal rolls with clearance decreased from one set to the next, an arrangement that squeezes out the serum and densifies the wet rubber. Water is run over the wet coagulum to wash out non-rubber materials and dirt. The last unit consists of ribbed rolls, which imprint ribbed markings on the sheet. After drying in air for a few hours, the sheets are hung in a drying shed at 40–50 °C until dry. Modern installations use efficient drying tunnels. Sheets are inspected by holding them over a strong light to determine clarity, color, presence of dirt and other factors. The rubber is classified by various grades. Sheets then are piled up and squeezed in a baling machine to form 250-pound (~113–kilogram) bales that measure 19 × 19 × 24 inches (~48 × 48 × 61 centimeters).

Crepe. Another popular type of commercial rubber, known as crepe, consists of two major classes — *pale crepe* and *thick blanket crepe*. Pale crepe is made by adding sodium hydrogen sulfite, $NaHSO_3$, to field latex to inhibit discoloration and softening during processing. Formic acid is used as the coagulant. The wet coagulum is passed through rolls with longitudinal grooves, which give the rubber a crepe-like appearance. Water running over the surface cleans out dirt and other nonrubber ingredients. Sheets are hung up to dry in circulating warm air. The quality of pale crepe is assessed on its whiteness and how good the finished rubber appears.

Blanket crepes are of lower quality and are made from wet slabs obtained usually from small landholders. These are creped, dried, and baled. Other types of crepe are made from coagulum left in collection cups and from dried skin remaining from the tapping incision. In addition to collecting latex, a tapper collects all dried and coagulated rubber that remains from the previous round, usually as skin in the cup or on the tapping panel.

Grading of Rubber. Commercial grades of natural rubber are classified into two main groups: (1) "Green Book International Grades," and (2) "Technically Specified Forms." The former depends on a visual grading system, the source of the rubber and the method of preparation. This system, dating back many years and kept current by the International Rubber Quality and Packing Conference Committee, consists of 35 grades under 8 major types, such as Ribbed Smoked Sheets, White and Pale Crepe, Estate Brown Crepes, Compo Crepes, Thin Brown Crepes (Remills), Thick Blanket Crepes, and Pure Smoked Blanket Crepe. Publisher of the "Green Book" is the Rubber Manufacturers Association, Inc., New York.

Technically Specified Rubbers (TSR), originated by the Malaysian Rubber Producers Association, classifies rubber not only on the basis of the source of rubber, but on its physical properties, such as dirt content, ash, and nitrogen content, volatile matter, plasticity, and, with the higher-quality grades, cure rate and color are standardized. This type of rubber is packaged in 75-pound (34-kilogram) bales, wrapped in transparent plastic, and the color of the printing on the bale identification strips indicate whether the source is latex grade, sheet material grade, blended grades, or field grades. An additional convenience of this rubber is that the bales can be charged into the mixing machine (Banbury) without removing the wrapper. This is in contrast with the Green Book grades, which are bonded together by a press, with the outside layer treated with soapstone to keep the bales from sticking together. These larger bales require cutting before they can be charged into the mixer.

Guayule, Rubber

Although over 2500 plants are known to produce natural rubber, few synthesize commercial quality or quantities. A notable exception is guayule pronounced "why-you-lee" from the desert shrub *Parthenium argentatum* (Gray), a species classified in the Class Angiospermae, the Subclass Dicotyledonae, the Superorder Asteridae, the Order Asterales, the Family Asteraceae (Compositae), the Subfamily Asteroidae, and the Tribe Helianthae. Guayule is a woody shrub native to the Chihuahuan Desert of northern Mexico and the Big Bend region of Texas. Guayule produces linear, high molecular weight natural rubber that can have physical properties and applications equivalent to those of Hevea rubber. Guayule rubber can be extracted as a solid bulk polymer or as a latex. Guayule also is one of very few rubber-producing plants to have ever been used commercially for rubber production. Although guayule rubber was commercially produced in the early part of the last century, more recent efforts to reinstate production have not led to commercial success because the production costs of bulk rubber were too high to permit direct competition with Hevea rubber. Guayule commercialization has been revitalized in recent years by use of the plant to produce hypoallergenic latex, a higher value rubber raw material.

Biology and Biosynthesis

Natural rubber is a secondary product, compartmentalized in cytosolic rubber particles, which is not recatabolized during the life of the plant. Rubber particles are often made in laticifers, as in Hevea, but guayule produces them in generalized bark parenchyma cells. The rubber particles probably originate in the rough endoplasmic reticulum, but little is known about ontogeny or development. In guayule, as tissues age and the cytosol fills with particles, the rubber particles also move from the cytosolic compartment to fill the vacuole. See Fig. 3. As in all rubber-producing plant species investigated to date, rubber is synthesized in guayule by an enzyme called rubber transferase. The purified product is equivalent in chemical properties to the Hevea rubber. An advantage of guayule is that it can be grown on semiarid land that is not suitable for other crops. Its bark naturally produces high quality, safe latex.

Production

Cultivation. In general terms, guayule likes alkaline, well-drained soil, hot summers, and cold winters without snow cover or serious frosts. Stands can be established using transplants or by direct seeding. As a crop, guayule has many environmental advantages, requiring relatively little water and fertilizer, and no pesticide. Major advances have been made within the last five years in the development of new, improved germplasm. The time to harvest was generally considered to be from 3 to 5 years, but with the latest germplasm releases this time has been reduced to harvesting in 2 to 3 years.

Harvesting. The guayule research carried out in the 1980s demonstrated that guayule can be harvested effectively by pollarding as well as by digging the entire shrub. The advanced lines from the plant breeding programs have been selected for their ability to regrow after pollarding, in addition to high rubber yield and biomass. Thus, the current commercialization effort is based on farming guayule as a perennial crop harvested biennially using pollarding (cutting the shrub about 10 cm (4 inches) above the soil). The plants regrow rubber-containing branches and can be harvested again in two years, avoiding costs associated with crop replacement.

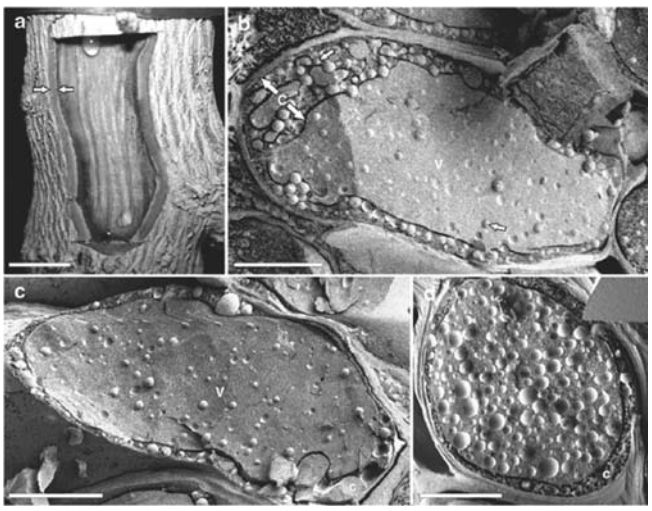

Fig. 3. (**a**) Guayule stem segment (line O-16-1, large, older stem) showing the region where the excised tissue piece for SEM study was taken. The cells containing the rubber particles are located in the tissue indicated between the two arrows, just beneath the bark. (**b–d**) Cryo scanning electron micrographs of rubber-containing cells showing cells from (**b**) young tissue containing rubber particles in the cytosol as well as in the vacuoles, (**c**) maturing cells from medium-sized stems showing an increasing accumulation of rubber particles in the large central vacuole and rubber particles compressed into a single layer in the much-diminished, surrounding cytosol, and (**d**) mature cells from large-sized stems showing a central vacuole filled with rubber particles, and a single layer of rubber particles in the remaining cytosol. Cells are from the following lines: O16-1 (**b**); AZ101 (**c**); N9-5 (**d**). C, cytosol; cw, cell wall(s); V, vacuole. Magnification bars: (**a**) 5 mm; (**b–d**) 10μm. (K. Cornish and D. F. Wood, USDA)

However, once a stand begins to decline, or when new, improved lines warrant its replacement, the entire stand would be dug so that the rubber latex could be extracted from the roots as well as from the above-ground branches.

Processing. Guayule produces its rubber in the form of membrane-bound rubber particles suspended in the aqueous cytosol and vacuole of the bark parenchyma cells (Fig. 3). There is no laticifer system that would allow tapping, as with Hevea, even if this were a cost-effective procedure. Whether processing guayule for latex or dry rubber, it is necessary to rupture the latex-bearing cells.

Latex. To produce guayule latex, the rubber particles must be removed intact from the parenchyma cells while maintaining an aqueous suspension. Thus, the shrub must remain in a hydrated condition through harvest, shipping, and storage until homogenized in an alkaline aqueous extraction medium. The rubber particles, which have a specific gravity of slightly less than 1, can then be purified from the homogenate using a series of centrifugation steps and/or flotation with alginate creaming agents. This process results in an artificially-produced natural rubber latex from which the cytoplasmic components have been removed. The guayule shrub must be wet-ground in an aqueous, alkaline medium to extract the latex.

Ammoniated homogenate appears to provide a stable environment for latex, without refrigeration, provided that the pH is kept basic (eg, pH 10) and the concentration of rubber particles is at least 5 mg/mL. The latex concentration and polymer molecular weight remains stable for 20 weeks before significant degradation occurs. Interestingly, the polymer polydispersity varies little even while the polymers are being degraded after 20 weeks of storage, indicating a uniform degradation process throughout the homogenate. Degradation does not appear to generate the mixture of small and large polymers seen in harvested branches over time.

The latex can be separated from the clarified homogenate and purified and concentrated using continuous flow centrifugation, and/or creaming agents, purified and concentrated. Purified latex (in 0.2% NH_4OH, 0.1% Na_2SO_3, and 0.05% ammonium alginate) appears to be stable for months.

In summary, guayule latex is stable within the living plant, the ammoniated homogenate, and in purified form, and is unstable in harvested shrub. This means that, as in the dairy and fresh vegetable industries, harvesting must be coordinated with processing, to minimize the delay between shrub harvest and homogenization. Unavoidable post-grinding delays in a latex extraction and purification process are unlikely to cause serious latex losses.

Dry Rubber. Typically, the plant material is coarsely ground and then subject to compression and shear forces. Dry bulk guayule rubber has been produced by two basic methods: flotation and solvent extraction. Flotation processing was in common use during the early part of the 20th century. Ground shrub was mixed with a dilute caustic solution that coagulated the rubber and resin (extractable low molecular weight secondary metabolites) as solid particles called “worms”. The worms were skimmed from the surface, deresinated with an acetone wash, dried, and compressed into bales. Alternatively, the deresinated rubber was dissolved in a nonpolar solvent such as hexane. Antioxidant was added to the hexane cement prior to filtration and desolventization. The weaknesses of flotation processing included the rate-limiting nature of the deresination step and the need to dispose of large volumes of caustic flotation medium.

Solvent extraction addresses the need to remove nonrubber resinous components from the rubber product. Evaluated at the USDA Northern Regional Research Center, sequential extraction involves deresination with a polar organic solvent, followed by rubber removal with a nonpolar hydrocarbon solvent.

Sequential extraction does not accommodate an important constraint on the quality of the rubber product: unlike Hevea, cultivated guayule does not produce rubber that meets established product specifications. The process would have to incorporate an additional operation for the selective recovery of the high molecular weight fraction of the rubber polymer.

In simultaneous extraction, the grounded shrub is initially extracted with a rubber solvent to produce a dilute solution, or miscella, of rubber and resin. The rubber solvent may have a single component such as xylene, or it may be a mixed system such as the acetone–pentane azeotrope. A polar solvent such as methanol or acetone is then added to the miscella to coagulate the high molecular weight rubber fraction.

Latex Properties. Rubber particles are surrounded by a monolayer membrane, the lipid and protein composition of which is species-specific. Guayule rubber particles contain relatively few different proteins compared with Hevea. The latices from *F. elastica*, guayule, and *Helianthus annuus* (sunflower) contain far fewer potential allergy-causing epitopes than either Hevea or *Taraxacum kok-saghyz* (Russian dandelion).

Guayule latex not only contains few proteins compared with Hevea but also contains very little protein, ranging from 0.2 to 4% of the amount in Hevea latex. The low protein content of guayule latex, and the hydrophobic nature of these proteins, makes it unlikely that large-scale use of guayule latex products will induce a widespread guayule latex allergy in its turn.

The lipid composition of rubber particles also differs among species. Guayule particles contain a rather ordinary complement of fatty acids in contrast to the unusual, but disparate, membrane compositions in Hevea (high in furanoid fatty acid) and *Ficus elastica* (high in long-chain fatty acids). The guayule particle composition may reflect their origin in bark parenchyma cells — a much less specialized cell type than the laticifers producing the rubber particles in Hevea and *F. elastica*.

Applications.

Latex. The physical properties of guayule latex differ from those of Hevea latex, and a Hevea compounding recipe will generate a guayule latex film with poor performance characteristics. However, successful compounding formulations, with excellent physical properties, were developed by the Akron Rubber Development Laboratory, Akron, Ohio. The first guayule latex prototype medical products included surgical gloves, examination gloves, household gloves, industrial gloves, miniature gloves, surgical tubing, assorted surgical balloons, condoms, and children's balloons. Even after four years of storage, films from condoms and examination gloves were proved to provide an effective barrier to the transmission of human viruses. No signs of film deterioration have yet been observed (now seven years post-manufacture).

Research by Apex Medical Technologies, http://www.apexmedtech.com/, San Diego, Calif, in collaboration with Yulex Corporation, http://www.yulex.com/technology.html, has led to a report that a novel cure process creates even better performance properties in guayule latex films than synthetic polyisoprene films. The guayule latex films have essentially the same tensile strength as those obtained from Hevea latex under similar processing conditions. Guayule latex films exceed ASTM standards for surgical gloves and are 33% stronger than synthetic polyisoprene latex films produced under similar conditions. They are considerably stronger than enzymatically deproteinized Hevea latex films made from enzyme-treated but unwashed latex.

Dry Rubber. Because of its enhanced crystallizability, guayule rubber can exhibit superior failure properties in unfilled rubber compositions. As a double network, an elastomer cured a second time while in a deformed state guayule rubber exhibits substantially better fatigue resistance than deproteinized Hevea rubber. When compounded with carbon black, guayule rubber and Hevea rubber behave similarly. In tread and wire skim stocks, the compounding and performance behavior of guayule rubber was comparable to that of Hevea rubber.

Recent evaluations of guayule rubber in finished rubber goods have focused on military applications. Guayule rubber has been evaluated in tank track pads, in aircraft tires, and in light truck tires. The performance of rebuilt aircraft tires built with guayule rubber was comparable to the performance of those containing Hevea rubber. However, new aircraft tires fabricated either from 100% guayule rubber or from a 50:50 blend of guayule rubber and NR did not pass all dynamic testing requirements. Guayule rubber was not a direct drop-in replacement for NR in this application. Comparative performance tests have been run on light truck tires containing 100% guayule rubber or a 50–50 blend of guayule and Hevea rubbers, with guayule rubber or the guayule–Hevea rubber blend being substituted in all component stocks normally containing Hevea rubber. Commercial tires served as controls. Overall, the performance of the tires containing guayule rubber was comparable to that of the controls.

Commercialization. High quality guayule latex rubber and bulk rubber can both be produced from guayule, but the economics of latex production favor commercialization based upon hypoallergenic latex as the primary product. The solvent-based extraction process proved too expensive to produce guayule rubber commercially competitive with the low cost of Hevea bulk rubber. The water-based latex extraction process not only is cheaper than the solvent-based process but produces guayule rubber in the higher value latex form. In addition, the low protein, hypoallergenic properties of the guayule latex allow market entry into the hypoallergenic medical products market where high priced synthetic polymers are the principal competitors, and Hevea latex products are less usable because of Type I latex allergy. The exclusive licenses to the USDA's guayule latex process and product patents were awarded to Yulex Corp in 1997. Yulex has identified over 75 commercial farms in southern Arizona and the desert southwest United States with the interest and established infrastructure to grow guayule. The company has developed large-scale commercial processes for producing, harvesting, cleaning, and conditioning guayule seed for transplant operations, and currently maintains seed banks for the advanced lines (from the plant breeding programs) to plant several thousand hectares. Yulex Corp began operation of their first commercial pilot latex bioprocessing facility (750 ton shrub per year) in 2003, and moved guayule farming from an experimental industrial crop into main-stream agriculture. In addition, Yulex has entered into product development agreements with several major medical device manufacturers. The bioprocessing operations extract the natural rubber latex from the Guayule biomass utilizing environmentally friendly ("green") processing. Although prior Guayule bulk rubber extraction operations required toxic (and costly) solvents, the Yulex® process uses only aqueous (water-based) solutions for processing. Guayule natural rubber latex is a safe alternative to tropical rubber latex for people who have latex allergy. Yulex may be reached at www.yulex.com for additional information.

Conclusions. New rubber-producing crops face substantial barriers they must overcome before they can successfully enter the commercial arena. Decades of guayule research have allowed guayule to overcome these barriers and reenter the commercial arena. Researchers have investigated a plethora of approaches seeking ways to best exploit and consume the crop, and research into new applications and uses for the latex and the resins and lignocellulosic coproducts is continuing. Guayule latex can be used to make high quality medical products and substitute for latex from *H. brasiliensis*. However, latex characterization has also revealed novel properties that affect manufacturing processes and product quality. Some of these properties may lead to natural rubber products superior to those currently available. Continuing research on novel polymers and properties, and on utilization of the coproducts and bagasse, will not only increase the profitability but will allow conversion of the entire guayule crop to a plethora of products, while essentially eliminating the negative environmental impact of agricultural waste. Thus, guayule is positioned as a model industrial crop feeding a new generation of biorefineries capable of producing a wide range of bioproducts and biofuels.

RUBBER PLANT. See **Euphorbiaceae**; and **Latex**.

RUBBER, SYNTHETIC. Any of a group of manufactured elastomers that approximate one or more of the properties of natural rubber. Some of these are: sodium polysulfide ("Thiokol") [CAS: 1344-08-7], polychloroprene [CAS: 9010-98-4] (neoprene) [CAS: 126-99-8], butadiene–styrene copolymers (SBR), acrylonitrile butadiene copolymers (nitril rubber), ethylenepropylene-diene (EPDM) rubbers, synthetic polyisoprene ("Coral," "Natsyn"), butyl rubber (copolymer of isobutylene [CAS: 115-11-7] and isoprene [CAS: 78-79-5]), polyacrylonitrile ("Hycar"), silicone [CAS: 63148-6-9] (polysilorane), epichlorohydrin [CAS: 106-89-8], polyurethane [CAS: 9009-54-5] ("Vulkollan").

The properties of these elastomers are widely different. All require vulcanization. In general, sulfur is used only for unsaturated polymers, peroxides, quinones, metallic oxides, or diisocyanates effect vulcanization with saturated types. Many are special-purpose rubbers, some can be used in tires when loaded with carbon black, others have high resistance to attack by heat and hydrocarbon oils and thus are superior to natural rubber for steam hose, gasoline and oil-loading hose. Most are available in latex form.

RUBELLA (German measles). This disease is caused by the rubella virus, a member of the togavirus family. Symptoms of the disease are mild — fever, a characteristic rash, viremia, and subsequent involvement of lymph nodes in the region of the neck. Incubation period is 18 days. Relatively uncommon complications include encephalitis, arthritis, and rarely, thrombocytopenia. Even with vaccination, reinfection may occur in 4% of the population. In the absence of a specific therapy for the disease, treatment is directed toward alleviating symptoms.

A principal concern with this disease is the major fetal damage that may occur when mothers in the first trimester of pregnancy are infected with rubella. Statistics show that from 20 to 35% of children born under such conditions will have one or more congenital defects, which usually involve the heart, eyes, ears, brain, and bones. Some of these abnormalities are not fully manifested until the child is several years old. The risk remains but is lower when the infection occurs during the second trimester.

Since 1969, when the first vaccine was licensed, vaccination programs in the United States and a number of other countries have greatly lowered the incidence of rubella. Nevertheless, nearly 12,000 cases were reported to the Centers for Disease Control (Atlanta, Georgia) in 1979. This number had dropped to 4,000 in 1980 and by 1984 to 752 cases. Although adolescents and young adults continue to have the highest age-specific incidences of rubella, reductions in incidence of more than 35% in 15-, 19-, and 20–24-year-olds have been showing up in the statistics.

Health authorities recommend routine immunization of all children between the ages of 15 months and 12 years of age. Frequently, combined measles, mumps, and rubella immunizations are given. With women of childbearing age whose serum test shows a lacking of hemagglutination inhibition antibody, vaccination at least 2 months prior to becoming pregnant is a seriously recommended precaution. Rubella vaccinations have been given in the United States since 1969 to well over 70 million people.

R. C. V.

RUBIACEAE. A family comprising some 4,500 species, particularly abundant in tropical regions. Some species are found in temperate regions, and a few in Arctic climates. The family includes trees, shrubs, and herbs having opposite entire or sometimes toothed leaves with stipules, the latter often large and conspicuous. The flowers are perfect, regular and epigynous, and four- or five-parted. Few members of the family are important. Species of *Gardenia*, natives of tropical Old World regions, are frequently grown for their fragrant showy flowers. *Rubia tinctorium*, the madder plant, was formerly a very important source of the dye madder, also called alizarin. Now, however, the dye is prepared synthetically. Gambier, *Uncaria gambii*, a climbing plant native in tropical Asia and the Oceanic Islands, yields quantities of pyrogallol tannin, extracted with boiling water from the leaves and young shoots. This is used in tanning leathers, often mixed with other tannins. It is also used as an astringent in medicines.

Ipecac, *Cephaelis Ipecacuanha*, a native of South American tropics, is a shrubby plant, the roots of which are 6 millimeters thick. From the dried roots and the lower part of the stem the drug ipecac is obtained. Used in small doses, ipecac is a stimulant; in large doses it is an eliminant, causing vomiting, sweating, and elimination through the kidneys and bowels. It is a very efficient means for clearing an overloaded stomach. Quinine and coffee are two other important products from members of this family.

RUBIDIUM. [CAS: 7440-17-7]. Chemical element symbol Rb, at. no. 37, at. wt. 85.468, periodic table group 1, mp 39.31 °C (102.76 °F), bp 688 °C (1270 °F), density 1.53 g/cm^3 (20 °C (68 °F). Elemental rubidium has a body-centered cubic crystal structure.

Rubidium is a silver-white, very soft metal; tarnishes instantly on exposure to air, soon ignites spontaneously with flame to form oxide; best preserved in an atmosphere of hydrogen rather than in naphtha; reacts vigorously with H_2O forming rubidium hydroxide solution and hydrogen gas. Discovered by Robert Wilhelm Bunsen (University of Heidelberg, Germany) and Gustav-Robert Kirchhoff in 1861 by means of the spectroscope.

There are two naturally occurring isotopes ^{85}Rb and ^{87}Rb, of which the latter is unstable with respect to beta decay ($t_{12} = 5 \times 10^{10}$ years) into ^{87}Sr. There are eight other known radioactive isotopes ^{81}Rb through ^{84}Rb, ^{86}Rb, and ^{88}Rb through ^{90}Rb, all with comparatively short half-lives, measured in terms of minutes, hours, or days. In terms of abundance, rubidium ranks 34th among the elements in the earth's crust. In terms of content in seawater, the element ranks higher (18th) with an estimated 570 tons of rubidium per cubic mile of seawater. First ionization potential 4.176 eV; second, 27.36 eV. Oxidation potential $Rb \rightarrow Rh^+ + e^-$, 2.99 V. Other important physical properties of rubidium are given under **Chemical Elements**.

Rubidium occurs in lepidolite (lithium aluminosilicate, in amount up to 1% Rb), in certain mineral waters and rare minerals. Rubidium salts may be recovered from the mother liquor upon crystallization of (1) lithium salts, (2) potassium salts. Rubidium metal is obtained by electrolysis of the fused chloride out of contact with air.

Uses

The main uses of rubidium are in photocathodes and photo-electric cells. However, rubidium cells are inferior to cesium cells in their sensitivity and range. Although very small quantities are involved, rubidium gas cells now perform as secondary time standards, on the order of quartz crystal

oscillators, inasmuch as they must be referenced to more accurate systems. The rubidium systems have a characteristic resonance at 6,835 MHz and, unlike other atomic frequency standards, require little power and are relatively compact. Portable rubidium atomic clocks were introduced by the U.S. Army in 1963. They weight as little as 44 pounds (20 kilograms) and occupy a volume of only about 1 cubic foot (0.028 cubic meter). The units operate on 110-V current, on the 24-V output of military vehicles, or both. Clocks of this type are used to synchronize radar nets, to assist in the accurate tracking of missiles and satellites, and to set precise radio broadcasting frequencies. Rubidium-vapor instruments also were developed as absolute-type magnetometers and introduced in 1958 by U.S. government scientists. The rubidium-vapor magnetometer uses a rubidium lamp, mounted in the tank coil of a radio-frequency oscillator. After collimating and filtering, the rubidium light is circularly polarized and then passed through a rubidium-vapor cell, after which it is focused on a sensitive photocell. Numerous combinations of amplifier parameters and various rubidium isotopes permit considerable range in the measurement of ambient magnetic fields. Inasmuch as the total world range is from 15,000 to 80,000 gammas, a system capable of this span finds use anywhere in the world.

Potential uses of rubidium include use as a fuel for ion-propulsion engines and as a heat-transfer medium.

Rubidium alloys easily with potassium [CAS: 7440-09-7], sodium [CAS: 7440-23-5], silver [CAS: 7440-22-4], gold [CAS: 7440-57-5], and forms amalgams with mercury [CAS: 7439-97-6]. Rubidium and potassium are completely miscible in the solid state. Cesium and rubidium form an uninterrupted series of solid solutions. These alloys, in various combinations, are used mainly as getters for removing the last traces of air in high-vacuum devices and systems.

Small quantities of rubidium are found in certain foods, including coffee, tea, tobacco, and several other plants. There is evidence indicating that trace quantities of the element are required by living organisms.

Chemistry and Compounds

Rubidium is more electropositive than potassium (or the lower alkali metals) as is consistent with its position in main group 1. It reacts more vigorously with H_2O, and ignites on exposure to oxygen.

Because of the ease of removal of its single 5*s* electron (4.159 eV) and the difficulty (27.36 eV) of removing a second electron, rubidium is exclusively monovalent in its compounds, which are electrovalent.

In its solutions in liquid NH_3 [CAS: 7664-41-7], rubidium is, like the other alkali metals, a powerful reducing agent, so that in such solutions titrations of rubidium polysulfide with rubidium are made by electrometric methods. The solubility of rubidium salts in liquid NH_3 increases markedly with the radius of the anion (rubidium chloride, [CAS: 7791-11-9] RbCl, 0.024 moles per kilogram, rubidium bromide, RbBr, 1.35 moles per kilogram, and rubidium iodide, [CAS: 7790-29-6] RbI, 10.08 moles per kilogram). However, in water they exhibit minimum solubility at cation: anion radius ratio of 0.75 (rubidium fluoride, [CAS: 13446-74-7] RbF, 12.5 moles/kilogram, RbCl 6.8 moles/kilogram, RbBr, 6.6 moles/kilogram, RbI 7.2 moles/kilogram).

As in the case of the other alkali metals, rubidium forms compounds generally with the inorganic and organic anions; for a general discussion of these compounds, see the entry on **Sodium**, because the sodium compounds differ principally in their greater extent of hydration and greater number of hydrates. However, rubidium coordinates with large organic molecules, such as salicylaldehyde, even though it does not with H_2O.

One respect in which rubidium and cesium [CAS: 7440-46-2] are outstanding among the alkali metals is the readiness with which they form alums. Rubidium alums are known for all of the trivalent cations that form alums, Al^{3+}, Cr^{3+}, Fe^{3+}, Mn^{3+}, V^{3+}, Ti^{3+}, Co^{3+}, Ga^{3+}, Rh^{3+}, Ir^{3+}, and In^{3+}.

As in the case of potassium and cesium, rubidium forms four oxides Rb_2O, Rb_2O_2, Rb_2O_3, and Rb_2O_4 on reaction of the metal with oxygen. The compound is dark brown in color and paramagnetic, and hence believed to contain the O_2^- ion with an odd electron, and to have the formula RbO_2[CAS: 12137-25-6]. On heating, it loses oxygen to form Rb_2O_3. Rubidium also forms a peroxide Rb_2O_2[CAS: 23611-30-5], and a normal oxide, Rb_2O [CAS: 18088-11-4], which is prepared by heating rubidium nitrite with metallic rubidium.

Rubidium hydroxide, CAS: 1310-82-3. RbOH, is the strongest, except for cesium hydroxide, [CAS: 21351-79-1] CsOH (and francium hydroxide, FrOH), of the alkali hydroxides, as would be expected from its position in the periodic table. For the same reason, it has the next smallest lattice energy (146.6 kilocalories per mole).

The most numerous organic compounds of rubidium are those of oxy compounds, such as the salts of organic acids, the alcohols and phenols (alkoxides, phenoxides, etc.). An ethyl rubidium-zinc diethyl adduct has been reported, $RbZn(C_2H_5)_3$, which is certainly the true salt, rubidium triethylzincate, $Rb[Zn(C_2H_5)_3]$.

RUBNER, MAX (1854–1932). Max Rubner was a German physiologist and hygienist who worked on biological conservation of matter and energy. Born in Munich, Rubner studied medicine with Carl Voit in Munich and with Carl Ludwig in Leipzig. Rubner received his MD degree in 1878 and in 1883 the venia legendi (habilitation). In the same year he started his scientific career in physiology at the University of Munich. In 1887 he was appointed to the new chair of hygiene in Marburg and in 1891 he succeeded Robert Koch as Professor of Hygiene in Berlin. In 1909 he moved from the Robert Koch Institute to the Humboldt University of Berlin to teach physiology. He founded the "Institut für Arbeitsphysiologie" (industrial physiology) at the Kaiser-Wilhelm-Gesellschaft in 1913. See also **Koch, Heinrich Hermann Robert (1843–1910)**.

Rubner worked on special problems of bacteriology and hygiene. He was engaged in calorimetry and metabolism, especially energy transformation and food requirements. Rubner fought against the neovitalism of Hans Driesch and his co-workers. His final statement on this subject was given in his best known speech about energy and matter in 1908: "The energy conservation principle was the last blow to the old vital force.: The surface law, that is the relation of resting metabolic rate and body surface is mainly connected with his name. He also discovered the law of isodynamics, concerned with the equivalence of different forms of organic energy. See also **Bacteriology**; **Bacteriology (The History)**; and **Driesch, Hans Adolf Eduard (1867–1941)**.

RULED SURFACE. A surface that can be generated by the motion of a straight line. The straight lines lying in the surface are the *generators of the surface*. The point into which the common perpendicular to two neighboring generators degenerates as these are brought into coincidence is the *central point* of the generator. The locus of the central points of all the generators of the surface is the *line of striction* of the surface. It is, of course, perpendicular to every generator of the surface.

See also **Coordinate System**; and **Surface**.

RUM. A spirit distilled directly from sugarcane products and usually produced in sugar-growing countries. The Chinese are known to have produced a spirit from sugarcane many centuries ago, and sugarcane was cultivated in Spain and on the Mediterranean islands as well as Madeira as early as the 3rd century A.D. The cultivation of sugarcane in the West Indies was not reported until the 15th century. Nevertheless, the origin of rum as it is known today is generally attributed to the West Indies and particularly with reference to the era of the pirates. Like gin, rum over the years has been called by a number of uncomplimentary names — Rumbullion, Rumbustion, and "kill-devil," among others. One early dictionary defined rum as "a great tumult or a strong liquor."

Although rum can be produced directly from sugarcane juice, it is traditionally and principally made from molasses (blackstrap), a by-product of the cane sugar industry. The molasses is mixed with water, yeast is added, and the mixture allowed to ferment in large tanks. Some of the variations in rums are due to the strain of yeast that is used, but also importantly by the distillation techniques employed. Depending upon local methodology, the fermentation process will span from a minimum of 2 days to nearly 2 weeks. In recent years, the Jamaican distillers have depended upon natural or "wild" yeast, with inoculation occurring directly from the vats or air. Generally, the procedure for making rum follows that for making whiskeys and gin.

Both the pot still and continuous stills are used to separate alcohol from the *wash*, a term equivalent to mash in the manufacture of grain spirits. See accompanying illustration. The distillate in either case is colorless. Caramel (burnt sugar) is the principal coloring agent used, although dyes may be used in the very dark rums. Continuous distillation produces a much more neutral, light rum with much less character than is obtainable with the pot still, where the separation of flavor- and aroma-containing components picked up from the molasses is less sharp. Consequently, ageing or maturing is required of the heavier, pot distilled rums.

Rums can be classified in a number of ways, possibly the most meaningful being the *light rum* and *full-bodied* rum categories.

Light rums, such as those produced in Puerto Rico and Cuba, are distilled to a proof range of 160° to 180° proof. Continuous stills are used. See Fig. 1. Ageing is not required. The lighter rums are preferred in the West Indies and Latin countries. They are also widely used in the United States for preparing cocktails. Bacardi rum, once exclusively Cuban, is now produced elsewhere as well.

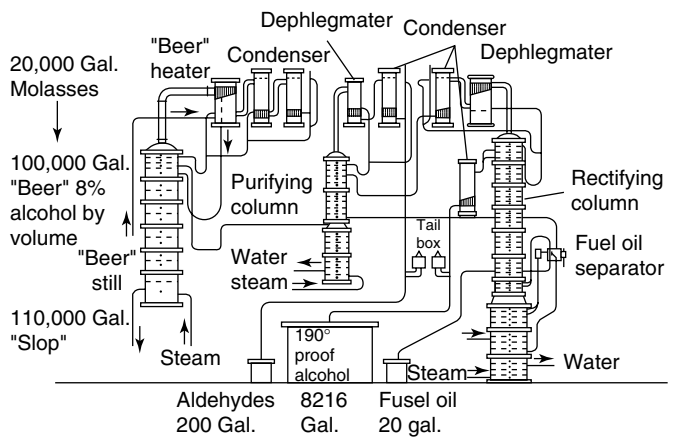

Fig. 1. Continuous still of the type used in the production of light rums.

Heavy, or full-bodied, rums, such as those produced in Jamaica, are usually preferred in Western Europe and in the United Kingdom, particularly in the Midlands and northern England. These rums are of good quality and pungent. They are distilled to a proof range of 140° to 160° proof in pot stills. So-called "Continental Flavor" rum is particularly favored in Germany. It is highly flavored and aromatic. Commonly, the Germans mix this rum with neutral spirits to form Rum Verschnitt.

Rum for the United Kingdom is shipped from the West Indies in casks, ranging in size from 40 and 56 to 110 gallons, the latter containers called *puncheons*. The rum usually ranges between 130° and 145° proof, as received at the London docks. Law requires that it be matured for 3 years in wood before bottling, but some rums require a minimum of 6 years to reach acceptable good quality. Shipment of the rum in wood reduces the time required for further maturing in England. However, the casks, barrels, and puncheons are difficult to handle and the shipping method is under revision. Rum is shipped to France in metal containers and upon arrival is transferred to large wooden vats (small wood ageing is not specified by law), where it is matured for a minimum of 2 years. A few countries, such as Eire and New Zealand, require ageing in small wood for at least 5 years prior to bottling.

RUNOFF. See **Drainage Systems**.

RUPTURE DISK. An intentionally designed weak spot within a pressurized system. The rupture disk is expected to fail before other more valuable equipment is damaged or destroyed, or before an explosive force can be created that will endanger human life. Pressure relief devices of an emergency nature may be required because of the generation of abnormal pressures which may result from: (1) faulty manual operation or automatic control of equipment; (2) presence of accidental fires or other unexpected sources of heat near the equipment; (3) sudden expansion or contraction of a liquid in a closed system; and (4) flow stoppage that may cause sudden pressure buildup and clogging of conventional pressure relief devices. See Fig. 1.

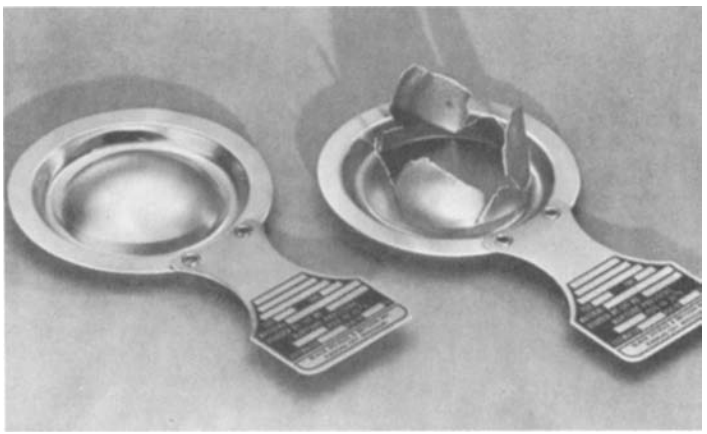

Fig. 1. Solid-metal rupture disk.

Rupture disks are relatively simple in concept and virtually have no moving parts (except at time of rupture). The disks are designed to provide instant relief at a predetermined pressure and temperature rather than a gradual bleeding off of the excess pressure. The disks provide positive failure. Little can be done to alter the disks after installation in a pressure system to change their rupturing pressure. In selecting rupture disks, the following points are important: (1) type and thickness of metal; (2) mechanical methods of construction; (3) operating margin; (4) temperature extremes during operation and (5) types of loads the pressure system will impose on the disk during operation.

RUSAS DEER. See **Deer**.

RUST FUNGI. See **Fungus**.

RUTABAGA. See **Brassica**.

RUTHENIUM. [CAS: 7440-18-8]. Chemical element, symbol Ru, at. no. 44, at. wt. 101.07, periodic table group 8 (platinum metals), mp 2,310 °C (4,190 °F), bp 3,900 °C (7,052 °F), specific gravity 12.41 (20 °C (68 °F). Elemental ruthenium has a close-packed hexagonal crystal structure. The seven stable isotopes are 96Ru, 98Ru through 102Ru, and 104Ru.

The five unstable isotopes are 95Ru, 97Ru, 103Ru, 105Ru, and 106Ru. In terms of earthly abundance, ruthenium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for ruthenium at 0.019. No notable presence of ruthenium in seawater has been found. Ruthenium was discovered by Karl Karlovich Klaus a Russian chemist in 1844. See also **Chemical Elements: The History of Origin**.

Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^7 5s^1$. Ionic rad ius Ru^{4+} 0.60 Å. Metallic radius 1.3251 Å. First ionization potential 7.5 eV. Other physical properties of ruthenium will be found under **Platinum and Platinum Group**. See also **Chemical Elements**.

The chemistry of Ru is still poorly understood. The existence of at least eight valence states, coupled with the tendency to complex with many ions, often results in the presence of several different complexes in a given solution.

Ru metal is quite refractory. It is not significantly soluble in any single acid; even aqua regia has little effect. At room temperature, the metal does not react with O_2, but, when heated in air, a film of the dioxide appears. The metal is insoluble in fused sulfates. Molten alkali slowly dissolves the metal. The rate of attack is rapid under oxidizing conditions, and a molten mixture of sodium hydroxide [CAS: 1310-73-2] NaOH and sodium binoxide [CAS: 1313-60-6] Na_2O_2 will readily dissolve the metal.

The finely divided metal is soluble in hypohalites if an excess of alkali is present. At red heat, the metal combines with Cl_2 to form the dichloride. Ruthenium(VIII) oxide (ruthenium tetraoxide) [CAS: 20427-56-9] RuO_4 is formed when an alkaline ruthenium solution is treated with a strong oxidant, such as chlorine, or bromate ion when the Ru is in acid solution.

Ruthenium(III) hydroxide is formed by the action of alkali on a solution of ruthenium(III) chloride. It is easily oxidized by air to the tetravalent state. The dioxide, ruthenium (IV) oxide [CAS: 12036-10-1] RuO_2, forms when the metal is heated in air. Hydrous RuO_2 can be precipitated by adding alcohol to a less than 3 *M* NaOH solution of ruthenium (VIII) oxide, followed by boiling. Above 3 *M* NaOH, complete reduction is not obtained. The hydrous oxide that is soluble in concentrated hydrochloric acid [CAS: 7647-01-0] HCl tends to occlude impurities.

The only known octavalent Ru compound is the tetroxide, RuO_4, which exists in a yellow and a brown form. The volatile and poisonous tetroxide melts at about 25 °C (77 °F) and sublimes readily. It may explode in contact with oxidizable substances or when heated above 100 °C (212 °F). It is formed by distillation from either an alkaline or acid solution under strongly oxidizing conditions. The tetroxide is moderately water-soluble. When dissolved in alkali, it initially forms a green solution of heptavalent perruthenate of the form $MRuO_4$, which further reduces to the orange ruthenate M_2RuO_4. The reduction to the hexavalent state is quicker in strong alkali. The ruthenates also are made by fusing finely divided metal with a mixture of alkali hydroxide and nitrate or peroxide.

Anhydrous ruthenium (III) chloride, [CAS: 10049-08-8] $RuCl_3$, is made by direct chlorination of the metal at 700 °C (1,292 °F). Two allotropic forms result. The trihydrate is made by evaporating an HCl solution of ruthenium (III) hydroxide to dryness or reducing ruthenium (VIII) oxide in a HCl solution. The trihydrate, $RuCl_3 \cdot 3H_2O$, is the usual commercial form. Aqueous solutions of the trihydrate are a straw color in dilute solution and red-brown in concentrated solution. Ruthenium (III) chloride in solution apparently forms a variety of aquo- and hydroxy complexes. The analogous bromide, ruthenium (III) bromide [CAS: 14014-88-1] $RuBr_3$, is made by the same solution techniques as the chloride, using hydrobromic acid [CAS: 10035-10-6] HBr instead of HCl.

Ruthenium (III) iodide, [CAS: 13896-65-6] RuI_3, is a black, insoluble compound precipitated by the addition of iodide ion to a solution of $RuCl_3$.

Tetravalent ruthenium chloride, $RuCl_4$, and the hydroxychloride, $Ru(OH)Cl_3$, are intermediate products when $RuCl_3$ is prepared by evaporating the tetroxide in HCl. When the hydroxychloride in hot HCl is treated with Cl_2, it is converted to the tetrachloride. The anhydrous tetrachloride also is known. The tetrabromide and tetraiodide have not been isolated; attempts to prepare these compounds result in the formation of the respective trihalides.

The only pentavalent Ru compounds known are the fluorides; ruthenium (V) fluoride [CAS: 14521-18-7] $[RuF_5]_4$ is made by combining the elements. The compound melts at 107 °C (225 °F) and boils at 313 °C (595 °F). The salt $NaRuF_6$ was recently made by mixing ruthenium (III) chloride [CAS: 10049-08-8] $RuCl_3$, with sodium chloride NaCl [CAS: 7647-14-5] and treating the mixture with bromine trifluoride [CAS: 7787-71-5] BrF_3.

Ru forms many complex ions. The nitrosyl compounds are frequently encountered by accident due to the great affinity of Ru for the nitrosyl group. Ruthenium (III) nitrosylchloride, $Ru(NO)\ Cl_3 \cdot 4H_2O$, is a by-product of most solutions of $RuCl_3$ in aqua regia or solutions containing nitric acid [CAS: 7697-37-2] HNO_3. It also is present in HCl solutions resulting from a potassium hydroxide [CAS: 1310-58-3] KOH and nitrate fusion of the metal. The chloride and bromide are respectively raspberry and violet in solution. Alkaline chlorides form complex salts of the type $M_2Ru(NO)Cl_5$, which can be crystallized from solution. A black gelatinous precipitate of the nitrosylhydroxide, $RuNO(OH)_3$, is slowly formed when a solution of the nitrosylchloride is heated with a strong base. A series of nitrato- and nitro- derivatives of nitrosylruthenium also have been described and separated.

It is generally accepted that the disulfide is the only certain sulfide of Ru. It is formed by the action of H_2S on a solution of Ru or from the elements at about 1,000 °C (1,832 °F). When ruthenium (IV) sulfide [CAS: 12166-20-0] RuS_2 is treated with HNO_3, the sulfate is formed.

Dichlorodicarbonylruthenium (II), $Ru(CO)_2Cl_2$, is formed when $RuCl_3$ is heated above 210 °C (410 °F) in the presence of CO. It is a yellow, insoluble, volatile compound. The bromine and iodine analogs are similarly formed.

When finely divided Ru metal is heated at 180 °C (356 °F) under 200 atm of CO, pentacarbonylruthenium (0), [CAS: 16406-48-7] $Ru(CO)_5$, is formed.

Ruthenium forms a large number of complex ions with amines.

Recently, a new group of organometallic sandwich compounds, called *metallocenes*, has been discovered. Ruthenocene is made in about 50% yield by reacting $RuCl_3$ with cyclopentadienylsodium in tetrahydrofuran. After refluxing and distilling the solvent, the light-yellow crystals of ruthenocene are sublimed. The compound, $Ru(C_5H_5)_2$, undergoes a large number of substitution reactions typical of aromatic systems.

Ruthenium is commonly used with other platinum metals as a catalyst for oxidations, hydrogenations, isomerizations, and reforming reactions. The synergetic effect of mixing ruthenium with catalysts of platinum, palladium, and rhodium has been found for the hydrogenations of aromatic and aliphatic nitro compounds, ketones, pyridine, and nitriles.

RUTHERFORD, ERNEST (1871–1937). Rutherford was a British physicist who was born in the South Island of New Zealand and is famous for his pioneering work in nuclear physics and for his theory of the structure of the atom.

Rutherford was awarded a scholarship to be a research student at the University of Cambridge and began research under J.J. Thomson. He soon abandoned research on his radio wave detector to work on the power of X-rays to confer electric charge on gases but soon turned to researching the

problem of the rays emitted by thorium. Rutherford found three kinds of radiation, which he named alpha, beta, and gamma. In collaboration with Frederick Soddy, he was able to isolate a substance, thorium X, and identify the phenomenon of radioactive half-life and formulated an explanation of radioactivity. Rutherford was awarded the 1908 Nobel Prize for chemistry for his work in radioactivity.

In 1907, Rutherford moved to the University of Manchester and in 1909 he discovered the atomic nucleus. In 1911 he announced his revolutionary idea on the nature of the atom and he developed a model of the atom showing it similar to the solar system. He proposed the idea that almost all the mass and all the positive electricity in an atom was densely concentrated in a tiny nucleus and the electrons circled around it like planets around the sun.

While at Manchester, Rutherford produced the first human "nuclear reaction" with the disintegration of a non-radioactive atom, dislodging a single particle. He became famous as the man who "split the atom." In 1919, Rutherford succeeded J.J. Thomson as Cavendish Professor of Physics at Cambridge. He was a leader of a research team encouraging others in the investigation of the nucleus.

RUTILE. A mineral, composed of titanium dioxide [CAS: 13463-67-7], which occurs in three distinct forms: as rutile, a tetragonal mineral usually of prismatic habit, often twinned; as octahedrite (anatase), a tetragonal mineral of pseudo-octahedral habit; and as brookite, an orthorhombic mineral. Both octahedrite (anatase) and brookite are relatively rare minerals.

Rutile has a sub-conchoidal fracture; is brittle; luster, metallic-adamantine; color, commonly reddish-brown but sometimes yellowish, bluish or violet; streak, brown; transparent to opaque. Rutile may contain up to 10% of iron.

Experiments in the artificial preparation of titanium dioxide appear to show that rutile is the most stable form and produced at the highest temperature, brookite at a lower temperature, and octahedrite (anatase) at a still lower temperature.

Rutile is found as an accessory mineral in many kinds of igneous rocks, and to some extent in gneisses and schists. In groups of acicular crystals it is frequently seen penetrating quartz as the "fléches d'amour" from Grisons, Switzerland, and Brazil. Rutile is found also in Austria, Italy, Norway, South Australia, and Brazil. In the United States it occurs in Vermont, Massachusetts, Connecticut, New York, Pennsylvania, Virginia, Georgia, North Carolina, and Arkansas.

Rutile derives its name from the Latin *rutilus*, red, in reference to the deep red color observed in some specimens when viewed by transmitted light.

RUZICKA, LEOPOLD STEPHEN (1887-1976). Leopold Ruzicka was born on 13 September 1887 at Vukovár, Croatia, the son of a cooper. (The surname is pronounced "Rouge-itchka.") He began his chemical studies in 1906 at the Technische Hochschule (Technical University) in Karlesruhe, Germany, and gained a doctorate in chemical engineering in 1910. He then studied with Hermann Staudinger at the Eidgenössische Technische Hochschule (ETH) Zurich, Switzerland (The Swiss Federal Technical University Zurich), gaining his teaching diploma there in 1916. In 1917 he took Swiss citizenship and became a professor at the University of Zurich in 1923. He was an active consultant to many Swiss industrial companies throughout his career. In 1926 he assumed the chair of organic chemistry at the University of Utrecht, Netherlands, returning in 1929 to the ETH in Zurich as professor of organic chemistry.

During the 1920s, funded by Swiss perfumeries, Ruzicka began to investigate terpene chemistry, leading to the elucidation of many structures such as civetone and muscone, and to the preparation of many new odiferous alicyclic ketones. In 1930, supported by Ciba, he made structural studies of male sex hormones. In 1935 Ruzicka perspicaciously suggested that terpenes and steroids shared a common origin, namely isoprene, and postulated the formula of the unknown male sex hormone later called testosterone. He shared the Nobel prize for chemistry with Adolf Butenandt in 1939 for his syntheses of multi-membered rings and especially of the higher terpenes that include the sex hormones. During the 1940s he abandoned chemistry to work with refugees. He returned to chemistry in the 1950s, using new instrumental methods of analysis and electronic theories of bonding to reinterpret his earlier terpene research. See also **Butenandt, Adolf Friedrich Johann (1903-1995)**.

RYDBERG CONSTANT. A quantity that enters into the frequency or wave number formula for all atomic spectra. Bohr showed that, in terms of known constants, the Rydberg constant is given by

$$R = \frac{2\pi^2 me^4}{ch^3(1 + m/M)}$$

where e is the charge on the electron, c is the velocity of light, h is Planck's constant, m is the mass of the electron, and M is the mass of the atomic nucleus. Since m/M is very small, R can vary only slightly for different elements. In the limit, as m/M approaches zero, a recommended numerical value of the constant is

$$R_\infty = 109{,}737.31 \text{ cm}^{-1}$$

with an estimated error limit of 3 based on 3 standard deviations in the last digit given. If R is multiplied by c, the dimension of the constant is frequency and so used in a formula for series in line spectra gives the frequency of the calculated lines rather than the wave number. See also **Atomic Spectra**.

RYEGRASS. See **Grasses**.

RYE *(Secale cereale; Gramineae).* Rye is an annual plant, which has a tendency to become perennial. It is a sturdy cereal grass having a much-branched root system which penetrates 4–6 feet (1.2–1.8 meters) into the ground and tough slender stems which may grow as tall as 6 feet (1.8 meters). The leaves are like those of other cereal grasses, but have a definite bluish color, as does the stem. The inflorescence is a spike, with the individual spikelet three-flowered and occurring singly at each of the 20 or more joints of the rachis. See Fig. 1. Of the three flowers in a spikelet, only the two lower ones mature, the third aborting. The two glumes are narrow, the lemma is broad, distinctly keeled, and has a long stiff terminal awn, while the palea is thin and blunt. Unlike most of the cereal grasses, rye must be cross-pollinated in order to set fruit abundantly. The fruit, a grain, is very similar to that of wheat in structure, and readily separated from the lemma and palea when mature. The grain is long and slender and of much darker color than wheat grains.

The principal parts of the rye plant are shown in Fig. 2.

Authorities estimate that rye has been cultivated for about 2000 years, although historical records on this plant are considerably less detailed than for other major cereal grasses. There is no evidence of rye in early records of the Greeks or of Swiss lake-dwellers. It is known that rye was grown and consumed extensively during the medieval period in Europe. During that time, rye became a major bread grain. During the past century, the popularity of rye bread has decreased in favor of wheat breads, but it does remain very popular in much of Europe and western Asia. In

(*USDA diagram*.)

the United States, only about one-quarter of rye production is used in bread and related products. Approximately one-quarter of rye production is used in the manufacture of alcohol and distilled spirits, notably for rye whiskey. The majority of rye grain is used for livestock feed. Another major use is that of a green manure for crops and as pasture. When rye concentrate is used for feed, it usually is diluted with other cereal grains. Rye straw finds a number of uses, including packing and paper manufacture.

Varieties. There are winter and spring varieties of rye, but the largest portion of world production is from the winter varieties. The latter that do well in northern latitudes are not suited to conditions of the lower latitudes. For the southern United States, where considerable amounts of rye are produced, particularly during recent years, strains have been developed from the varieties that are grown in southern Europe and the Mediterranean region.

Culture. Rye should not be planted on the same land more often than once every three years if maximum yields and disease resistance are to be achieved. Although rye will germinate at a temperature as low as 33 °F (18.3 °C), the optimal planting temperature is 55 °–65 °F (12.8 °–18.3 °C).

Rye is harvested much as other small grains. A predominant amount of rye grown in the United States is harvested with a combine.

Production. Of the cereal crops, rye ranks eighth in world tonnage and seventh in tonnage of cereal crops produced in the United States. Continental Europe leads by far with over 90% of world production. North and Central America account for nearly 4%, Asia, 3.5%, and South America, 1.3%. Production of rye in Africa is negligible on a world scale.

S

SABATIER, PAUL (1854–1941). A French chemist who received the Nobel Prize in Chemistry in 1912 for his method of hydrogenating organic compounds in the presence of finely disintegrated metals whereby the progress of organic chemistry has been greatly advanced in recent years. Sabatier shared the Nobel Prize with Victor Grignard. When he started his investigations into the phenomenon of catalysis, Sabatier soon pointed out anomalies in Faraday's physical theory and he in turn formulated his chemical theory which postulated the formation of unstable intermediaries. His subsequent painstaking work and discovery of the use of finely-divided metal hydrogenation catalysts subsequently formed the bases of the margarine, oil hydrogenation, and synthetic methanol industries. He demonstrated the selectivity of catalytic action and also the selectivity of catalysts to poisons, as well as introducing the use of supports and showing the resultant enhanced activity. He also made a close study of catalytic hydration and dehydration, examining carefully the feasibility of specific reactions and the general activity of various catalysts.

Sabatier was educated at the local Lycée and then prepared at Toulouse for the entrance examinations to the École Polytechnique and the École Normale Supérieure. He was accepted for both and chose the latter which he entered in 1874; three years later he graduated, first in his class. He received the degree of Doctor of Science in 1880 in Nimes, France. Sabatier took charge of courses in physics in the Faculty of Sciences at Bordeaux until January, 1882, when he accepted a similar post at the University of Toulouse. He additionally became responsible for courses in chemistry in 1883 and was elected Professor of Chemistry in 1884, a post which he retained until his retirement in 1930. He became Dean of the Faculty of Science in 1905 and continued to lecture after his retirement until his death in 1941.

SABLE. See **Mustelines**.

SACCHARIDE. See **Carbohydrates**.

SACCHARIMETER. A saccharimeter is an instrument for measuring the concentration of sucrose solutions. A saccharimeter differs from a polarimeter in that the saccharimeter uses white light, whereas a polarimeter is operated with sharply monochromatic light. Consequently, a saccharimeter can only be used with sugar solutions (in which case the quartz compensates for the rotatory dispersion of sucrose). Conversely, a polarimeter is suitable for the measurement of optical rotation of any solution, including sugar. However, saccharimetric sugar determinations are the basis of internationally accepted *sugar degrees* (°S), and saccharimeters are appropriately calibrated. When a polarimeter is employed that utilizes monochromatic light rather than a quartz wedge, deviations from sugar degrees will be found in some solutions, and they may not be inconsequential. The International Sugar Scale assigns 100°S to a pure sucrose solution of normal weight (26 grams (0.92 ounces) in 100 milliliters (3.38 ounces (US, fluid) of pure water) at 20 °C (68 °F) and a 200-millimeter (8-inch) light path, measured in a saccharimeter with white light and a dichromate filter. Of course, an exact numerical conversion from sugar degrees to angular degrees is possible with pure sucrose (100°S corresponds to $\alpha = 34.6°$), but in practical, more or less impure solutions, the relationship is not exactly predictable, and the sugar scale is conventionally and legally binding. It is not surprising, then, that virtually all sugar laboratories use visual saccharimeters (also called *polariscopes*). They differ in vintage, the half-shade presentation, and in construction features, but they all use the quartz-wedge compensating principle, and they read out in sugar degrees. A typical instrument will have a split half-shade field or a triple field for observation. The quartz wedge is equipped with a fine scale that is read off a second observation tube. It is graduated in °S (e.g., −30 to +110°S) and comes with a vernier, readable to 1/10°S.

A saccharimeter is used in food processing industries, brewing and distilled alcoholic drinks industry.

SACCHAROSE. See **Carbohydrates**.

SACRUM. The portion of the spinal column of vertebrates, usually formed of several fused vertebrae, with which the pelvis is articulated.

SADDLE POINT. A point (x_0, y_0) on a surface $f(x, y)$ where $f(x, y_0)$ is a maximum at $x = x_0$ and $f(x_0, y)$ at the same time is a minimum at $y = y_0$. A familiar example is the hyperbolic paraboloid, which has a saddle point at the origin if its standard equation is taken as $x^2/a^2 - y^2/b^2 = 2cz$. A person walking toward the origin in the XZ-plane would be ascending a mountain peak while he would be descending into a valley if he walked in the YZ-plane. It is also called a *minimax* or a *col*.

See also **Game Theory**; **Paraboloid**; and **Surface**.

SAFETY (Intrinsic). See **Intrinsic Safety**.

SAFETY SWITCH. See **Limit Switch**.

SAFETY VALVE. The common form of the safety valve is the pop valve. It is held against its seat by a heavy spring and having a "huddling chamber" to make it open quickly and remain open until a predetermined pressure drop (2–4% of the working steam pressure) has occurred. The A.S.M.E. Boiler Construction Code requires boilers having more than 500 square feet (∼46 square meters) of heating surface, or those generating better than 2000 pounds (907 kilograms) of steam per hour, to have two or more safety valves. The safety valves should have sufficient relieving capacity to prevent more than 6% pressure rise at maximum rate or combustion. Required discharge capacity of a safety valve may be based

either on the heat units in the fuel consumed or on the amount of steam generated.

In case more than one safety valve is used, the smaller one can be set to pop at the desired maximum pressure and the larger at 2 or 3 pounds per square inch (0.1 or 0.2 atmospheres) higher.

The relief valve is a form of safety valve, but usually intended for less severe service and of less importance from the safety viewpoint. Relief valves are applied to air, to water, and to steam lines, and also to tanks, heaters, and so on. Among them could be mentioned the back pressure valves and atmospheric relief valves.

SAFFIR/SIMPSON HURRICANE SCALE. See **Cyclones**; and **Fronts and Storm**.

SAFFLOWER *(Carthamus tinctorius; Compositae).* This plant, a native of the East Indies, is now widely cultivated in tropical Asia and Egypt and to a lesser extent in southern Europe and elsewhere. It is a low annual plant with yellowish-red flowers that have tubular corollas.

SAFFLOWER SEED OIL. See **Vegetable Oils (Edible)**.

SAFFRON *(Crocus sativus; Iridaceae). Crocus sativus* is a perennial herb, the native home of which is the eastern Mediterranean region. The stem is an underground flattened corm, the surface of which is covered by a few scaly leaves. At the top of the corm is a terminal bud, which develops into linear leaves 5–9 inches (12.5–22.5 centimeters) long and flowers. The flowers are white or lilac-tinted, with the perianth six-parted and with a very long tube, so that the ovary remains below the surface of the ground. The three stigmas are bright red. These, when dried, are known as saffron, an orange-yellow dye with a considerable percentage of volatile oil present. See also **Flavorings**.

SAGE. See **Antioxidant**; and **Flavorings**.

SAGE-3 (METEOR). See **Earth Observing System (EOS)**; and **Space Science Missions: Earth**.

SAGEBRUSH *(Artemisia tridentata; Compositae).* A number of other species of this genus are also called sagebrush, but *A. tridentata* is more prominent and of wider distribution than the others. This shrub has an extensive root system and may attain heights up to 7 feet (2.1 meters). The gray-green foliage and aromatic odor of this shrub are distinctive. The flowers occur in inconspicuous heads. This plant is distributed from the Black Hills to southern British Columbia to southeastern California to northern Arizona. It reaches its best development, however, in the Great Basin region, where it may occur over large areas in nearly pure stands. See also **Artemisia**. See Table 1 for record trees.

SAGITTARIUS (the archer). This large constellation is the ninth sign of the zodiac. Lying as it does in a particularly rich portion of the Milky Way, it contains a large number of star clusters and gaseous nebulae of great beauty visible in a moderate-sized telescope. From the large number of faint stars, cepheid variables, and globular clusters that seem to congregate in this region, we can deduce that the stellar galactic system has its greatest extension and hence its center in this direction. Long-exposure photographs indicate that large numbers of dark or obscuring nebulae lie in this portion of the Milky Way. The only way to penetrate these clouds is by means of radio astronomy. (See map accompanying entry on **Constellations**).

SAGITTA (the arrow). A northern constellation located next to Aquila.

SAIGA. See **Goats and Sheep**.

SAILFISH. See **Billfishes**.

SAILINGS (The). The position of a vessel at sea or in the air is defined by the latitude and longitude. The position at any particular instant is connected with any other position, either the one just left or the one toward which the vessel is proceeding, by means of the true course and distance.

Any given course and distance may be resolved into two components at right angles to each other: the northing or southing and the easting or westing, each expressed in nautical miles. The northing or southing may be immediately converted into difference of latitude, expressed in angular units, for the nautical mile is, by definition, approximately equal to a minute of arc along a great circle. However, the conversion from easting or westing, commonly known as departure, into difference of longitude, can be accomplished only after taking into account the shape of the earth and the approximate latitude of the ship.

The navigator is continually faced by one of two problems. (1) Given the difference of latitude and longitude between two points on the surface of the earth, to find the course and distance between them. (2) Given the course and distance followed by a ship, to find the difference of latitude and longitude between the point of starting and the destination. The different methods of solving these problems are known as the sailings and include plane, parallel, middle latitude, mercator, great-circle, and composite sailings.

See also **Course**; and **Navigation**.

SAILMAST ULTRA LIGHTWIEGHT BOOM. See **Space Technology 8 (ST8) Mission**.

SAILPLANE. A sailplane is a highly efficient glider. Being designed for the use of expert glider pilots, it is unsuited for primary training. It is characterized by very low sinking speed, nearly flat glide and perfection of construction. It is capable of rising flight on weak thermal air currents and is the type of aircraft employed for cross-country motorless flights of a sporting nature. The sailplane has high aspect ratio (about 20), careful streamlining, clean and smooth external surfaces, and minimum weight consistent with structural safety. The gliding angle in still air is often as flat as 22:1 and the sinking speed as small as 2 feet (0.6 meter) per second.

SAINT ELMO'S FIRE (or Corona Discharge). A brush-like, luminous, and often audible discharge from charged objects in the atmosphere. It occurs on ship masts, on aircraft propellers, wings, and other projecting parts, and on objects projecting from high terrain when the atmosphere is charged and a sufficiently strong electrical potential is created between the object and the surrounding air. Aircraft most frequently experience

TABLE 1. RECORD SAGEBRUSH TREES IN THE UNITED STATES[1]

	Circumference[2]		Height		Spread		
Sagebrush trees	Inches	Centimeters	Feet	Meters	Feet	Meters	Location
Big sagebrush (1991) *(Artemisia tridentata)*	17	43	17	5.2	16	4.9	Washington
Big sagebrush (1995) *(Artemisia tridentata)*	20	51	13	4	17	5.2	Oregon

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

St. Elmo's fire when flying in or near cumulonimbus clouds or thunderstorms, in snow showers, and in dust storms.

SAITHE. See **Codfishes**.

SAKI. See **Monkeys and Baboons**.

SALAMANDERS *(Amphibia, Urodela)*. A vertebrate with a slender body, short legs, and a long tail. The moist skin of the amphibians limits them to protected habitats, either near water or under some protection on moist ground, usually in the woods. Some species are aquatic throughout life, some take to the water intermittently, and some are entirely terrestrial as adults. The salamanders resemble the lizards superficially, but they are easily distinguished from lizards by their moist skin, which is without scales. See also **(Salamanders)**; and **Hellbender**.

SALICACEAE. See **Willow Trees**.

SALICYLIC ACID. [CAS: 69-72-7]. Salicylic acid or $C_6H_4(OH)(COOH)$ is a white solid, melting points 159 °C (318 °F), sublimes at 76 °C (169 °F), insoluble in cold water, soluble in hot water, alcohol, or ether. With ferric chloride solution, salicylic acid solutions are colored violet (distinction from benzoic acid).

Salicylic acid may be obtained (1) from oil of wintergreen, which contains methyl salicylate, or (2) by heating dry sodium phenate C_6H_5ONa plus carbon dioxide under pressure at 130 °C (266 °F) and recovering from the resulting sodium salicylate by adding dilute sulfuric acid.

Uses. Approximately 60% of the salicylic acid produced in the United States has been consumed in the manufacture of aspirin. However, several applications of the acid are growing. Salicylic acid USP, EP, and other pharmacopeial grades are used medically as antiseptic, disinfectant, antifungal, and keratolytic agents. Carbonless copypaper using salicylic acid and alkyl salicylic acid derivatives has become an active application area. The salicylic acid is incorporated into a resin or is encapsulated as one of the agents for pressure or thermally activated imaging.

Salicylic acid derivatives form surfactants that can influence the rheologic properties of solutions. They impart controllable and useful viscous and elastic properties to aqueous liquids.

Salts of Salicylic Acid. A large number of salts of salicylic acid have been prepared and evaluated for therapeutic or other commercial use. Sodium salicylate has analgesic, antiinflammatory, and antipyretic activities. Magnesium salicylate, an analgesic and antiinflammatory agent, appears to have exceptional ability to relieve backaches. It is also used for the symptomatic relief of arthritis. Bismuth subsalicylate is taken orally in combination with other ingredients for protective, antacid action as well as antidiarrheal and antiseptic effects.

Esters of Salicylic Acid. The esters of salicylic acid are commercially produced by esterification of salicylic acid with the appropriate alcohol using a strong mineral acid such as sulfuric as a catalyst. To complete the esterification, the excess alcohol and water are distilled away and recovered. The main commercial applications for salicylate esters are as uv sunscreen agents and as flavor and fragrance agents. Several have application as topical analgesics.

Other Derivatives of Salicylic Acid. *p*-Aminosalicylic acid [CAS: 65-49-6] and its salts have been used in the treatment of tuberculosis. *p*-Aminosalicylic acid can be prepared by the carboxylation of m-aminophenol. Methylene-5,5-disalicylic acid, produced by heating two parts salicylic acid with 1–1.5 parts of 30–40 wt% formaldehyde in the presence of an acid catalyst, is used as an intermediate in the production of bacitracin methylenedisalicylate.

Salicylamide, prepared by the reaction of methyl salicylate with ammonia, has mild analgesic, antiinflammatory, and antipyretic properties. Salicylanilide, prepared by heating salicylic acid and aniline in the presence of phosphorus trichloride, is used as an intermediate in the production of other chemicals and as a slimicide, fungicide, and medicament.

Acetylsalicylic Acid (Aspirin). Acetylsalicylic acid [CAS: 50-78-2], (*o*-acetyoxybenzoic acid) was first synthesized in 1853 by reaction of acetyl chloride with sodium salicylate. As a drug, acetylsalicylic acid was introduced in Germany in 1899 and into the United States in 1900. Aspirin is a registered trademark of Bayer in many nations, but in the United States and the United Kingdom, aspirin is accepted as the generic name for acetylsalicylic acid. See also **Acetylsalicylic Acid**; and **Aspirin**.

m-Hydroxybenzoic Acid. [CAS: 99-06-9]. Of the three hydroxybenzoic acids, the metaisomer is of least commercial importance.

Unlike salicylic acid, m-hydroxybenzoic acid does not undergo the Friedel-Crafts reaction. It can be converted in 80% yield to m-aminophenol by the Schmidt reaction, which involves treating the acid with hydrazoic acid in trichloroethylene in the presence of sulfuric acid at 40 °C. *m*-Hydroxybenzoic acid is reported as an intermediate in the manufacture of germicides, preservatives, pharmaceuticals, and plasticizer.

p-Hydroxybenzoic Acid. [CAS: 99-96-7]. *p*-Hydroxybenzoic acid is of significant commercial importance. The most familiar application is the use of several of its esters as preservatives, known as parabens. See also **Antimicrobial Agents (Foods)**. Also of interest is the use in liquid crystal polymer applications.

Salicyl Alcohol. Salicyl alcohol [CAS: 90-01-7]: (saligenin, o-hydroxy benzyl alcohol) crystallizes from water in the form of needles or white rhombic crystals. It occurs in nature as the bitter glycoside, salicin CAS: 138-52-3, which is isolated from the bark of *Salix helix*, *S. pentandra*, *S. praecos*, some other species of willow trees, and the bark of a number of species of poplar trees such as *Polpulus balsamifera*, *P. candicans*, and *P. n*igra.

The alcohol, which sublimes readily and is very soluble in alcohol and ether, has the following properties: melting point, 86 °C; density 13°/25°, 1.161 g/cm^3; heat of combustion, 3.542 mJ/mol (846.6 kcal/mol); and solubility in 100 mL water at 22 °C, 6.7 g.

Saligenin has been used medically as an antipyretic and appears to possess marked topical analgesic powers in concentrations of 4–10%. Saligenin's taste is pungent at first and then numbing. Unsymmetrical diphenylolmethanes prepared from salicyl alcohol and substituted phenol at 160–170 °C in the presence of alkaline catalysts have been claimed as resin components and resin-hardening agents.

Thiosalicylic Acid. Thiosalicylic acid, [CAS: 147-93-3], (*o*-mercapto benzoic acid), a sulfur-yellow solid that softens at 158 °C (316 °F), has a melting point of 164 °C (327 °F). It sublimes, is slightly soluble in hot water but freely soluble in glacial acetic acid and alcohol, and yields dithiosalicylic acid, [CAS 527-89-9], upon exposure to air.

Thiosalicylic acid has been used as an anthelmintic, bactericide, and fungicide. It has also been used as a rust remover, a corrosion inhibitor for steel, and a polymerization inhibitor. In photography, it has application in print-out emulsions and as an activator for photographic emulsions.

SALINITY. A measure of the quantity of dissolved salts in seawater. It is formally defined as the total amount of dissolved solids in seawater in parts per thousand (0/00) by weight when all the carbonate has been converted to oxide, the bromide and iodide to chloride, and all organic matter is completely oxidized. These qualifications result from the chemical difficulty in drying the salts in seawater. In practice, salinity is not determined directly but is computed from chlorinity, electrical conductivity, refractive index, or some other property with a relationship to salinity that is well established. The relationship between chlorinity Cl and salinity S as set forth in Knudsen's tables is.

$$S = 0.03 + 1.805\ Cl$$

In 1940, however, a better expression for the relationship between total dissolved salts Σ and chlorinity was found to be.

$$\sum = 0.07 + 1.811\ Cl$$

In more recent times, with the advent of devices that measure continuous records of conductivity electronically (e.g., CTD or conductivity–temperature–depth profiler), a new "practical salinity scale" has been determined. It is defined in terms of its electrical conductivity relative to a prescribed standard and it is given the units psu, for "practical salinity

units." For most purposes one can assume that the new unit, psu, and the older unit, 0/00, are synonymous.

See also **Ocean Water**.

SALINOMETER. An instrument for determining salt concentration (salinity), particularly one based upon electric-conductivity measurements. See also **Electrical Conductivity**.

SALIVA. See **Caries, Cariology, and Dentistry**.

SALK, JONAS EDWARD (1914–1995). Salk, an American physician, is famous for making a killed-virus vaccine that was effective in preventing poliomyelitis. His vaccine eliminated polio as a public health threat. For his vaccine he was awarded the Lasker Award of the American Public Health Association in 1956 and in 1958 he received the Bruce memorial Award of the American College of Physicians.

Salk began his work in virology and immunology in 1938 at New York University. Over the years, he worked with Thomas Francis, Jr. who was working on ways to kill influenza virus without destroying the virus's ability to stimulate production of antibodies. In 1947, Salk went to the University of Pittsburgh School of Medicine where he became the head of the Virus Research Center. Here he confirmed there were only three types of polio virus and then proceeded in developing his polio vaccine. In 1963, Salk became the director of the Salk Institute for Biological Studies at San Diego, California. He retired in 1975.

SALMONELLOSIS. See **Foodborne Diseases**.

SALMON *(Osteichthyes).* The order *Salmoniformes* consists of eight suborders, with some quite unlike others. Most important commercially is the suborder *Salmonoidei*. These fishes are primarily migrating species and associated with the freshwater of the Northern Hemisphere. The three subfamilies of *Salmonoidei* include the *ayus* and *smelts*. Many of the salmon species are good eating not only because of their flavorful, fatty meat, but also because they lack those bones that in most fishes are embedded in the cartilaginous walls between the muscular segments. Salmonidae contains such familiar fishes as *salmon*, *trout*, and *chars*.

Atlantic Salmon. The species *Salmon solar*, prior to extensive pollution of certain waters, was one of the most prevalent fishes in the Atlantic drainage areas. Its distribution extended from Kara in northeastern Russia, along the coast of Europe to Douro in the northwestern part of the Iberian peninsula, and on to Iceland, the southern tip of Greenland, and across Newfoundland to Cape Cod in the northeastern United States. Salmon migrate extensively. The early part of the salmon's life is spent in the upper courses of large rivers. Then they migrate into the sea, where they grow relatively quickly, and then return to swim up rivers for spawning. During their stay in the oceans, salmon traverse great distances. Thus, salmon marked off the European coast have been recovered in waters of western Greenland. Generally, however, the salmon stays near the shore. Feeding grounds are primarily in the southern Baltic Sea and off northwestern Norway. When preying upon other fishes, they are found in the upper water levels to a depth of about 32 feet (10 meters), but may penetrate deeper.

Some studies indicate that their distribution at various depths depends upon daily and seasonal changes. During their period in the sea, salmon grow at a remarkable rate, often exceeding 2.2 pounds (1 kilogram) per month. They spend 1 to 3 years in the ocean before returning to the rivers to spawn. During this period, they have stored great quantities of fat, so much that their skin is orange-red. They leave freshwater when they are from 4 to about 8 inches (10 to 20 centimeters) long. After a year in the ocean, they measure nearly 20 to 26 inches (51 to 66 centimeters) in length and weigh from 3.3 to 7.7 pounds (1.5 to 3.5 kilograms). After 2 years, their length is from about 28 to 36 inches (71 to 91 centimeters), with a weight of from 9 to 17.5 pounds (4 to 8 kilograms). After 3 years, salmon are from 36 to 41 inches (91 to 104 centimeters) long and weigh from 17 to nearly 28 pounds (8 to 13 kilograms). Salmon probably reach a maximum age of 10 years. Occasionally, old males up to 41 inches (104 centimeters) in length and weighing as much as 80 pounds (36 kilograms) are caught. Females are generally smaller and rarely exceed a length of 39 inches (100 centimeters). Their greatest weight is 44 pounds (20 kilograms). See Fig. 1.

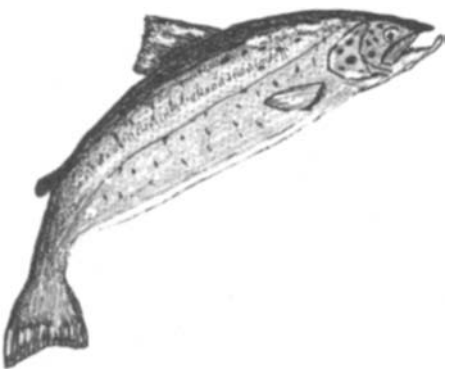

Fig. 1. Atlantic salmon.

Salmon from various rivers meet at the feeding grounds. When the spawning season comes, they separate once again, and each salmon seeks out the river in which it was born. The exact manner in which salmon find their way back to their home river is not understood. It is only known for certain that their olfactory sense plays a crucial role in the second phase of their ascent up the river. This ascent takes place throughout the year in some rivers, while in others it is found only at certain seasons. Often, larger salmon are seen ascending a river at one period, while smaller ones are found at some other time. Four major types are distinguished — large and small summer salmon and large and small fall or winter salmon. When they meet at the river mouths, the salmon can be distinguished by the development of their gonads. The individual groups then seek out their various spawning sites. If these sites are far from the mouths of rivers, it is generally the large fall salmon that ascend the river. Their germ cells are still immature when they begin their ascent. The ascent is interrupted by the onset of frost; at this time, the salmon winter somewhere upriver and will reach their spawning sites in the following fall.

While the energetic large salmon are capable of swimming great distances upstream, the smaller species generally find spawning sites near the river mouths. Each day these salmon cover greater distances. In small Scottish rivers, daily distances of up to 34 miles (58 kilometers) have been recorded. It must also be recalled that the salmon only migrate for 5 to 6 hours per day, during which time they swim with great strength and endurance. Their highest speed has been estimated at 10 miles (13 kilometers) per hour. They can also swim through rapids. Against a current of 19.6 feet (6 meters) per second, a salmon can push ahead at a rate of over 3.3 feet (1 meter) per second. Small waterfalls are passed by jumping over them, and leaps of up to 10.8 feet (3 meters) high and 16.4 (5 meters) long have been observed. To jump out of the water, the salmon swim up through the water surface on a slant, and with a particularly strong beat of the tail they gain additional acceleration at the surface. While jumping, salmon typically show a distinct lateral arching of the body. If the first attempt fails, the leaps are repeated constantly. This often results in skin injuries in stony waters, which sometimes become infected and cause death prior to reaching the spawning site.

During the entire migration, the salmon virtually cease feeding from the time they enter the river. During the journey, their fat reserves are converted into energy, and the orange-red hue of the skin disappears. As the germ cells mature, the salmon also alter their appearance. In the ocean, salmon have rather plain coloration, with a gray-green back, silvery sides, and white belly. X-shaped spots are above the lateral line and round

black spots mark the head. However, when migrating upstream, a brilliant coloration develops. The back becomes considerably darker, while the sides take on a bluish shimmer and the stomach becomes reddish. Purple-red spots appear beside the black ones, and even the lower sides of the pectoral, anal, and caudal fins take on reddish hues. The color change is accompanied by a major anatomical modification of the lower jaw. The jaw points upward and develops cartilaginous growths from which a hook-shaped appearance develops.

The salmon-spawning period in central European waters occurs generally from mid-November to mid-December. In the north, the onset of spawning is in mid-September and in some groups may last until February. Spawning sites are located in regions with clear, cold, oxygen-rich, fast-flowing water and a clean gravel bottom. Salmon typically seek gravel banks in the upper water levels at a depth of about 1.5 feet (0.5 meter). Once the female arrives at the spawning site, she prepares the nest. The female digs up the floor with powerful rump and tail motions and constructs a depression some 4 to 8 inches (10 to 20 centimeters) deep and often well over 3 feet (1 meter) long. Bohemian fishermen have said that a horse could fit in one of these nests! During the entire period, there are usually several males in the vicinity, but they do not assist with construction of the pit. All salmon species carry out their spawning habits in a similar manner. After maneuvers of rivalry among males, the male and female salmon will swim side-by-side, pressing close together with mouths open just above the spawning pit, and the eggs and sperm are released. Eggs are released several times, interrupted by additional rivalry fights and more courtship display behavior. A single female lays a total of from 10,000 to 30,000 eggs. It lays about 500 to 2000 eggs per kilogram (2.2 pounds) of body weight. This is actually a low number when compared to some fishes, such as the carp. The yolk-rich, sticky eggs are from 5 to 7 millimeters large and, according to water temperature, will lie between the stones in the spawn pit for some 70 to 200 days. The young hatch in April or May. As long as the larvae still have yolk upon which to feed, they remain hidden in the pit. When that supply is exhausted they move into the water and initially feed on small crustaceans and insect larvae. As they get older, the young salmon increasingly feed on fishes and, at the end of their juvenile period, their diet is exclusively small fishes. The young stay in fresh water for 1 to 2 years (in the north, up to 5 years), after which they enter the oceans and take on their typical oceanic coloration.

The *effects of pollution* on the Atlantic salmon population have been marked and have been going on for decades. These fishes have almost completely disappeared from the Rhine, Weser, and Elbe Rivers in Germany. A few isolated salmon still appear in the lower Rhine, but they are inedible because their fat is contaminated with phenol and other wastes in the river. In Europe, the decline of the salmon began in the mid-1890s as the rivers became polluted. In England, industrialization began earlier, and thus the Thames, once a salmon river, became contaminated still earlier. The last salmon caught in the Thames was recorded in 1833. Until the early part of the twentieth century, the East Prussian coast was the most productive one for German commercial fishing. Large catches no longer are made. Currently, most European salmon are caught in Norway and Denmark. Canada has the greatest catch in the world. Salmon are generally smoked.

Inevitable dying after the first spawning is a rare phenomenon among vertebrates. Death of the adult salmon occurs in nearly all instances within 1 to 2 weeks after spawning. The immediate cause of the post-spawning death is not well understood. Physical exhaustion from the long migrations does not appear to be the principal cause of death, since salmon running up short streams may reach the spawning site in very good condition, but they still undergo degeneration that rapidly leads to death after shedding their sex products.

Species of Salmon

Pacific Salmon. There are several species: *chinook* (*Oncorhynchus tshawytscha*); the *coho* (*O. kisutch*); the *sockeye* (*O. nerka*); the *chum* (*O. keta*); and the *pink* (*O. gorbuscha*). These are generally known as the North American species. There is an additional Asian species (*O. masou*), the common name of which is *masu* salmon.

The various species of salmon vary greatly in size reached at maturity (Harry 1969). The chinook is the largest of the Pacific salmon, with a record weight of 126 pounds (57.2 kilograms), but with an average weight of about 20 pounds (9.1 kilograms). Coho salmon range in size up to 30 pounds (13.6 kilograms), with most of the fish being in the 8-to-12-pound (3.6-to-5.4-kilogram) category. Chum salmon weigh as much as 33 pounds (15 kilograms) and the average weight is about 8 pounds (3.6 kilograms). Sockeye salmon are usually between 5 and 7 pounds (2.3 and 3.2 kilograms), but weights up to 15 pounds (6.8 kilograms) have been recorded. Pink salmon usually weigh between 3 and 5 pounds (1.4 and 2.3 kilograms) and specimens up to 12 pounds (5.4 kilograms) have been taken. The masu salmon has an average weight of about 10 pounds (4.5 kilograms) and a maximum weight of 20 pounds (9.1 kilograms).

Chinook Salmon. This fish can be distinguished from the other species by the heavy black spotting on the back, the dorsal fins, and both lobes of the caudal fin, as well as by the black pigmented skin along the base of the teeth. Young chinook salmon can be recognized in freshwater by strongly developed parr marks (marks characteristic of young fishes). The chinook salmon enter the Sacramento-San Joaquin system of California to spawn, but are found only rarely in streams south of San Francisco Bay. Spawning occurs in rivers north to the Bering Sea and on the Asiatic side down to the Amur River, although rarely that far south, and in Japan in the rivers' of northern Hokkaido. In the North Pacific Ocean, chinook salmon are found generally to the north of 46° north latitude in the eastern half of the ocean, but west of the 180th meridian they occur about as far south as 42° north latitude. Chinook salmon generally ascend the larger streams to spawn, and they are abundant in such rivers as the Sacramento, Columbia, Fraser, and Yukon. The center of abundance of this species is the Columbia River, in which adults return to spawn during every month of the year. Each female chinook salmon carries from 2,000 to 13,000 eggs. After the eggs are deposited, they are protected by a cover of gravel. Hatching may take as long as 4 months, depending upon water temperature. From a commercial tonnage standpoint, the chinook salmon represents only about 4% of the total salmon catch of the major fishing countries (Canada, the United States, Japan, and the U.S.S.R.).

Coho Salmon. This fish is found in North American rivers and streams from Monterey Beach, California, in the south, to the Chukchi Sea the north. In Asia, they are rarely found in the Anadyr River, but occur in large numbers in Kamchatka and south almost to the Amur River. The species is also present on Sakhalin Island and in Hokkaido. During their fast-growing period in the ocean, coho salmon are distributed across the northern Pacific Ocean and in the Bering Sea. They are found as far south as California waters in the eastern half of the northern Pacific and in the western North Pacific, they are found as far south as 42° north latitude.

Adult coho salmon begin the freshwater migration between September and December, often coincident with a freshet (stream of freshwater flowing into the sea). This species enters the larger rivers, but also is common in the very small coastal streams throughout its range. Spawning takes place often in tiny tributaries only 3 to 4 feet (1 meter plus) wide. The young emerge from the gravel in the early spring. Coho salmon usually remain in fresh water for about 1 year after fry emergence and then begin their downstream journey to the sea. In Alaskan streams, coho commonly remain in fresh water for 2 years. Larger coho salmon feed principally on squid, small fish, and euphausiids. Adult coho salmon return to spawn late in the year following that in which they entered the ocean. In their last summer of ocean life, coho salmon grow very rapidly and commonly double their weight during this period. Of the commercial tonnage taken by the four major salmon fishing countries previously mentioned, the coho catch represents about 7% of the total. See also **Aquaculture**.

Chum Salmon. This fish is distributed along the North American coast from the Klamath River in California, north to the Arctic coast of Alaska and even in the Mackenzie River. In Asia, chum salmon are abundant in the Amur River and are found on the island of Sakhalin and in Hokkaido streams and south almost to Tokyo. Chum salmon are in the Pacific Ocean north of 45° north latitude in the eastern part of the ocean, and south almost to 36° north latitude in the western Pacific, as well as in the Bering Sea.

Chum salmon enter freshwater to spawn from July to January. To the north, in Alaska and northern British Columbia, the runs are primarily between July and early September, while south of Vancouver Island the runs are from October through January. Chum salmon usually spawn in smaller coastal streams or in the lower portions of larger rivers. However, they ascend several hundred miles (kilometers) up the Yukon to spawn and also spawn in the headwaters of some Asian rivers. Chum salmon

frequently dig their nests in the same area as used by pink salmon. The young emerge from the gravel in March through May. Newly emerged chum salmon are a little over 1 inch (2.5 centimeters) long. In most North American streams, young chum salmon almost immediately move downstream to salt water, but in some Asian streams and the Yukon River, it may be several weeks before the young reach the ocean. Chum salmon usually mature at 4 years, but 3- and 5-year-old fish are common. Of the commercial tonnage taken by the four major salmon fishing countries, the chum salmon catch represents about 24% of the total.

Sockeye Salmon. This fish occurs rarely in North American coastal streams south of the Columbia River, but it can be found north to the Yukon River of Alaska, along the Asian coast from the Anadyr River, in the rivers of Kamchatka, where it is the principal species in the Kamchatka River, and south to northern Hokkaido, where it is very rare. Sockeye salmon are distributed in the ocean throughout the northern North Pacific and the Bering Sea.

The mature sockeye salmon male in freshwater becomes a brilliant red and the female is a dark red. This species is distinguished from others by having 28 to 40 long, slender, closely set gill rakers on the first gill arch. There are no black spots. Young sockeye salmon have oval parr marks, which extend only slightly below the lateral line. Sockeye salmon are typically lake-dwelling during the brief freshwater part of their life. After migrating from the lake they usually spend 2 to 3 years at sea. Adult sockeye may begin the upstream migration as early as May and in some areas the migration may extend into October. Sockeye salmon spawn in outlet and inlet streams of lakes and also along some lake shores. After leaving the protection of the gravel, the young move into lakes, where they remain for 1 to 3 years before migrating to the ocean at a length of from 3 to 6 inches (7.5 to 15 centimeters). The downstream migration takes place from April to June, usually under the protection of darkness. In the North Pacific, sockeye salmon feed heavily on amphipods, copepods, euphausiids, pterepods, fish, squid, and similar animals. In the ocean, growth is rapid and those fish that return to freshwater after spending 2 years in the ocean are about 21 inches (53 centimeters) long.

In the ocean, there is a considerable overlap of sockeye salmon from Kamchatka and North America. Maturing sockeye salmon in the high seas begin moving shoreward in May and June. The very important Bristol Bay (Alaska) runs travel an average of about 24 miles (39 kilometers) per day when heading toward their home stream.

Of the commercial tonnage taken by the four major salmon fishing countries, the sockeye salmon catch represents about 24% of the total.

Pink Salmon. This fish occurs occasionally in streams south of Puget Sound and from there northward into Arctic Ocean streams of Alaska. Pink salmon are also found in the Mackenzie River. On the Asiatic side of the Pacific, pink salmon have been reported from the Lena River and south into the streams of the Sea of Okhotsk, the Kurile Islands, Sakhalin, Hokkaido, and on the northeastern coast of Hondo. Pink salmon are found usually north of the 40th parallel across the entire north Pacific Ocean.

Pink salmon move from the ocean into the streams where they spawn from July to November. Adults usually migrate only a short distance from salt water and sometimes spawn in streams in areas that are affected by the tide. In larger rivers, pink salmon may move considerable distances upstream. The young migrate to salt water as soon as the yolk sac is absorbed, in March through early June, but principally in April. In many of the smaller coastal streams of Alaska, the young pink salmon emerge from the gravel and migrate to the sea in one night. Downstream movement begins as darkness approaches and ceases before morning. In the estuaries, schools of young fish migrate along the shore near the surface where the currents gradually carry them toward the ocean. Here their food consists of euphausiids, amphipods, pterepods, small fish, crustaceans, larval squid, and copepods. Pink salmon migrate from the stream to the estuaries at about 1.5 inches (3.8 centimeters) in length and, when they return to spawn after 15 to 17 months of life in the ocean, their average length is about 20 inches (51 centimeters). See Fig. 2.

Of the commercial tonnage taken by the four major salmon fishing countries, the pink salmon catch represents about 41% of the total.

Masu Salmon. *Masu salmon* are found only in streams on the Asiatic side of the Pacific Ocean, from the Amur to the Pusan River, in Sakhalin streams, and on the island of Hokkaido and Hondo. They are also occasionally taken on the western coast of Kamchatka.

Fig. 2. Male pink or humpback salmon.

Freshwater Salmon. An important sport fishery for salmon has been developed in the Great Lakes.

Salmon Products

Salmon are sold as fresh fish and are also canned, smoked, and fresh-frozen. Salmon eggs are used as bait for sport fishermen or are eaten as red caviar or salted as food. Salmon for the fresh market are usually troll caught in the ocean within a few miles of the port of landing. Coho salmon is the principal species used in the fresh market, but fresh chinook and pink salmon are also marketed. By far the greatest percentage of sockeye, pink, and chum salmon are processed in cans weighing 1 pound (0.45 kilogram) or less.

Commercial salmon fishing, as an industry, commenced in North America in the early 1860s, with the first commercial pack produced at Sacramento, California. The industry soon moved north where canneries on the Fraser River in British Columbia, on Puget Sound, and on Prince of Wales Island in Alaska were established by the late 1870s. The salmon catch in North American waters reached its first peak in the 1930s, after which production has been cyclic. Japanese salmon fisheries commenced in the early 1950s and developed rapidly. Somewhat later, the U.S.S.R. entered into serious commercial salmon fishing operations and is now a major factor.

Salmon Technology

Much research has been devoted to protecting and expanding the traditional salmon fisheries as well as developing sport fisheries for salmon in freshwater areas, such as the Great Lakes. Experimental stockings have been carried out with coho and chinook salmon in these lakes, notably Lake Michigan and Lake Superior.

In the area from British Columbia to California, and to some extent in Alaska, an increasing percentage of adult salmon found passage hindered or blocked by power, irrigation, or flood control dams. The Columbia River and its wild tributary, the Snake River, have increasingly become polluted by wastes as well as thermally. Fishways have been constructed over the low dams of the main Columbia and Snake Rivers, and these have been generally successful in passing adult salmon. Downstream migrating salmon pass through the turbines of the low dams or over the spillways with usually only a small percentage of loss.

In recent years, fish passage facilities have been provided at most dams, but at some high dams, fishway construction has not proved feasible and other methods have been provided for maintaining the runs. Chief among these has been the production from salmon and steelhead hatcheries. In recent years, research efforts have resulted in a great improvement in the success of rearing salmon in hatcheries. Many hatchery diseases can now be controlled, and nutritious diets have been developed for young salmon. Scientists have also given attention to improving survival of salmon eggs and fry by constructing spawning channels. An artificial spawning channel generally consists of a dam at the head to control the flow of water and an artificial channel of appropriate width and slope with gravel of optimum size for best egg and fry survival. Many of the conditions detrimental to the survival of salmon eggs and fry in nature can be controlled in such artificial spawning areas. The optimum number of adults can be allowed to spawn. Flood waters, which wash eggs and fry from the gravel, can be prevented. Predators can be controlled. Gravel can be selected to allow optimum circulation of water with its life-giving oxygen, and the amount of water needed to ensure best production of fry can be maintained. At Jones Creek, a tributary of the Fraser River in British Columbia, one of the first artificial spawning channels for salmon was constructed as early as 1954, where it was found that the survival of pink salmon eggs and fry

was from 4 to 6 times greater than that of the natural environments See also **Aquaculture**.

The smelt, closely related to the salmon, is described in the entry on **Smelt.**

SALPINGITIS. Infection of the fallopian tubes. This common disease is most frequently due to a gonorrheal infection. More rarely, it may be due to tuberculosis, *streptococcus*, or *pneumococcus* infection. Gonorrheal salpingitis is not only the most prevalent but is the most disabling in its aftereffects. Salpingitis may not occur for months or even years after the original gonorrheal infection.

SALSIFY. See **Composite Family**.

SALT. A compound formed by replacement of part or all of the hydrogen of an acid by one (or more) element(s) or radical(s) that are essentially inorganic. Alkaloids, amines, pyridines, and other basic organic substances may be regarded as substituted ammonias in this connection. The characteristic properties of salts are the ionic lattice in the solid state and the ability to dissociate completely in solution. The halogen derivatives of hydrocarbon radicals and esters are not regarded as salts in the strict definition of the term.

In the classical concept of the process of neutralization, whereby an acid and a base in solution react to form a salt, the proton of the acid and hydroxyl ion of the base react to form water, leaving the cation of the base and the anion of the salt by recombination.

Upon evaporation of the solvent, the salt is obtained as such, frequently as crystals, sometimes with and sometimes without water of crystallization. A salt, when dissolved in an ionizing solvent, or fused (e.g., sodium chloride [CAS: 7647-14-5] in water), is a good conductor of electricity and when in the solid state forms a crystal lattice (e.g., sodium chloride crystals possess a definite lattice structure for both sodium cations (Na^+) and chloride anions (Cl^-), determinable by examination with x-rays).

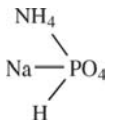
A broader definition than that confined to solutions is demanded in some fields of chemistry (e.g., in high temperature reactions of acids, bases, and salts). In the formation of metallurgical slags, at furnace temperatures, calcium oxide is used as base and silicon oxide and aluminum oxide as acids; calcium aluminosilicate is produced as a fused salt. Sodium carbonate and silicon oxide when fused react to form the salt sodium silicate with the evolution of carbon dioxide. In this sense:

[Oxide of any element functioning as a metal — that is, as a base] plus [Oxide of any element functioning as a nonmetal — that is, as an acid] yields [Salt]

Iron and sulfur when heated react to form the salt ferrous sulfide. In this sense:

metal plus nonmetal yields salt

Salts therefore, are prepared (1) from solutions of acids and bases by neutralization and separation by evaporation and crystallization; (2) from solutions of two salts by precipitation where the solubility of the salt formed is slight (e.g., silver nitrate [CAS: 7761-88-8] solution plus sodium chloride solution yields silver chloride [CAS: 7783-90-6] precipitate [almost all as solid], and sodium nitrate present in solution as sodium cations and nitrate anions [recoverable as sodium nitrate [CAS: 7631-99-4], solid by separation of silver chloride and subsequent evaporation of the solution]); (3) from fusion of a basic oxide (or its suitable compound — sodium carbonate [CAS: 497-19-8] above) and an acidic oxide (or its suitable compound — ammonium phosphate), since ammonium and hydroxyl are volatilized as ammonia and water. Thus, sodium ammonium hydrogen phosphate



yields sodium metaphosphate, [CAS: 35270-09-8], $NaPO_3$, upon heating. (4) Salts also are prepared from reaction of a metal and a nonmetal.

Reactions of salts as such in solution, without decomposition of cation or anion, are dependent upon the presence of the cation and the anion of salt.

An *acid salt* is a salt in which all of the replaceable hydrogen of the acid has not been substituted by a radical or element. These salts, in ionizing, yield hydrogen ions and react like the acids (e.g., sodium bisulfate, [7681-38-1], $NaHSO_4$, potassium bicarbonate, [CAS: 298-14-6], $KHCO_3$, sodium hydrogen phosphate, [CAS: 7558-79-4], Na_2HPO_4).

An *amphiprotic* (also called *amphoteric*) *salt* is a salt that may ionize in solution either as an acid or a base, and react either with bases or acids, according to the conditions.

A *basic salt* is a salt contains combined base as $Pb(OH)_2$ $Pb(C_2H_3O2)_2$, a basic acetate of lead. These salts may be regarded as formed from the basic hydroxides by partial replacement of hydroxyl (e.g., HO−Zn−Cl). They react like bases and, when soluble, ionize to yield hydroxyl ions.

A *complex salt* is a saline compound having the structure of a combination of two or more salts and that is regarded as the normal salt of a complex acid. Complex salts do not split into a mixture of the constituent salts in solution, but furnish a complex ion that contains one of the bases (e.g., potassium molybdophosphate and potassium platinochloride).

A *double salt* is a substance consisting of two simple salts that crystallize together in definite proportions and exist independently in solution (distinction from complex salts). The alums are representative double salts.

An *inner salt* is a member of a special class of internal salts in which an acid group and a neutral group coordinate with metals to form a cyclic complex. These salts occur widely in analytical chemistry, (where they are formed between metallic ions and organic reagents) in dyestuffs, in life processes (chlorophyll and hematin belong to this class of compounds), and in many other fields.

An *internal salt* is a compound in which the acidic or basic groups that react to produce the salt linkage (which may or may not entail the formation of water) are in the same molecule. This particular salt linkage may consist of a polar or a nonpolar bond.

A *mixed salt* is a salt of a polybasic acid in which the hydrogen atoms are replaced by different metallic atoms or positive radicals.

A *pseudo salt* is a compound that has some of the normal characteristics of a salt, but lacks certain others, notably the ionic lattice in the solid state and the property of ionizing completely in solution. The absence of these properties is due to the fact that the bonds between the metallic and nonmetallic radicals are covalent or semicovalent instead of polar. Because these salts do not ionize completely, they are also called *weak salts*.

See also **Sodium Chloride**.

SALTATION. This term, as proposed by McGee, in 1908, is used by geologists to designate the particular mode of the stream transportation of clastic sediments by intermittent leaps or bounds. Probably an important factor in the ultimate transportation of the coarser fragments by streams and rivers.

SALT BATH. A molten mixture of sodium, potassium, barium, and calcium chlorides or nitrates to which sodium carbonate and sodium cyanide are sometimes added. Used for hardening and temperature of metals and for annealing both ferrous and nonferrrous metals. Temperatures used may be as high as 1,315 °C (2,399 °F) for hardening high-speed steels. Commercial mixtures are available for a variety of specifications.

SALT BRIDGE. A type of liquid junction used to connect electrically two electrolytic solutions. It consists commonly of a U-tube filled with a strong solution, and provided with porous plugs. It is used for such purposes as to connect electrolytic half cells in making measurements of electrode potential.

SALT FINGERING. A form of double-diffusive convection that occurs when warm, salty water overlies cold freshwater.

A parcel of freshwater moved upward will gain heat more quickly than it gains salt and so will become lighter than the surrounding water. It will rise unstably as a result. Salt fingering has been observed in the Caribbean Sea where it gives rise to stable layers hundreds of kilometers in extent. The process transports salt much more efficiently than heat. See also **Turner Angle**.

AMS

SALTING OUT. Reduction in the water solubility of an organic solid or liquid by adding a salt (usually sodium chloride) to an aqueous solution of the substance. Ions of the dissolved salt attract and hold water molecules, thus making them less free to react with the solute. The result of this is to decrease the solubility of the solute molecules with consequent separation or precipitation. Colloidal suspensions of proteins, soaps, and similar substances are precipitated in this way.

SALT (NaCl). See **Sodium Chloride**.

SALTPETER. Potassium nitrate [CAS: 7757-79-1]. Sodium nitrate [CAS: 7631-99-4] is often called Chile saltpeter, and calcium nitrate [CAS: 10124-37-5] is sometimes called Norway saltpeter. Uses include: manufacture of gunpowder, the manufacture of sulfuric [CAS: 7664-93-9] and nitric [CAS: 7697-37-2] acids, glassmaking, an oxidant and flux in metallurgical operations, curing of meat when mixed with salt and sugar, the preparation of fluxing and denoting powders, manure, used in many pharmaceutical preparations, and preparing Heaton steel.

SALT RIVER. Although many rivers of the world contain relatively high contents of salt, a salt river is usually identified as a river that penetrates into a huge deposit of rock salt and forms glistening white cliffs of salt in its course. One of these formations occurs in a broad bend of the Huallaga River in eastern Peru. The salt cliff extends some 8 kilometers in length and is about 100 meters in height. The Huallaga is a major tributary of the Amazon River. Several exposed salt deposits of this kind are found in the region of the Amazon headwaters. It is reasoned that during the formation of the Andes, compression forces caused rock salt to flow in a way somewhat analogous to the manner of flow of glacial ice. Salt deposits in the Andes region greatly affect the chemical composition of the Amazon tributaries and it is estimated that dissolved salt in these tributaries accounts for about half of the sodium and chlorine content in the Amazon River.

SALT SEEDING. A form of cloud seeding in which salt particles are released into the atmosphere with the objective of increasing precipitation. The salt particles are hygroscopic and readily condense water and grow large enough to become centers for coalescence growth of precipitation, or participate in the ice accretion process. See also **Cloud Seeding**; and **Weather Modification**.

AMS

SALVE BUG *(Crustacea, Isopoda).* A marine crustacean, *Aega psora*, parasitic on various fishes. It is elongate oval in form and is a little more than one-half inch long. Found on both sides of the Atlantic.

SAMARIUM. [CAS: 7440-19-9]. Chemical element symbol Sm, at. no. 62, at. wt. 150.35, fifth in the Lanthanide Series in the periodic table, mp 1,073 °C (1,963 °F), bp 1,791 °C (CAS: 3,256 °F), density 7.520 g/cm^3 (20 °C (68 °F). Elemental samarium has a rhombohedral crystal structure at 25 °C (77 °F). The pure metallic samarium is silver-gray in color, retaining a luster in dry air, but only moderately stable in moist air, with formation of an adherent oxide. When pure, the metal is soft and malleable, but must be worked and fabricated under an inert gas atmosphere. Finely divided samarium as well as chips from working are pyrophoric and ignite spontaneously in air, burning at 150–180 °C (302–356 °F). There are seven natural isotopes of samarium ^{144}Sm, ^{147}Sm through ^{150}Sm, ^{152}Sm, and ^{154}Sm. Eleven artificial isotopes have been identified. The natural ^{147}Sm isotope is weakly radioactive with a half-life of 2.5×10^{11} years. The samarium isotope mixture is the second highest (after gadolinium) of all elements in terms of its thermal-neutron-absorption cross-section (5,800 barns at 0.025 eV). The cross-section of ^{149}Sm is about 40,000 barns. Samarium ranks 62nd in abundance of the elements in the earth's crust, exceeding tantalum, mercury, bismuth, and the precious metals, excepting silver. The element was first identified by Lecoq de Boisbaudran in 1879. See also **Chemical Elements: The History of the Origin**. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^5 5s^2 5p^6 5d^1 6s^2$$

Ionic radius Sm^{2+} 1.11 Å, Sm^{3+} 0.964 Å. First ionization potential 5.6 eV; second 11.1 eV. Other important physical properties of samarium are given under **Rare-Earth Elements and Metals**.

The principal sources of samarium are monazite (4.5% Sm_2O_3) and bastnasite (0.5% Sm_2O_3). Current demands for the element are met by the coproduction with europium and gadolinium from these minerals. The residues of uranium mining (Canada) also contain about 4.5% Sm_2O_3. Unlike the other light rare-earth metals, the salts and oxide of samarium do not reduce to metal using barium, calcium, or lithium, nor can electrolytic processes be used. The most effective reducing agent is lanthanum, which is mixed with samarium (III) oxide [CAS: 12060-58-1] Sm_2O_3 and heated under vacuum in a tantalum crucible. The samarium metal volatilizes and is condensed as powder or sponge on coiled tantalum or copper condenser plates. Subsequently, the samarium must be remelted under an argon or inert atmosphere before it is cast into graphite or tantalum molds.

Samarium has been alloyed with gadolinium and aluminum to produce nuclear reactor hardware that will absorb neutrons for short periods. The use of samarium in intermetallics, cermets, and other chemical forms for use in nuclear applications holds promise. Small quantities of Sm_2O_3 are used in optical-glass filters and to encase lanthanum borate glass rods, which then are drawn into fine fibers for fiberoptics applications. The element has been used as a coding agent for inks used in data handling systems. Small amounts also have been used for activating phosphate-type phosphors. The addition of samarium oxide produces a strong narrow emission in the near-infrared spectral region. The most significant use of samarium is in the permanent-magnet alloys $SmCo_5$ and Sm_2Co_{17}. The strength of these magnets Second to that of $Nd_2Fe_{14}B$ by only a small margin. But, because of costs the utilization of the $SmCo_5$–Sm_2Co_{17} alloys is much less than that of the Nd–based permanent magnets. The Sm–base permanent magnets have a much higher magnetic ordering temperature and are used in high temperature greater than 250 °F (or 120 °C) applications. See also **Cobalt**.

SAMPLE-AND-HOLD AMPLIFIER. Also known as a track-and-hold amplifier, this device has an output that is proportional to the input until a "hold" signal is received. Upon receipt of that signal, the amplifier output is maintained essentially constant even though there may be changes in the input signal. The input and output waveforms of a sample-and-hold amplifier are shown in Fig. 1.

As shown in Fig. 2, the conceptual design of a sample-and-hold amplifier comprises two independent amplifiers connected by a switch. With sampling switch S_1 closed, holding capacitor C is charged when an input signal is applied to the first amplifier. Upon receipt of the "hold" command, switch S_1 is opened, thus leaving capacitor C charged at the instantaneous value of the input signal. Capacitor C is not discharged

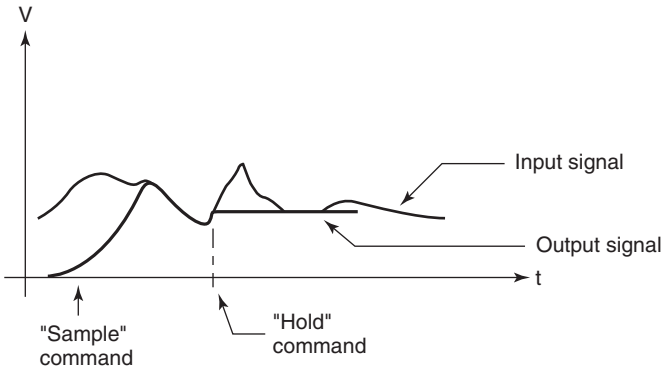

Fig. 1. Action of sample-and-hold amplifier.

because the second amplifier has a high input impedance. The output of the second amplifier remains essentially steady for a period of time. The "hold" signal may be generated by an external circuit (coupled to a process or experiment) or by a computer or digital control unit under control of a stored program.

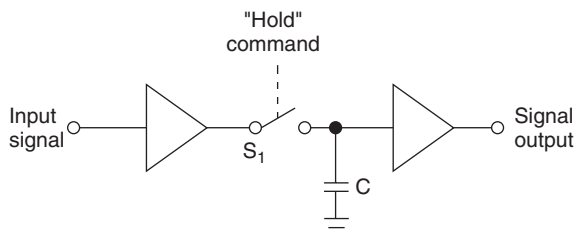

Fig. 2. Schematic circuit of a sample-and-hold amplifier.

Sample-and-hold amplifiers meet certain specialized needs in digital-data acquisition systems. Usually one or both of the following requirements exist: (1) the value of a single signal must be determined at a precise instant of time, or (2) the values of two signals must be compared at a precise instant of time. These requirements cannot be met by a time-shared amplifier and analog-to-digital converter system because these systems require a finite settling and conversion time. Where a sample-and-hold amplifier is used, it is possible to retain the instantaneous value of one or more input signals over the time interval required to convert them to digital values.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

SAMPLE (Statistics). A sample is a collection of individuals drawn from a population. Ordinarily, inferences are to be made from the sample to the population, and the one must be in some way representative of the other.

When sampling from an actual population, the simplest method is to draw a random sample. The members of the population are numbered off, and the sample selected with the aid of a table of random numbers or some similar device. To ensure more even coverage, stratified sampling may be adopted. The population is divided into a number of homogeneous groups (the strata) and a random sample is selected from each. If only a random selection of the strata are sampled, we have a two-stage sample; three or more stage samples are similarly constructed. In two-phase sampling one type of observation is taken only on a small calibrating sample, while another (which may be easier or cheaper to obtain) is taken on a larger sample; regression or ratio relationships derived from the small sample are used to predict values of the first measurement for individuals in the large sample.

The introduction of a random element can ensure the absence of bias from an estimate based on a sample, and also makes possible a valid estimate of the error to which such an estimate is subject. (For various types of samples, and various methods of sampling, see **Sampling (Statistics)**.

SAMPLING CONTROLLER. An automatic controller using intermittently observed values of a signal, such as the setpoint signal, the actuating error signal, or the signal representing the controlled variable, to effect control action. Also termed *sampled data system*.

Applications of sampled data systems include those applications in which the actuating or error information is only available in sample form, as well as those arrangements in which deliberate conversion of continuous data to sampled data is made. Examples of the first situation include an automatic tracking radar system and a gas chromatograph. The radar system scans in two coordinates and thus can furnish information on a particular target only at the discrete time intervals when the antenna direction permits radio frequency every to intercept the target. In the chromatograph, information on a particular variable is available at the completion of each sample analysis. An illustration of the second possibility arises in direct digital control. In this application, the digital computer is used to operate, simultaneously, numerous feedback control systems. By use of sampled data techniques the computer may be used periodically to process data from one system, then from the second, and so on until it completes the operating cycle and accepts data from the first system again. Figure 1 is a typical schematic for this type of system.

The hold circuit shown in Fig. 1 is an integral part of any sampled data control system. Its function is to hold or remember the value of assigned variable at the sampling instant for a finite portion of the sampling period T. See Fig. 2. Its position in the loop will depend on the particular application. Wave form for a zero order hold following a sampler is shown in Fig. 3. Although higher order holds are possible, they are seldom used in practice due to their complex nature.

See also **Control Action**; and **Sample-and-Hold Amplifier**.

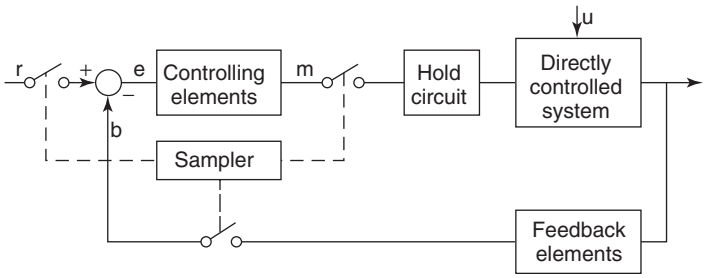

Fig. 1. Block diagram of sampled data control system.

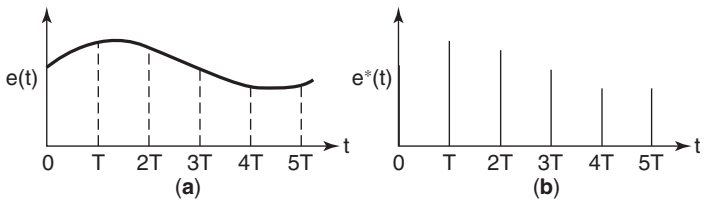

Fig. 2. Actuating or error signal: (**a**) Continuous function of time; (**b**) sampled pulse train.

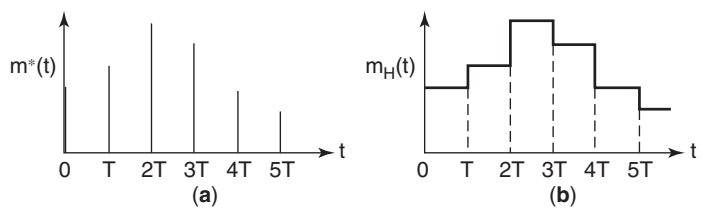

Fig. 3. Output waveforms of sample-and-hold circuit.

SAMPLING (Statistics). The process of taking a sample. If repeated samples are drawn from a probability distribution and the value of some statistic is calculated for each sample, the resulting set of values will define a new probability distribution known as the *sampling distribution* of the statistic. The *sampling fraction* is the proportion of the total number of sampling-units in the population, stratum, or higher-stage unit within which simple random sampling (with multiple counting of sample-units when sampled with replacement) is made. There are thus sampling fractions corresponding to different strata and different stages of sampling. Exactly the same definition is sometimes (loosely) applied to other sampling schemes, e.g., in sampling with variable probability or *multistage sampling* (ratio of total number of ultimate units included in the sample to total units in the population). However, for other general application it appears desirable to define it as the reciprocal of the raising-factor of the sample when it exists, i.e., when the sample is self-weighing. A *uniform sampling fraction* is obtained when a sample is selected from a population which has been grouped into strata, in such a way that the number of units selected from each stratum is proportional to the number of units in that stratum. If from a stratified population a simple random sample is selected from each stratum in such a way that the proportion of units sampled in each stratum varies from stratum to stratum, the sample is said to be selected with *variable sampling fraction*. Applicability of the term to other sampling schemes rests upon the general definition of sampling fraction. There are many methods of sampling depending upon the procedure to be followed and the distribution of samples, which are determined in turn by the character of the population to be sampled.

Area sampling is a method of sampling used when no complete frame of reference is available. The total area under investigation is divided into small sub-areas, which are sampled at random or by some restricted random process. Each of the chosen sub-areas is then fully inspected and enumerated, and may form a frame for further sampling if desired. The term may also be used (but it is not to be recommended) as meaning the sampling of a domain to determine area, e.g., under a crop.

Bulk sampling is the sampling of materials which are available in bulk form, that is to say, it is the population which is in bulk; the term does not mean the drawing of a sample in bulk. Examples of such sampling would be the sampling of a shipment of coal for ash-content, or tobacco for moisture content.

Capture release sampling is a method of sampling specially suited to the estimation of the size of total populations of wild animals. It is also known as capture-recapture sampling. The method was practiced by Lincoln (1930) and involves capturing, marking and releasing a random sample, say, of animals of a particular kind. Subsequently, a further random sample is taken and the proportion of marked animals in this sample forms the basis of estimates of total population.

Cluster sampling. When the basic sampling unit in the population is to be found in groups or clusters (e.g., human beings in households) the sampling is sometimes carried out by selecting a sample of clusters and observing all the members of each selected cluster.

Direct sampling is a term used when the sample units are the actual members of the population and not, for instance, some kind of record relating to such numbers, such as census form, ticket, or registration card. The term relates to the directness of the observation of the units that enter into the sample, not to the process by which they are selected.

Sampling error is that part of the difference between a population value and an estimate thereof, derived from a random sample, which is due to the fact that only a sample of values is observed. This is distinct from errors due to imperfect selection, bias in response or estimation, errors of observation and recording, etc. The totality of sampling errors in all possible samples of the same size generates the sampling distribution of the statistic used to estimate the parent value.

Extensive sampling is a term used to denote sampling where the subject matter, or geographical coverage, of a sample is diffuse or widespread as opposed to intensive, where it is narrowed to a small field. Extensive sampling may refer either to a case where a variety of topics is covered superficially (rather than a few topics in detail) or a large area is surveyed broadly (rather than a small area studied in detail). The term could also be used with reference to time, that is to say, of sampling covering a long period.

It would be convenient to distinguish the cases as space-extensive, item-extensive and time-extensive, respectively.

Grid sampling is a form of cluster sampling, the clusters being individual areas of a grid and hence consisting of groups of basic cells arranged in some standard geometrical pattern. The term *configurational sampling* is also used in the same sense.

Indirect sampling is sampling from documents, or some record of the characteristics of a population, rather than the recording of information obtained at first hand from units of the population themselves. For example, it is becoming customary to obtain preliminary information on the results of, say, a national census by analyzing a sample of the census forms before the full analysis is undertaken; the population is then subject to indirect sampling. (See also Direct sampling.)

Intensive sampling. Like extensive sampling this expression may mean two different things: either (a) sampling in a particular area with a dense scatter of sampling points, or (b) sampling wherein information on a restricted range of topics is sought by probing on them very deeply with an intricate schedule of questions. (See also Extensive sampling.)

Inverse sampling is a method of sampling that requires that drawings at random shall be continued until certain specified conditions dependent on the results of those drawings have been fulfilled, e.g., until a given number of individuals of specified type have emerged. In this sense, it is allied to sequential sampling. The term is not a good one.

Lattice sampling is a method of sampling in which substrata are selected (for the sampling of individuals) according to some pattern analogous to the allocation of treatments on a lattice experimental design. For example, if there are two criteria of stratification, each p-fold, so that there are p^2 substrata, it is possible to choose p sub-strata so that none occurs in more than one "row" or "column" of the array representing the p^2 possible substrata; in short, in the manner of a Latin square. Similar schemes are possible for three-way, or more, classification. Various schemes of the lattice type are known under the name of "deep stratification."

Line sampling is a method of sampling in a geographical area. Lines are drawn across the area and all members of the population falling on the line, or intersected by it, are included in the sample. If the lines are straight parallels equally spaced across the area concerned, then the sampling becomes one form of systematic sampling. If, instead of all intercepts on the lines, a series of evenly spaced points are chosen on each line, the sampling is equivalent to choosing the points on a lattice and may also be regarded as two-stage line sampling.

Lottery sampling is a method of drawing random samples from a population by constructing a miniature of the population (e.g., by inscribing the particulars of each member on to a card) and drawing members at random from it (e.g., by shuffling the cards and dealing a set haphazardly). It is the method usually employed at a lottery — hence its name — but suffers from the disadvantage that the preparation of the cards entails considerable labor and strict precautions must be taken in the shuffling process to guard against bias.

Mixed sampling is where a sampling plan envisages the use of two or more basic methods of sampling. For example, in a multistage sample, if the sampling units at one stage are drawn at random and those at another by a systematic method, the whole process is "mixed."

Usage is not uniform, but where samples at one stage were drawn at random with replacement and at another stage were drawn at random without replacement, it would seem better not to describe the whole process as "mixed," since the essential basic method of random selection being employed throughout.

Multiphase sampling. It is sometimes convenient and economical to collect certain items of information from the whole of the units of a sample and other items of (usually more detailed) information from a subsample of the units constituting the original sample. This may be termed *two-phase sampling*, e.g., if the collection of information concerning variate, y, is relatively expensive, and there exists some other variate, x, correlated with it, which is relatively cheap to investigate, it may be profitable to carry out sampling in two phases. At the first phase, x is investigated, and the information thus obtained is used either (a) to stratify the population at the second phase, when y is investigated, or (b) as supplementary information at the second phase, a ratio or regression estimate being

used. Two-phase sampling is sometimes called *double sampling*. Further phases may be added if desired. It may be noted, however, that multiphase sampling does not necessarily imply the use of any relationships between the variates x and y. The expression is not to be confused with multistage sampling.

Probability sampling. Any method of selection of a sample based on the theory of probability; at any stage of the operation of selection the probability of any set of units being selected must be known. It is the only general method known which can provide a measure of precision of the estimate. Sometimes the term random sampling is used in the sense of probability sampling.

Proportional sampling is a method of selecting sample numbers from different strata so that the numbers chosen from the strata are proportional to the population numbers in those strata.

Quota sample is a sample (usually of human beings) in which each investigator is instructed to collect information from an assigned number of individuals (the quota) but the individuals are left to his personal choice. In practice, this choice is severely limited by "controls," e.g., he is instructed to secure certain numbers in assigned age-groups, equal numbers of the two sexes, certain numbers in particular social classes and so forth. Subject to these controls, which are designed to make the sample as representative as possible, he is not restricted to the contracting of assigned individuals as in most forms of probability sampling.

Representative sample. In the widest sense, a sample which is representative of a population. Some confusion arises according to whether "representative" is regarded as meaning "selected by some process which gives all samples an equal chance of appearing to represent the population"; or, alternatively, whether it means "typical in respect of certain characteristics, however chosen." On the whole, it seems best to confine the word "representative" to samples which turn out to be so, however chosen, rather than apply it to those chosen with the object of being representative.

Route sampling. A procedure similar to line sampling and used in surveys of crop acreage in districts that are well provided with roads. A route that adequately covers the area is chosen and the roadside lengths of the different crops recorded. Since the location of roads is unlikely to be random, estimates of acreage so obtained are likely to be biased, but changes in acreages may be estimated by using the same route for a number of years. The method of route sampling as a form of systematic sampling can also be applied to crop estimation.

Sampling with replacement. When a sampling unit is drawn from a finite population and is returned to that population, after its characteristic(s) have been recorded, before the next unit is drawn, the sampling is said to be "with replacement." In the contrary case, the sampling is "without replacement."

A different usage occurs in sample-surveys when samples are taken on successive occasions. If the same members are used for successive samples there is said to be no replacement; but if some members are retained and others are replaced by new individuals there is "partial replacement."

Unbiased sample. A sample drawn and recorded by a method which is free from bias. This implies not only freedom from bias in the method of selection (e.g., random sampling) but freedom from any bias of procedure, e.g., wrong definition, nonresponse, design of questions, interviewer bias, etc. An unbiased sample in these respects should be distinguished from unbiased estimating processes which may be employed upon the data.

See also **Quota Sample**; and **Random Selection**.

SAN ANDREAS FAULT. See **Earth Tectonics and Earthquakes**.

SANDBOX TREE. See **Euphorbiaceae**.

SAND CRICKET *(Insecta, Orthoptera). Stenopelmatus*. Thick-bodied clumsy insects with large heads and long slender antennae. They live in loose soil, usually under some protective object, in the western United States. They are not true crickets but are more closely related to the long-horned grasshoppers.

SAND DAB. See **Flatfishes**.

SAND DOLLAR *(Echinodermata, Echinoidea).* A sea urchin with a very thin body, almost circular in outline and with a diameter of less than 3 inches (7.6 centimeters). It is common on both coasts of North America.

SAND FLY FEVER. See **Phlebotomus Fever**.

SAND GROUSE. See **Pigeons and Doves**.

SAND HAZE. Sand haze is best defined as reduced visibility in the atmospheric boundary layer caused by suspended particles of soil, mixed into the air during strong winds. Sand haze is particularly prevalent in desert regions where there is little moisture and few plants to hold the sand grains to the surface. After a sandstorm the larger sand grains will fall out of the air quickly, leaving a sand haze of medium size particles (1–100 μm diameters, including silt and fine sand) and small particles (<1 μm diameters, including clay particles).

AMS

SANDPIPER. See **Waders, Shorebirds, and Gulls**.

SAND SHARKS. See **Sharks**.

SANDSTONE. A sedimentary rock composed mainly of sand-size mineral or rock grains. Most sandstone is composed of sand grains cemented by such substances as silica, carbonate of lime or iron oxide, so as to form a solid rock is called sandstone. Like sand, sandstone may be any color, but the most common colors are tan, brown, yellow, red, gray, and white. Since sandstone beds often form highly visible cliffs and other topographic features, certain colors of sandstone may be strongly identified with certain regions. For instance, much of the North American West is well-known for its red sandstones. It occurs usually in beds of varying thickness, depending upon the conditions under which the original sediments were laid down. Because it is normally well-jointed and easy to work, sandstone has been much used for building purposes. Unfortunately, however, as most sandstones are quite porous, the weathering action of the atmospheric agencies may have a very deleterious effect upon them.

Rock formations that are primarily sandstone usually allow percolation of water and are porous enough to store large quantities, making them valuable aquifers. Fine grained aquifers, such as sandstones, are more apt to filter out pollutants from the surface than are rocks with cracks and crevices such as limestones or other rocks fractured from seismic activity.

SANDSTONE DIKE. Sandstone occurring in fissures that have been filled from above, or from beneath. The latter type are usually the result of earthquake fissures in great flood plain or delta deposits in which the sands have been injected from below.

SANDSTORM. A strong wind carrying sand through the air. The diameter of most of the particles ranges from 0.08 to 1 mm. In contrast to a duststorm, the sand particles are mostly confined to the lowest 3.5 meters (10 feet), rarely rise more than 15 meters (50 feet) above the ground, and proceed mainly in a series of leaps (saltation). Sandstorms are best developed in desert regions where there is loose sand, often in dunes, without much admixture of dust. Sandstorms are due to strong winds caused or enhanced by surface heating and tend to form during the day and die out at night.

SANGER, FREDERICK (1918–). Frederick Sanger is an English biochemist and a two times Nobel laureate in Chemistry. He is the fourth

person in the world who has been awarded two Nobel Prizes (the first three are Marie Curie, Linus Pauling and John Bardeen).

Sanger was educated at Bryanston School and at St. John's College, Cambridge, where he took his B.A. degree in natural sciences in 1939. Since 1940 he has carried out research in the Department of Biochemistry at Cambridge. From 1940 to 1943 he worked with Dr. A. Neuberger on the metabolism of the amino acid lysine and obtained a Ph.D. degree in 1943. From 1944 to 1951 he held a Beit Memorial Fellowship for Medical Research and since 1951 he has been a member of the External Staff of the Medical Research Council. His present position is Head of the Division of Protein Chemistry in the M.R.C. Laboratory for Molecular Biology at Cambridge.

Since 1943 his work has been concerned largely with problems related to the determination of the structure of proteins. Sanger determined the complete amino acid sequence of insulin. In doing so, he proved that proteins have specific structures. He began by degrading insulin into short fragments by mixing the trypsin enzyme (which splits protein) with an insulin solution. He then applied a spot of the mixture to a sheet of filter paper. He passed a solvent through the filter paper in one direction, and passed an electric current through the paper in the opposite direction. Depending on their solubility and electric charge, the different fragments of insulin moved to different positions on the paper, creating a distinct pattern. Sanger called these patterns "fingerprints". Like human fingerprints, these patterns were characteristic for each protein, simple and reproducible. He reassembled the short fragments into longer sequences to deduce the complete structure of insulin. Sanger concluded that the protein insulin had a precise amino acid sequence. It was this achievement that earned him his first Nobel Prize in Chemistry in 1958.

Following his work on insulin he developed further methods for studying proteins and particularly the active centres of some enzymes. Around 1960 he turned his attention to the nucleic acids, RNA and DNA. He developed methods for determining small sequences in RNA. Fred Sanger and his colleagues developed many of the techniques still used in genomic biology to this day. The fundamental method of 'reading' DNA using special bases called chain terminators, the use of very thin gel systems, the adaptation of efficient cloning methods to produce both DNA strands and the whole-genome shotgun were all developed by Fred and his group during the 1970s.

Fred's group produced the first DNA whole genome sequence (for a virus called phiX174 that grows in bacteria) of just over 5000 base-pairs in 1977. They went on to sequence the first human genome (albeit that of the DNA in mitochondria — small energy factories in all our cells that have their own genome of about 16,000 base-pairs) and the genome of an important virus for molecular biology, bacteriophage lambda, in 1982. To sequence this virus genome — about 48,000 base-pairs — Fred developed the whole-genome shotgun method. The sequence of lambda was the first whole-genome shotgun. Sanger retired in 1983.

The work for his second Nobel Prize (awarded in 1980) was developing the technique still used today — 'dideoxy' or 'Sanger' sequencing. In this method, stretches of 500-800 bases at a time can be read.

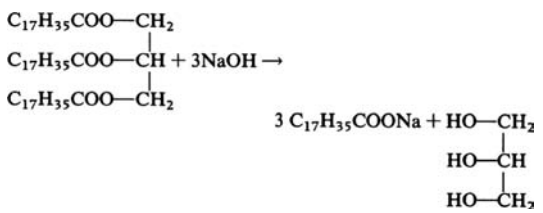
SAPODILLA *(Achras zapota, Sapotaceae).* A large tree native to the forests of Central and tropical South America, the fruit of which is very desirable. The yellow-brown flesh is translucent and very sweet and wholesome. The greatest value of the tree is in its latex product, which yields chicle. The chicle-gathering industry is centered in Yucatán and Central America. The tapping is done in the rainy season. The tapper climbs to a height of 30 feet (9 meters), and with a machete cuts a series of connecting zig-zig diagonal gashes in the bark as he descends. At the bottom of this series of cuts he attaches a cup, into which the latex flows. The crude substance is collected, boiled down to eliminate much of its water and the coagulated product pressed into 20–25 pound (9–11.3 kilogram) blocks. This substance, chicle, varies in quality from the best grade, which is milk-white in color, to pinkish or darker grades, which have received less care in preparation. Each tree yields about $2\frac{1}{2}$ pounds (1.1 kilogram) of chicle during one season and may be tapped every 3–4 years. The blocks of chicle are shipped largely to the United States, where they are melted and cleaned, flavored and sweetened, and then marketed as the familiar chewing gum. This use of the latex of the Sapodilla is not new, since the Aztecs and their predecessors knew of it and used it. When first introduced into the United States it was tried as a rubber substitute, but proved unsuitable.

See Table 1 for the record sapodilla trees growing in the United States.

SAPONIFICATION. A special case of hydrolysis in which an ester is converted into an alcohol and a salt of the appropriate acid by reaction with an alkali. Though the operation has numerous applications throughout the chemical industry, it is noteworthy because some 80% of standard soap is prepared by this method. The esters may be of mono- or polybasic acids and mono- or polyhydric alcohols, the physical conditions under which the reaction occurs being suitably varied to secure an adequate rate. The alkali most commonly used is sodium hydroxide, because of cost and water solubility, but other appropriate alkaline materials are suitable.

Since the preparation of soap is typical of a fairly complex reaction, chemically, and since it is common, it serves as a useful example of the saponification operation. The complication, of course, occurs because the usual esters used for soap are the glycerol esters of fatty acids, saturated and unsaturated. Thus the saponification of stearin (glycerol tristearate) is commonly shown as follows:

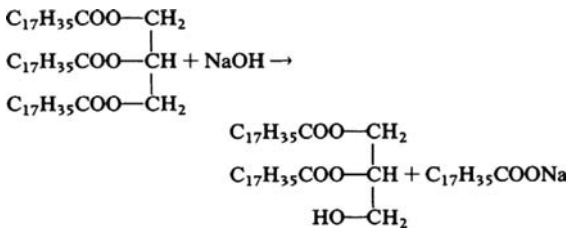


Actually, the saponification appears to progress stepwise, the first hydrolytic reaction taking place as follows:

TABLE 1. RECORD SAPODILLA TREES IN THE UNITED STATES[1]

	Circumference[2]		Height		Spread		
Specimen	Inches	Centimeters	Feet	Meters	Feet	Meters	Location
Sapodilla (1992) (*Manilkara zapota*)	156	396	72	21.9	62	18.9	Florida
Sapodilla (1993) (*Manilkara zapota*)	174	442	56	17.1	53	16.2	Florida

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).



The diglyceride formed is subsequently split to the monoglyceride, which finally is converted to glycerol, if sufficient alkali is present. Thus, the reaction is a bimolecular one rather than quadrimolecular, as is commonly indicated. In actual practice, the fats used are complex glycerides of a number of saturated and unsaturated acids, rather than the stearin shown here.

Technologically, the saponification operation varies in degree of difficulty depending on the ester. The reaction rate differs for different esters, for one thing, bu another determining factor is the contact area possible between the alkali and the ester. In the case mentioned above, the fat at the start is insoluble and immiscible in water, so that reaction in a nonagitated vessel would be very slow, occurring only at the limited interface.

Though saponification is the dominant reaction when the techniques described above are used, in many instances side reactions may occur which may profoundly modify the products. Oxidation, of course, is one of the more obvious things to guard against, since many times the esters being treated are unsaturated. Both isomerization and polymerization, however, may occur under the alkaline conditions obtaining, the unconjugated polyethenoid acids becoming conjugated during treatment. This especially appears to be true in the case of highly unsaturated compounds. However, by properly controlling reactants and conditions, saponification remains a very flexible and useful industrial and laboratory operation possible of wide application and at low cost.

SAPONIFICATION NUMBER. See **Vegetable Oils (Edible)**.

SAPPHIRE. See **Corundum**.

SAPROPHYTES. These are plants that obtain their food from nonliving organic material. Most of the saprophytes are fungi. Among the higher plants, a small number of flowering plants and perhaps a few mosses are also saprophytes. It is characteristic of these saprophytic plants that they have little or no chlorophyll, and so are not able to carry on photosynthesis. Their energy is derived from the complex organic substances they absorb. In many instances, the absorption of these substances is greatly advanced by the presence of mycorrhizae.

Especially is this the case with various species of saprophytic orchids which have mycorrhizae within the cells of the roots or rhizomes. The various species of Carol-roots (*Corallorrhiza*) are common saprophytic orchids of American woods. These orchids have no roots, absorption occurring in the much-branched fleshy rhizome which gives the plant its name. In this rhizome the mycorrhizae are found. These plants have erect stems, leaves reduced to scales, and no chlorophyll. Other saprophytic orchids occur in the continents of the Old World.

SARAH (Search and Rescue and Homing). A radio homing device originally designed for personnel rescue and now used in spacecraft recovery operations at sea.

SARCOMA. A malignant tumor originating in connective tissue. These growths are composed of densely packed cells, diffusely imbedded in a homogeneous ground substance. Their degree of malignancy varies greatly. They spread by local infiltration and by blood stream invasion. The most frequent sites in which sarcomas develop are bone, lymph nodes, and subcutaneous tissue.

Sarcomas are much less common forms of malignant tumors than are carcinomas.

SARDINE. See **Herring**.

SARDONYX. See **Agate**.

SAROS. The fact that eclipses occur in periodic intervals was known to the ancient Chaldeans, and probably even in prehistoric times. This period of 18 years, $11\frac{1}{3}$ days ($10\frac{1}{3}$ days if there happen to be 5 leap years in the interval) is known as the Saros. If an eclipse should occur on January 1, 1977, at noon, another similar eclipse would occur on January 12, 1995, at eight o'clock in the evening. The eclipse would not occur at the same point on the earth but would be about 8 hours farther west in longitude.

During the course of a Saros there are about 29 lunar and 41 solar eclipses, each repeated during the next Saros, but not at the same portion of the earth. See also **Eclipse**.

SARSAPARILLA *(Smilax* sp.; *Liliaceae)*. The genus *Smilax* contains some 200 species, most of which are tropical, though a few such as the carrion flower, *Smilax herbacea*, and the cat briar, *Smilax rotundifolia*, occur as far north as the New England states. The tropical species are mostly climbing shrubs or vines, usually with prickly stems. The leaves are entire and of oblong to ovate shape. At the base of the leaf is a pair of tendrils, which are perhaps to be interpreted as modified stipules, though such structures are not usually found in monocotyledons. The flowers are small, dioecious and borne in umbels. The fruit is a berry. Some of the South American species are the source of Sarsaparilla, which is obtained from the dried roots.

SASSABY. See **Antelope**.

SASSAFRAS. See **Laurel Family**.

SATELLITE (Astronomy). The term as used in astronomy usually refers to small, planet-like objects that are revolving about the individual planets in orbits. The moon is the satellite of the earth and has been known from remotest antiquity. Satellites over the years have served a useful purpose to astronomers since the mass of a planet can be determined accurately only if the planet has a satellite. By application of the rigorous expression for the harmonic Keplerian laws of planetary motion, the mass of any planet and satellite may be found in terms of the mass of the earth-moon system, after the distance of the planet from the satellite and its period of revolution are known. The problem of the determination of the masses of the satellites themselves is a more difficult problem.

Further information regarding the different satellites will be found in **Moon (Earth's)**; and **Planets and the Solar System**. See also entries on the specific planets.

SATELLITE INFRARED SPECTROMETER (SIRS). See **Nimbus Satellite Program**.

SATELLITE METEOROLOGY. See **Meteorology**.

SATELLITES (Communications and Navigation). Satellites are unmanned spacecraft orbiting the Earth above its atmosphere as components in information networks. *Communications satellites* serve as either broadcast distributors or switching/relaying stations for wireless communication circuits. These satellites receive and transmit microwave radio frequencies carrying voice, video, data, facsimile (fax), and/or paging signals generated by and addressed to subscribers in public and private networks; they also distribute coded television broadcast signals directly to residential and commercial receivers. *Communications satellites* have enabled the installation of telephones and television facilities in remote areas without investment in costly terrestrial networks. *Navigation satellites* provide global positioning services and extremely accurate time signals to receivers used on ships and boats, aircraft, many different types of land vehicles, and even persons on

foot, enabling military and civilian users to accurately determine, at any time, the location on the planet of their vessel, aircraft, vehicle, or person. Such satellites are also used to guide military missiles to their targets.

Although satellites seem to be expensive, they cost far less than the terrestrial infrastructure that would be needed to perform the same functions. Until communications satellites were implemented, many areas of the world were isolated from the networks serving telephones, television, and data networking. In developing countries where funding simply is not available to construct microwave or wireline terrestrial networks in remote areas, the use of satellite communications has helped to unify their populations and spurred development. In times of catastrophe, satellites enable communication when terrestrial facilities are damaged or destroyed. Located far above the Earth's atmosphere, these versatile machines are practically immune to the destructive effects of storms, floods, fire and earthquakes. See Fig. 1.

A satellite requires a launch vehicle in order to reach its operating altitude. Most satellites have been placed in orbit by mounting them on expendable huge multi-stage rockets fired from terrestrial facilities. The chief sites for launching commercial satellites are located in the United States (Cape Canaveral in Florida, and Vandenberg Air Force Base, California), Kazakhstan, central Asia (a former state of the USSR), French Guiana (in South America), China, and Japan.

The expendable rocket serving as the launch vehicle commonly has three stages. The first raises the satellite to about 50 miles (80 kilometers) above the Earth, where that stage falls away. A second stage ignites to lift the satellite up to an altitude of about 100 miles (160 kilometers). The second stage then falls away and a third stage ignites, placing the satellite above the atmosphere in the *transfer orbit*, a temporary elliptical path around the Earth. The third stage then drops away, leaving the satellite in space, where an on-board *apogee kick motor* ignites, in the *orbit injection phase* of the launch, moving the satellite into its assigned orbital slot, at which point the motor is turned off. The entire process generates various discarded components, such as rocket casings, bolts, covers, etc., which remain floating in space as debris, usually in an orbit below an altitude of 1,200 miles (ca. 2,000 kilometers). Many thousands of such items are carefully tracked to minimize the danger of accidental collision between "space junk" and satellite launches or manned spacecraft. Such collisions would be catastrophic because of the speeds involved (thousands of miles per hour).

The total weight of a communications satellite at the time of launch may be between 1,000 pounds (453 kilograms) and as much as 9,000 pounds (4,080 kilograms). Some are not much larger than a washtub, while others are more than four stories high. See Fig. 2. Perhaps the largest unmanned satellite in orbit, launched in 1991, is the *Compton Gamma Ray Observatory (CGRO)*, with a mass of over 17 tons (17,273 kilograms) and measuring 70 feet across its two solar arrays. See also **Compton Gamma Ray Observatory**.

According to the National Aeronautics and Space Agency (NASA) in the USA, more than 3,500 satellites were in orbit in 1998, serving many different purposes. Communications and navigation satellites have been and are being built in several different countries, primarily in the United States, but also in Russia, China, Japan, Canada, England, Italy, France, and Germany. A satellite, often called a "bird" by technologists, is a complex assembly of small rocket engines, auxiliary fuel, stabilizing and attitude control systems, computers and various subsystems, batteries, solar cells, and the payload that is its mission (such as communications amplifiers, frequency converters, switchgear, transmitter-receivers called "*transponders*," antennas, navigation gear, computers, imaging systems, etc.). See Figures 3, 4 and 5.

The solar power panels, sometimes built into the outer walls of the satellite housing but usually unfolding into large sail-like structures, convert the sun's photonic energy into direct current electricity to continuously charge the on-board batteries powering the electronic systems. The auxiliary propellant fuel–in multiple tanks or a single large tank–feeds "thruster" rocket engines that correct the satellite's position and "attitude" when necessary during the years of its service life. A final fuel reservoir is used to fire an on-board rocket when the satellite reaches the end of its useful life (the rocket "de-orbits" the satellite by pushing it into outer space, freeing its orbital slot for a new satellite). Most satellites require several years of assembly and testing before being launched into space, but the industry has been working toward speedier delivery of 18 months or less. Some manufacturers have created assembly-line techniques for fleets of related satellites, aiming for factory cycle times of 35 days including pre-assembly time for component testing.

Satellite Orbits

The orbit is the path of the satellite in relation to the planet as it moves through space above the Earth's atmosphere. The orbit must be at least 180 miles (300 kilometers) above sea level but is often 22,300 miles (35,680 kilometers) above the equator, where almost all commercial satellites were located as of 1998. Because of the two Van Allen radiation belts, consisting of ionized particles that damage solar cells and some electronic components, satellites are rarely orbited in "off-limits" spaces around the altitudes of about 930 miles (1,500 kilometers) and 6,213 miles (10,000 kilometers). Radiation caused by solar storms is even more serious.

A low orbit, under the lowest Van Allen belt, means the satellite's transmitters and receivers can serve only a small area of Earth at any given time. A medium orbit between the belts greatly expands the coverage area (the satellite's "footprint"). The highest orbit is far beyond the highest Van Allen belt and can serve almost half the planet with its antennas.

Although considered "weightless" in space, satellites are held in orbit by the Earth's gravitational grip. They do not fall down to Earth because of their forward speed or velocity. During the satellite's service life, periodic adjustments of its position are necessary to correct orbital changes due to the anisotropic nature of the Earth's gravitational field.

Various types of orbits are plotted for different altitudes, depending on the mission of the satellite. See Fig. 6. Most communications satellites are located high above the Earth's equator ("equatorial orbits") in a belt-like ring far out in space. Each position is identified by the longitude intersecting the equator. While such a satellite appears to hover above the same spot on Earth, it is in a *geostationary-Earth orbit* (GEO), 22,300 miles (35,800 kilometers) high, synchronized to keep pace with the Earth's rotation around its axis. The geostationary satellite is not actually orbiting *around* the Earth but rather moving *with* the Earth, which means it is actually moving through space at almost 7,000 miles/hour (11,265 kilometers/hour) as if it were attached to the spinning planet by an invisible tower. Navigation satellites and some communications satellites operate in a *medium-Earth orbit* (MEO), usually an altitude of about 12,500 miles (20,200 kilometers), and circle around the planet at an angle to the equator. Large fleets or "constellations" of communications satellites are scheduled for *low-Earth orbits* (LEO), circling the Earth at approximate altitudes as low as 485 miles (780 kilometers) to as high as 800 miles (almost 1,300 kilometers), with multiple satellites following each other in the same orbital path. (Various manned space flights and the *Mir* space station also have used or are using *low-Earth orbits*.)

A satellite in a "*polar orbit*" circles the Earth at right angles to the equator, passing near the planet's north and south poles. Still others circle the Earth in paths or "*planes*" at inclined angles to the equator. The altitude is usually scheduled to be about the same throughout the orbit. When an orbit is eccentric (not always the same distance from the planet), the most distant point from Earth is the *apogee*, while the closest point is the orbit's *perigee*. The difference between the *apogee* and the *perigee* is called the *orbit's degree of eccentricity*.

The first experimental communications satellites in 1962 and 1963 (AT&T's privately funded *Telstar I* and *Telstar II*, and RCA/NASA's *Relay I* and *Relay II*) were designed for *low-orbit* operations. See Fig. 7. A Hughes-built geosynchronous satellite, *Syncom II*, followed them in 1963, with which numerous demonstrations were made to prove the feasibility of communications from a high orbit. See Fig. 8. (A geosynchronous orbit is inclined relative to the equator, so *Syncom II* described a figure-eight pattern rather than hovering over a single point as in a *geostationary orbit*; a geostationary orbit is always a *geosynchronous orbit*, but a geosynchronous orbit is not necessarily a geostationary orbit.) The first *geostationary satellite* was the Hughes-built *Syncom III*, launched in 1964.

Theoretically, only three geostationary satellites would be needed to provide total (except for the extreme Polar Regions) coverage of the Earth's surface, since each would have a gigantic "footprint." But three

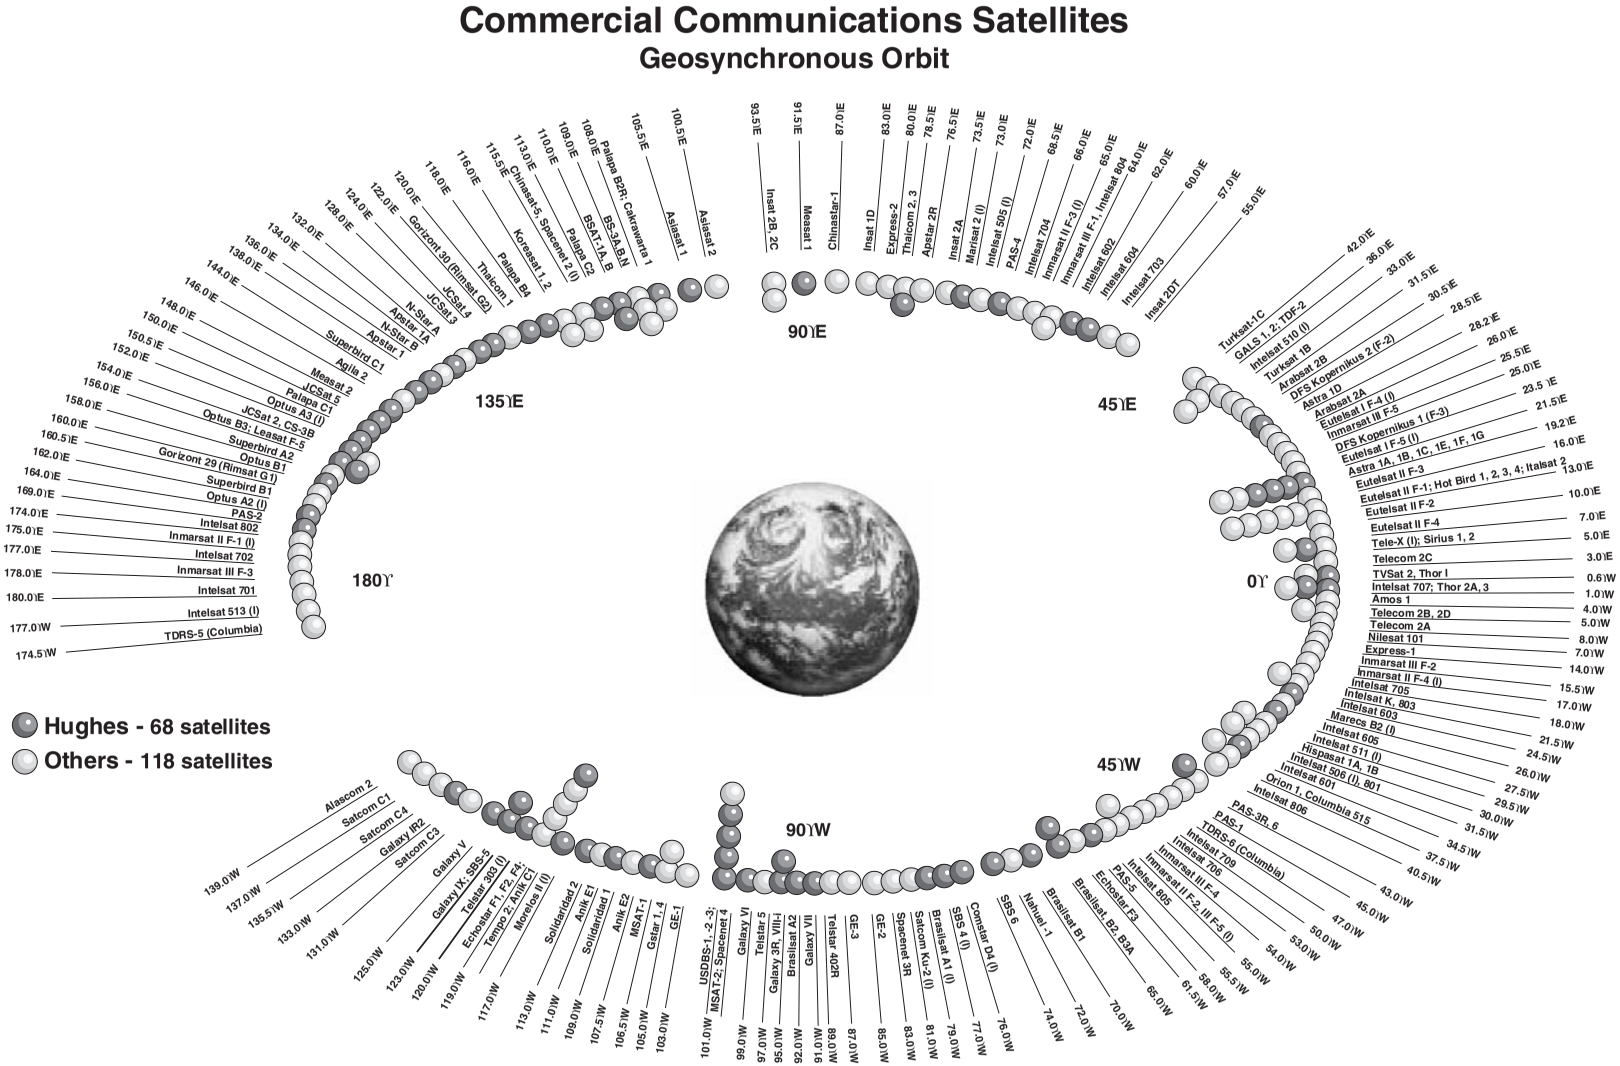

Fig. 1. As of late 1998, about 200 communications satellites were in geostationary orbit about 22,300 miles (35,800 kilometers) above the Earth's equator. This chart shows their positions and identifies each spacecraft. (*Courtesy of Hughes Space and Communications Company.*)

Fig. 2. Even when folded together on its handling dolly in preparation for shipment, PanAmSat's PAS-8 communications satellite is an imposing bulk that represents the size of many spacecraft in this field. Weighing 8,360 pounds (3,800 kilograms), the craft has 24 C-band transponders and 24 Ku-band transponders. They provide video, telecommunications and Internet access throughout the Asia-Pacific region. PAS-8 was built by Space Systems/Loral and was launched into geostationary orbit from Khazakstan, November 4, 1998. (*Courtesy of PanAmSat Corporation*.)

satellites would never have enough capacity to meet the world's demands for communications circuits. NASA reports more than 200 satellites in geostationary orbit, spaced some 900 miles (1,448 kilometers) apart along a circular path 165,000 miles (ca. 264,000 kilometers) long, far above the Earth's equator (which has a circumference of 24,901.6 miles or 40,075 kilometers).

There are thousands of fixed satellite earth stations, some with as many as 25 large and small antenna dishes, scattered around the globe. Most of these stations are linked by optical fiber cable and/or overland microwave radio circuits to either commercial or government television broadcasting facilities or electronic "gateway" switches serving public and private communication networks. In addition, there are many more mobile earth stations of varying sizes, such as those used by television reporting teams while on location for special events or catastrophes. During the 1990s, countless other satellite reception dishes–many as small as 12 inches (30 centimeters) in diameter–were installed throughout the world to receive television programming broadcast from satellites. Also in the 1990s, special handheld wireless telephones (sometimes called "*satphones*"), pagers, and text-messaging terminals were introduced, enabling a subscriber to link up with certain satellites using only a small built-in antenna on the handset; however, such systems still rely on the use of an earth station to complete the link to parties on terrestrial networks. In addition, a party on a conventional network phone can call a "satphone" user, whose terminal will be activated by a signal direct from the appropriate satellite.

Satellite Transmission Frequencies

Communications satellites are equipped with a variety of transponders (special transmitter-receivers). These operate within certain radio-frequency bands as specified by the Federal Communications Commission (FCC) and the International Telecommunication Union (ITU). The most common transponder settings employ C-band (*centimeter-band*, using wavelengths from 3.7 to 5.1 centimeters and operating within a frequency range of 4 to 6 gigahertz), and/or Ku-band (*K-under*, for a spectrum band under the K-band, operating within 11 to 14 gigahertz). Other settings include L-band (1 to 2 gigahertz) and S-band (2 to 3 gigahertz). The higher the frequency, the more susceptible the signal is to weakening or degrading when it passes through water vapor, rain or falling snow in which the size of the drops or crystals matches or exceeds the wavelength of the transmission frequency. Most geostationary communications satellites use the C-band, but that means television reception requires relatively large ground antennas (sometimes called "backyard antennas"). Since the introduction of direct-transmission of TV signals to businesses and residences, the Ku band has gained in popularity, since it can serve much smaller and less costly antenna dishes than the C-band.

A new frequency setting is the Ka-band (*K-above*, using a band above the K-band, for signals from 18 to 31 gigahertz). Introduced to low-orbit commercial use in 1998, this band has five times more spectrum than is available at lower frequency bands. The Ka band has been undergoing tests as part of NASA's *Advanced Communication Technology Satellite* (ACTS) project. ACTS was launched in 1993 and served in a geostationary slot before beginning inclined orbit operations in 1998. The craft also is testing new antenna systems for "multiple hopping beams," on-board switching to permit interconnectivity between users at the individual circuit level, and a microwave switch matrix to enable users to communicate at rates of gigabits per second.

Each of the thousands of satellites in space is assigned specific frequencies. The *uplink* (earth terminal to satellite) is a different frequency

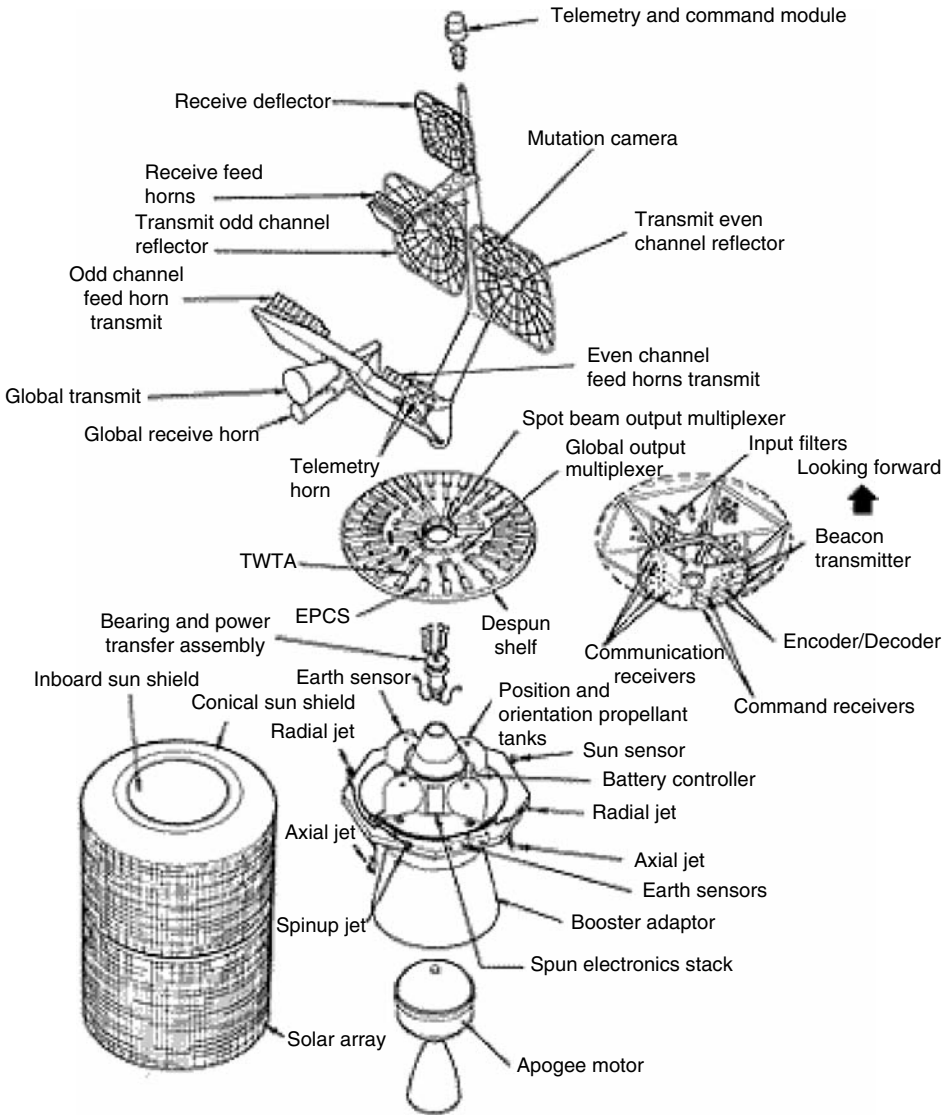

Fig. 3. This exploded view of and INTELSAT IVA communications satellite illustrates its chief components. Hughes Space and Communications Company built six INTELSAT IVAs (one was lost during its launch in 1977) to provide coverage of land masses on both sides of the Atlantic basin, using four spot beams so isolated from each other that the same frequencies can be used in the east and the west. This antenna design significantly increased satellite communications capability within the allocated frequency band. Each INTELSAT IVA had 20 transponders, compared to only 12 on the earlier INTELSAT IV satellites. The spacecraft weighed 3,335 pounds (1,515 kilograms) and had an overall height of almost 23 feet (7 meters) and a diameter of almost 8 feet (more than 2 meters). The first of the series was launched from Cape Canaveral on September 25, 1975, and the last two in 1978. Although their design life in orbit was specified as seven years, the INTELSAT IVA spacecraft operated an average of almost 11 years before being retired.

Cylindrical satellites are divided into two halves: the upper half spins to provide basic gyroscopic stability to the spacecraft; the bottom half remains pointed toward Earth. The spinning half of the INTELSAT IVA satellite was covered with nearly 17,000 solar cells, which absorbed energy from the sun and converted it to provide primary electrical power of 600 watts. The lower half contained the communications payload. The positioning and orientation (reaction control) subsystem was mounted on the rotor. Redundant jets were provided for orbital station-keeping, attitude control and spin-up with sufficient fuel (hydrazine) for the orbital life of the satellite.

The directional communication antennas were pointed to the roper point on Earth by the despin control system. Redundant sensor information (three earth sensors, two sun sensors, all rotor-mounted) was used by an on-board processor to establish the inertial attitude of the spacecraft and control the antenna platform. The apogee motor was carried in the aft half of the rotor section. The burn of that motor provided the needed impulse to place the satellite in its final synchronous orbit.

The despun section of the satellite contained the communications repeater electronics and telemetry and command electronics. Spacecraft commanding was performed through two cross-strapped command systems. Telemetry information from the spacecraft was provided by redundant pulse-code modulated systems with frequency modulated real-time mode available for transmission of certain data during spacecraft maneuvers. (*Courtesy of Hughes Space and Communications Company.*)

band than the *downlink* (satellite to earth terminal) so as to avoid signal interference. Because so many satellites are already in orbit, there is growing concern that the limited frequency spectrum may be fully assigned in the near future. Offsetting this fear is the ingenuity of communications engineers who have steadily improved their ability to compress the signals so they use less spectrum.

Geostationary Earth Orbit (GEO) Satellites

INTELSAT (INTernational TELecommunications SATellite), a consortium created August 24, 1964 by 11 nations, had 142 members by 1998. Since 1966, INTELSAT has covered all the continents with satellite communications. In 1998 INTELSAT diluted its holdings by spinning off a new company, New Skies Satellites, and transferring ownership of five in-orbit INTELSAT satellites, as well as the relevant assigned frequencies. The new company will compete in areas such as consumer-oriented video services and multimedia applications. Beginning the year 2000, INTELSAT had 17 satellites in operation. The United States is represented in INTELSAT by the Comsat Corporation, created by Congress as a quasi-private corporation via the Communications Satellite Act of 1962.

The first commercial geostationary satellite, the *INTELSAT I* or "*Early Bird*," was developed by Hughes Electronics for Comsat and launched

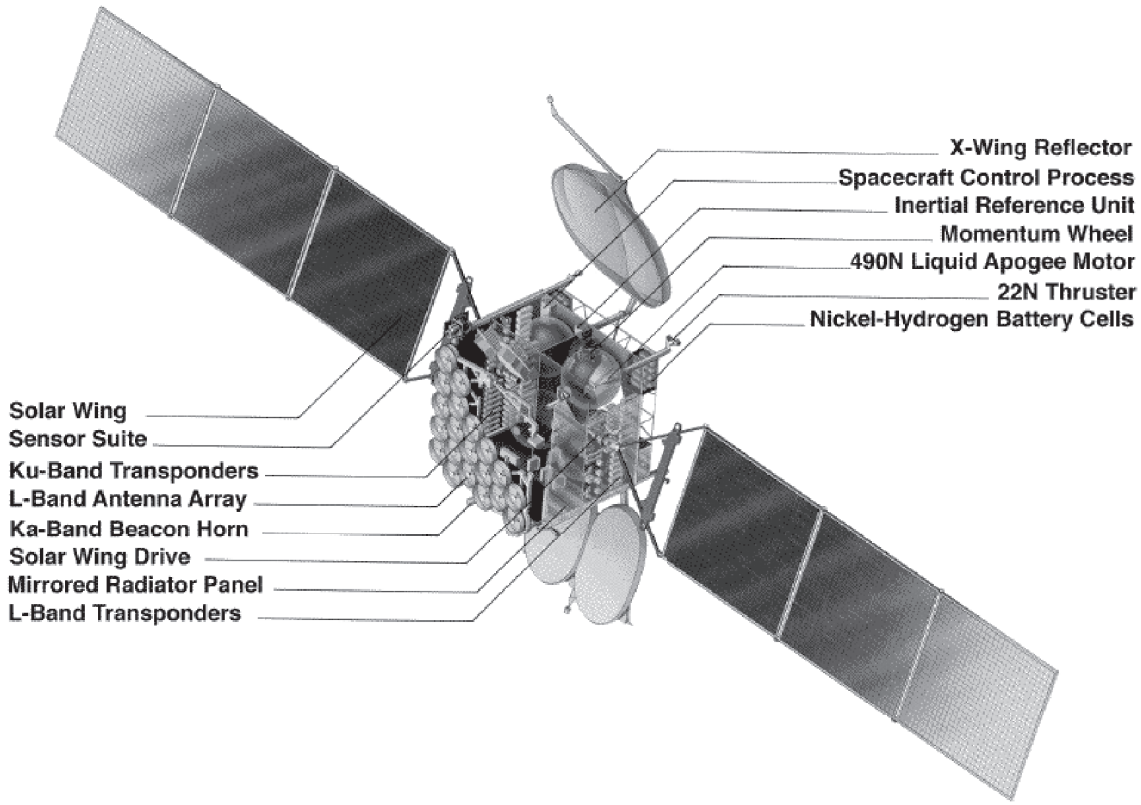

Fig. 4. The Hughes 601 satellite is body-stabilized, with internal components providing three-axis stabilization. Introduced in 1987, it is the world's best-selling large spacecraft model. By the fourth quarter of 1998, the company had received orders for 72 HS 601 communications satellites. The basic configuration features as many as many as 48 transponders and offers up to 4,800 watts of power. A more powerful model, the HS 601 HP debuted in 1995 and features up to 60 transponders and provides up to 10,000 watts. (*Courtesy of Hughes Space and Communications Company*.)

in July, 1965. See Fig. 9. It weighed only 85 pounds and measured 23 inches high by 28 inches wide. *Early Bird* was equipped with two transponders capable of serving up to 240 telephone circuits, and was designed for a life expectancy of 18 months; the cost per circuit-year came to $30,000. By 1998, improved technology had raised geostationary satellite life expectancies to 15 years and more, while costs per circuit-year dropped to less than $1,000. Modern geostationary satellites usually have a launching mass of more than 3,000 pounds (1,360 kilograms) but can weigh as much as 9,000 pounds (over 4,000 kilograms). They can be either cylindrical or rectangular in shape, the housing measuring as much as four stories high plus large solar panels and antennas which are folded onto the satellite during the launch, then opened in space. Each such satellite can cost as much as $250 million or more and is insured against loss due to launching accidents and space failures.

Individual communications carriers, such as AT&T, British Telecom, MCI, GTE, etc., have long-term leases of transponders on the *INTELSAT* vehicles, and others can rent them for short-term individual projects, such as a conference. Although the original communication satellites were operated with analog circuits the modern transponders and associated circuitry usually employ digital signal processing to improve quality, efficiency, and capacity of transmission. Digital signals can be compressed and combined (or *multiplexed*) more easily than analog signals, resulting in more two-way telephone circuits on a given frequency band.

For example, three *INTELSAT* series VIII satellites, orbited in 1997, each have 44 transponders (38 C-band, six Ku-band), capable of serving 22,500 two-way telephone circuits plus three TV channels, and up to 112,500 two-way telephone circuits with the use of digital circuit multiplication equipment (DCME) in the earth stations. The last in the series of the *INTELSAT* VIII/A satellites, orbited in 1998. The life expectancy of these satellites is 14 to 17 years in geostationary orbit. As of late 1998, seven *INTELSAT* series IX satellites were being developed. Spacecraft delivery and launch periods scheduled for the seven *INTELSAT* series IX satellites are as follows: the first four are to launch in 2001, and the remaining three in 2002.

PanAmSat Corporation, based in Greenwich, CT., is a leading provider of global video and data broadcasting services via satellite. The company builds, owns and operates networks that deliver entertainment and information to cable televisions, TV broadcast affiliates, direct-to-home TV operators, Internet service providers, telecommunications companies and corporations. PanAmSat merged in 1997 with part of Hughes Communications, a unit of Hughes Electronics Corporation, which is a wholly owned subsidiary of General Motors Corporation.

In September, 1998, PanAmSat launched a Hughes-built *PAS-7* satellite weighing 8,444 pounds (3,830 kilograms), for a geostationary slot above the Indian Ocean region. The spacecraft delivers satellite-based video and telecommunications services throughout that area. In 1999 PanAmSat launched the Galaxy XI satellite, the company's 20th spacecraft and the largest commercial communications satellite ever deployed in space. In 2000 PanAmSat successfully launched the Galaxy XR spacecraft, the first satellite of the new millennium and the fifth in the company's Galaxy cable neighborhood.

With 21 *PAS* spacecraft in orbit today, PanAmSat has the world's largest commercial geostationary satellite network. See Fig. 10. PanAmSat is scheduled to launch four additional satellites by mid-2001, increasing total capacity to more than 900 usable transponders worldwide.

Hughes also is the largest investor in *American Mobile Satellite Corporation* (AMSC), which in 1995 flew the first satellite dedicated to providing land mobile services for individual users in North America. The *AMSC* system has three satellites in geostationary orbit, offering voice, data, facsimile, messaging and other services to travelers in trucks, autos, boats and aircraft across the continent. It uses frequencies in L-band, a portion of the spectrum lower than that assigned to satellites providing direct broadcast or serving fixed earth stations.

Another major family of geostationary satellites is the *Inmarsat* system, which had nine satellites in operation by late 1998. The international cooperative organization was created as the International Maritime Organization on July 16, 1979 and began operating its first satellite circuits in 1982, using leased transponders on three *Marisat* craft it inherited from *Comsat*,

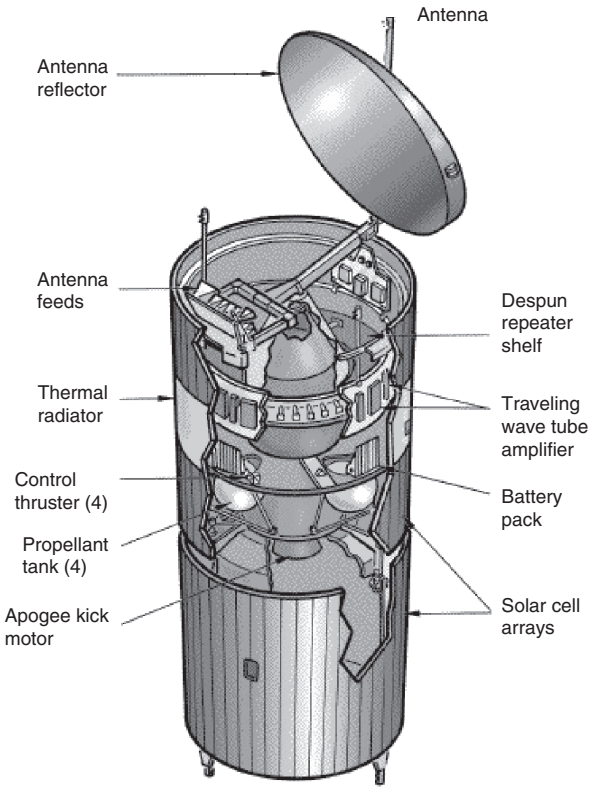

Fig. 5. The Hughes 376 satellite was introduced in 1977 and is one of the most popular commercial communications satellite models. More than a dozen customers in 14 countries on five continents have installed or ordered 54 HS 376 spacecraft as of mid-1998. Cylindrical satellites like this are designed for spin-stabilization, in which the spinning upper half is the stabilizing element, with the communications equipment housed in the bottom half. (*Courtesy of Hughes Space and Communications Company*.)

plus two *Marecs* satellites from the *European Space Agency* (ESA), followed by Maritime communications subsystems on several *Intelsat V* satellites. *Inmarsat* launched the world's first dedicated mobile communications satellites–four *Inmarsat 2* series–in 1990. These were followed in 1996, 1997 and 1998 by five *Inmarsat 3* satellites (one a spare) designed and assembled by Lockheed Martin Telecommunications; Matra Marconi Space of the United Kingdom manufactured the communications payload, including the antennas, repeater and other communications electronics. The Series 3 satellites expanded the *Inmarsat* services to include the aviation community's ability to use both the American and Russian *global positioning system* (GPS) satellite navigation systems (see the **Navigation Satellites** section below). The nine *INMARSAT* geostationary spacecraft are connected to the terrestrial telecommunications networks via 39 marine and aeronautical ground earth stations serving as gateways, and in 1998 were being accessed by more than 100,000 customer terminals. (During the first 10 years, from 1982 to 1992, only 15,000 terminals were sold.) Service is global except for the extreme polar regions.

Originally a dependent of the United Nations, *Inmarsat* was founded to provide wireless voice and data links between maritime mobile equipment (i.e., ships and ocean drilling platforms) and ground networks, covering the four major ocean areas of the world. Its services now also include various governmental functions, such as backing up terrestrial communications for embassies around the world, and various customs and fisheries patrol craft. Peacekeeping task forces rely on *Inmarsat* systems to keep in touch with civil authorities, but the system cannot be employed for direct military use or acts of war, nor is it certified for use within the continental United States. By 1998, *Inmarsat* had 83 member countries in its cooperative. However, they plan to privatize the organization, dividing it into two entities: a public limited company seeking an initial public offering of stock by late 2000, and an intergovernmental structure ensuring that Inmarsat meets its public service obligations. Those obligations include the Global Maritime Distress and Safety System (GMDSS).

A future satellite project involving Hughes Communications is the *Spaceway* system, which includes both geostationary and medium-orbit satellites. It currently plans to install eight satellites in geostationary orbit to provide high data rate transport services, and another 20 interconnected satellites in "nongeostationary" orbit to provide "advanced interactive broadband multimedia communications services in high traffic markets globally." The fleet of 20 *Spaceway* satellites will be divided into

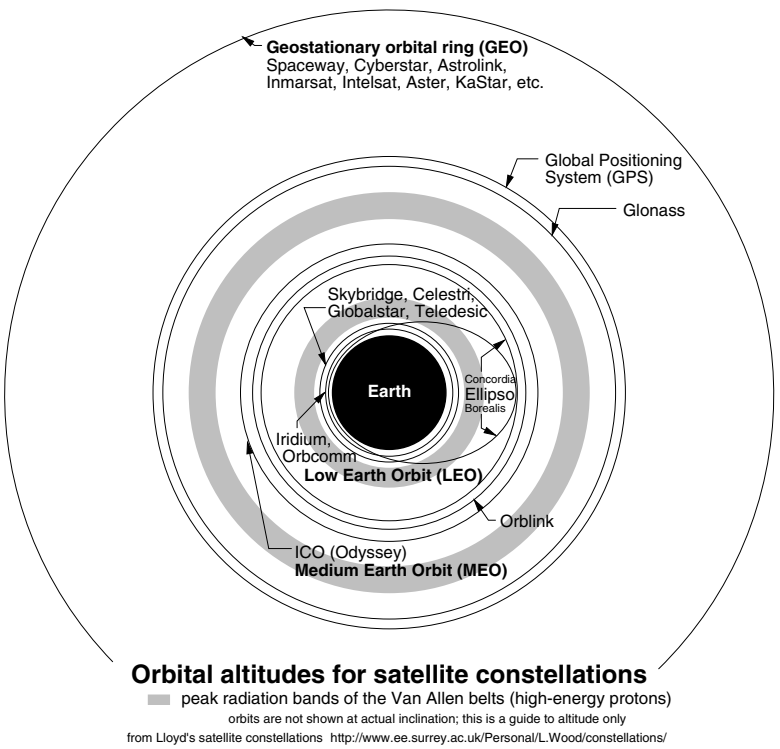

Fig. 6. Satellite orbits are described in three general classes: low-Earth orbit (LEO); medium-Earth orbit (MEO); and, geostationary-Earth orbit (GEO). This chart shows the various altitudes above Earth to scale, as well as their relationship to the two Van Allen radiation belts. (*Illustration by Lloyd Wood, from a representation by Dr. Thor E. Wisloff.*)

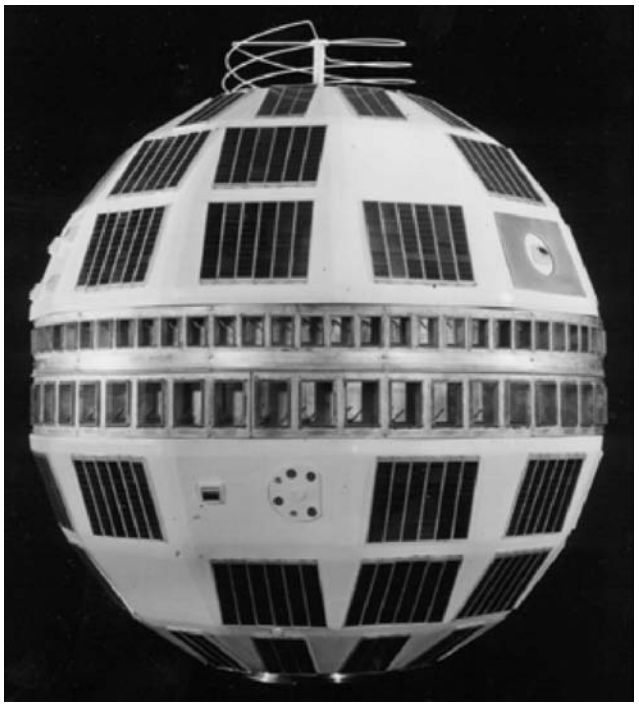

Fig. 7. On July 10, 1962, the worlds first international communications satellite, Telstar I, was launched into a low-Earth orbit. Privately funded by AT&T and built by Bell Telephone Laboratories, the satellite weighed 170 pounds (77 kilograms) and was 34 inches (about 86 centimeters) in diameter. The surface of Telestar 1 carried 3,600 silicon solar cells that were the source of its primary power. More than 6,000 transistors and diodes were used as individual components, because the integrated-circuit era was barely dawning. The near-omnidirectional helical antenna on top of Telstar received commands and transmitted a continuous VHF signal for initial acquisition and tracking. The communication antennas for receiving and transmitting voice and video signals consisted of radiating boxes along the satellite's equator, interconnected by a series of printed-circuit hybrids to a single 6-gigahertz input and a single of 4-gigahertz output of the repeater. Telstar's service area included North America and Europe, using three major Earth stations: Andover, Maine; Goonhilly Downs, England; and Pleumeur-Bodou, France. No fees were charged to AT&T for any transmissions during the experimental satellite's availability, a period of three months (its circuits were damaged by excessive radioactivity caused by a nuclear test over the Pacific the day before Telstar I was launched). (*Courtesy of Bell Laboratories, Lucent Technologies.*)

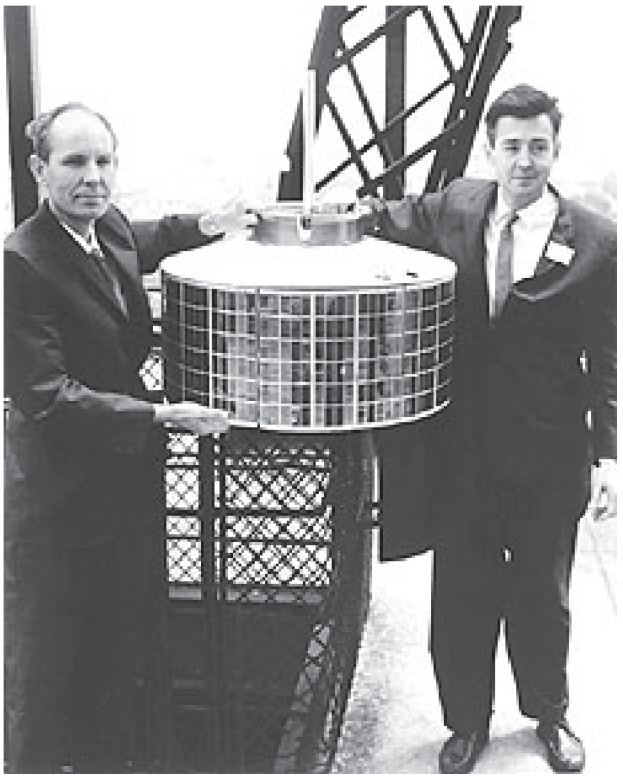

Fig. 8. The first communications satellite to achieve geostationary orbit above the equator was NASA's Syncom III, launched in 1964. Syncom I was lost during its launch on Valentine's Day, 1963, but Syncom II achieved a synchronous orbit on July 26, 1963. Although Syncom II was in orbit 22,300 miles (35,680 kilometers) above the equator, it was not truly geostationary. However, the experimental satellite successfully relayed telephone conversations between President John F. Kennedy and Nigerian Prime Minister Abubaker Balewa in Africa in 1963 — the first live two-way call between heads of state by satellite relay. Built by Hughes Aircraft Company (now Hughes Space and Communications Company) for NASA, the satellite series was designed by Donald D. Williams and Thomas Hudspeth, under Dr. Harold Rosen. The photo shows Tom Hudspeth, left, with Dr. Rosen and a Syncom prototype during the Paris Air Show in 1961, where they displayed the actual-size satellite on the Eiffel Tower — and endured wags who declared, "This is as high as it will ever get." Syncom II measured two feet, four inches (71 centimeters) in diameter and was one foot, three inches (39 centimeters) high. Its mass in orbit was 78 pounds (35 kilograms). Its communications capability was either one-way TV, one two-way telephone channel or 16 teletype (text) channels. Syncom III had an improved design that provided more bandwidth for better TV transmission. (*Photo and drawing courtesy of Hughes Space and Communications Company.*)

four different orbital paths or planes with five satellites in each plane, circling the planet at a medium-orbit altitude of about 6,400 miles (10,352 kilometers). The system is projected to be operating as early as 2002.

Lockheed Martin is developing another system, named *Astrolink*, as a major step forward in increasing data transmission rates. *Astrolink* will incorporate nine satellites in geostationary orbit, but the organization claims only five are needed for global connectivity. The users can select from a range of data transmission rates and pay only for what they use, as compared to paying the fixed cost of leased lines sized for the highest rate they might want. For example, a small office or home office could use a 35-inch (90-centimeter) diameter dish and be provided with data rates up to 416 kilobits per second. A medium-sized business could use data rates up to 2.1 megabits per second with a 39-inch (100-centimeter) dish, while a major enterprise could transmit data at up to 10.4 megabits per second with a six-foot (1.8-meter) dish. Up to 100 gateways will connect *Astrolink* to terrestrial networks worldwide. The first *Astrolink* satellite is tentatively scheduled for launching in 2001, at which time service could begin. The next four spacecraft will complete the global coverage, and the last four will be added as demand escalates.

Medium Earth Orbit (MEO) Satellites

A number of medium-orbit satellite systems involving multiple spacecraft were being developed in the late 1990s for mobile wireless telephony and data transmission. Several satellite constellations already existed in medium-orbit by the mid-1990s (see **Navigation Satellites**, later in this article).

The *ICONET* system, with Hughes Electronics as a major investor and satellite provider, plans to start operating services circa the summer of 2000. See Figs. 11, 12, and 13. The system will include 10 satellites (plus two spares) divided equally into two orbital planes 6,430 miles (about 10,350 kilometers) above the Earth and inclined by 45 degrees to the equator. Each satellite circles the planet once every six hours. The system will have 163 service-link transmit and receive beams, allowing frequency re-use by each satellite; the design supports at least 4,500 simultaneous telephone channels per satellite. Subscribers will use handheld mobile telephones and data terminals when the system is fully provisioned. Calls from a handset will be transmitted (*uplinked*) to an ICO satellite, processed and retransmitted (*downlinked*) on C-band frequencies to one of 12 earth stations called "*satellite access nodes*" (SANs) connected to gateway switches feeding into the world's terrestrial telephone networks. The ICO satellite, which handles the initial call, might pass out of the service area during the call, in which case the communication is handed off to the next satellite. Each satellite is designed to support up to 4,500 simultaneous

Fig. 9. After the successful demonstrations of Syncom II and III, Hughes Aircraft built the world's first commercial communications satellite, popularly known as Early Bird, for the Communications Satellite Corporation (COMSAT). Launched into geostationary orbit on April 6, 1965, Early Bird began commercial service on June 28, 1965, providing line of sight communications between Europe and North America. Early Bird was capable of relaying 240 circuits for telephone, telegraph of facsimile transmission, or one television channel. Similar to Syncom in size and mass, Early Bird weighed 76 pounds (34 kilograms), a bit less than Syncom, but was a bit higher — one foot 11 inches (59 centimeters). Designed to last 18 months in orbit, Early Bird actually remained in full-time service for nearly four years before being placed on reserve duty. In June of 1969, it was recalled into service during the Apollo 11 mission, and was retired again two months later. (*Photo and drawing courtesy of Hughes Space and Communications Company*.)

telephone conversations. The *ICONET* system also carries a navigation and positioning payload to augment similar transmitting systems in the *global positioning system* (GPS) (see **Navigation Satellites**). ICO Global Communications is an outgrowth of *Inmarsat*, mentioned earlier under geostationary satellite systems.

In addition to the *ICONET* system, another medium-orbit system, known as the *Ellipso* project, is being planned for mobile phone and data customers, with operations starting in 2001. See Fig. 14. Design, development and deployment of the future system has been assigned to Boeing Corporation. *Ellipso* consists of a unique medium-orbit combination of two inclined orbital planes, each equipped with four active satellites and a spare, and an equatorial plane equipped initially with six satellites and a spare that can be augmented with four more satellites for future increased daytime capacity. The inclined orbits of the *Ellipso* constellation are truly elliptical: the apogees of the *Ellipso-Borealis* sub-constellation orbits, serving the northern temperate latitudes with 10 satellites in two planes, are 4,725 miles (7605 kilometers) and the perigees are 393 miles (633 kilometers) with a three-hour orbital period; the apogees are near the northern extremity of the orbits. The *Ellipso-Concordia* sub-constellation serves the tropical and southern latitudes with seven satellites in a quasicircular equatorial orbit at an altitude of about 5,000 miles (8,050 kilometers). The system is designed to support voice telephony with digital voice encoding at several levels of quality depending on the customer's specification. *Ellipso* also will support various forms of data transmission, using *code division multiple access* (CDMA) or "*spread spectrum*" techniques to increase the number of voice and data channels carried within its assigned spectrum.

Low Earth Orbit (LEO) Satellites

Several organizations are developing low-orbit systems involving many satellites that trail each other along a given orbital plane. Most of these projects involve a number of orbital planes that are in contact with numerous earth stations. An orbital plane with multiple satellites is called a "constellation." A combination of several orbital planes with multiple satellites in a single system is also called a constellation.

The concept resembles that of cellular telephony, in which a series of stationary antenna towers transfer a wireless telephone circuit from one antenna to the next as a caller moves through the system. However, the low-orbit satellite systems operate in reverse, with the caller being relatively stationary and the "antennas" moving across the sky as they transfer the call from one satellite to another.

Low-orbit systems for mobile communications have one major handicap: the satellites cross the sky rapidly and the signals can be blocked if buildings, trees, hills or other solid objects come between the subscriber's telephone and the satellite. Some satellites use "*spot beams*," narrowly focused radio transmission and reception beacons that "stick" with the terrestrial user until it is necessary to switch or transfer the user to the next satellite. New communications systems between the satellites will transfer signals from one spacecraft to the other in some systems, without downlinking to an earth station. Such signal transfers are via microwave radio at present, but research is underway on the feasibility of using laser beams.

The first such system to attain operating status with voice and data transmission was *Iridium*, which in 1998 had a constellation of 66 low-Earth orbit satellites, each weighing about 1,528 pounds (689 kilograms). See Fig. 15. Only 15 launches were needed over a one-year time frame to place the 66 satellites in orbit, with as many as seven spacecraft on a single launch. The *Iridium* satellites are grouped into six orbital planes inclined at 86.4 degrees to the equator and at an altitude of about 485 miles (780 kilometers). Each plane has 11 satellites plus one spare that will come to life if any of the 11 craft fails. Each satellite orbits the planet once every 100 minutes and 28 seconds and travels at a velocity of about 17,400 miles/hour (28,000 kilometers/hour) with a "*footprint*" diameter of 2,920 miles (4,700 kilometers). The system was conceived and built by the Motorola Corporation, which announced the concept in 1988. The estimated service life of each satellite is between five and eight years. Each satellite is equipped with 48 spot beams, permitting re-use of assigned frequencies in the L band (at 1616 to 1626.5 megahertz) for connection to subscriber phones, pay telephone booths, etc. See Figs. 16 and 17. Subscribers to the service will have to pay several thousand dollars for a special telephone, or hundreds of dollars for a pager, but the market is expected to consist of business and government travelers who have longed for a global communications system that provides them with a single number to use wherever they are on the planet. The speech quality is not as good as a wireline telephone, since the bit-rate is a mere 2.4 kilobits per second for full-duplex or two-way voice calls (network quality standards for a digital wireline voice circuit call for 64 kilobits, which can be acceptably reduced with special algorithms to lower digital rates). Data and fax transmission via *Iridium* is handled at 2400 baud, significantly slower than the setting of most computer modems. The satellites can communicate directly with each other, without relay by an earth station, using the Ka band at 23.18 to 23.38 gigahertz for intersatellite links. When communicating with their gateways, their downlinks also use the Ka band, but at 19.4 to 19.6 gigahertz, while the uplinks employ 29.1 to 29.3 gigahertz. The system began operations with 12 terrestrial gateways.

Yet another low-orbit constellation project is *Globalstar*, founded in 1991 by Loral Space & Communications and QUALCOMM Inc. Strategic partners include Alenia Aerospazio (a Finmeccanica Company), China Telecom, DACOM, DaimlerChrysler Aerospace, Elasacom (a Finmeccanica Company), Hyundai, TE.SA.M (a joint venture between France Telecom and Alcatel), Space Systems/Loral and Vodafone AirTouch. This system became operational in the 3rd quarter of 1999. See Fig. 18. The *Globalstar* service is provided through a 48-satellite low-earth-orbiting (LEO) constellation. The system is divided into eight orbital planes having six satellites in each plane, plus four spare satellites remaining in orbit. The operating altitude is planned for 763 nautical miles (1,414 kilometers) and the orbital inclination is 52 degrees. Each satellite will circle the planet every 114 minutes. The participation by QUALCOMM means

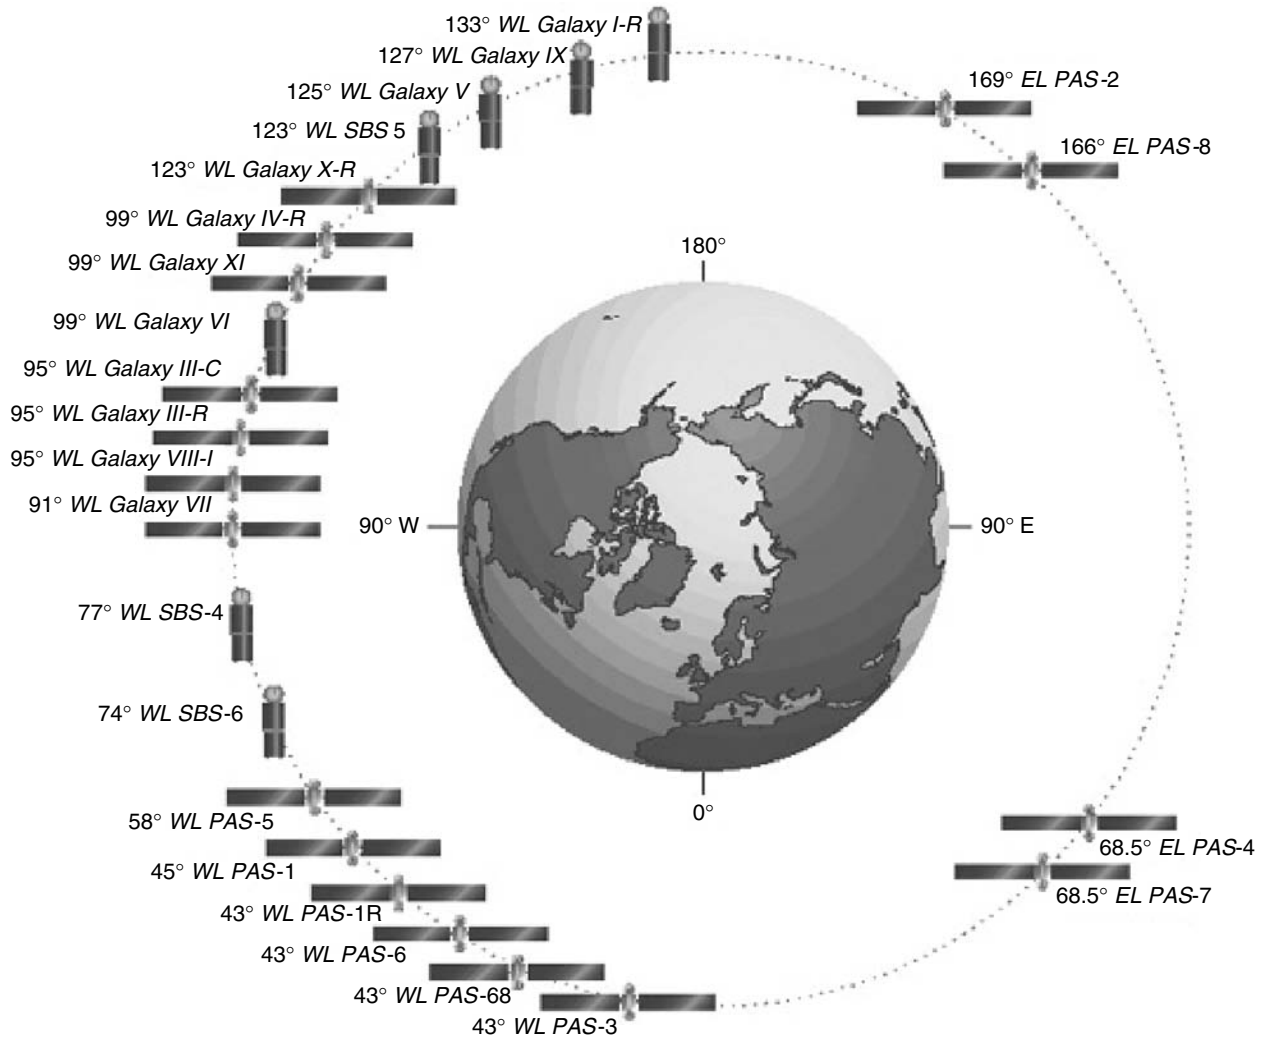

Fig. 10. Looking down at the Earth's north pole, the equatorial ring of PanAmSat communications satellites in geostationary orbit displays their positions, which are 22,300 miles (35,800 kilometers) above the equator. More satellites are grouped above the American and European continents. (*Courtesy of PanAmSat Company*.)

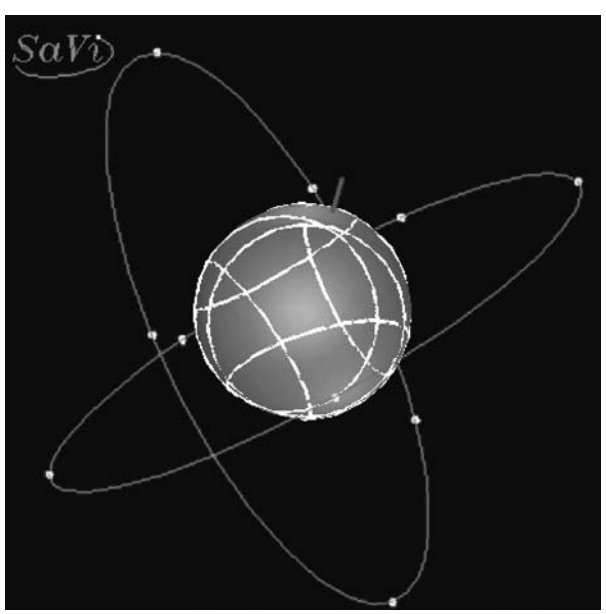

Fig. 11. This rendering shows the final design of the ICO constellation, consisting of two planes with five communications satellites in each. (*Constellation views rendered by Lloyd Wood, using SaVi, the Satellite Visualization software created by Patrick Worfolk and Robert Thurman at the Geometry Center, University of Minnesota*.)

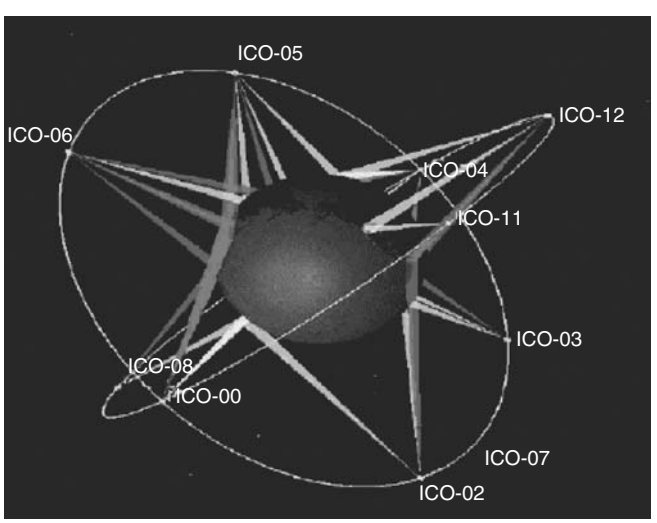

Fig. 12. The ICO constellation of 10 satellites (plus two spares) consists of two orbital planes 6,430 miles (about 10,350 kilometers) above the Earth, inclined by 45 degrees to the Equator. Each satellite contains spot beams designed to focus energy to a relatively small area so mobile telephones and data terminals can transmit and receive in direct links to and from the satellite passing overhead. As the satellite moves away from the user, the call is transferred to a spot beam of the next satellite. (*Animations by Raytheon Systems Company for ICO Global Communications*.)

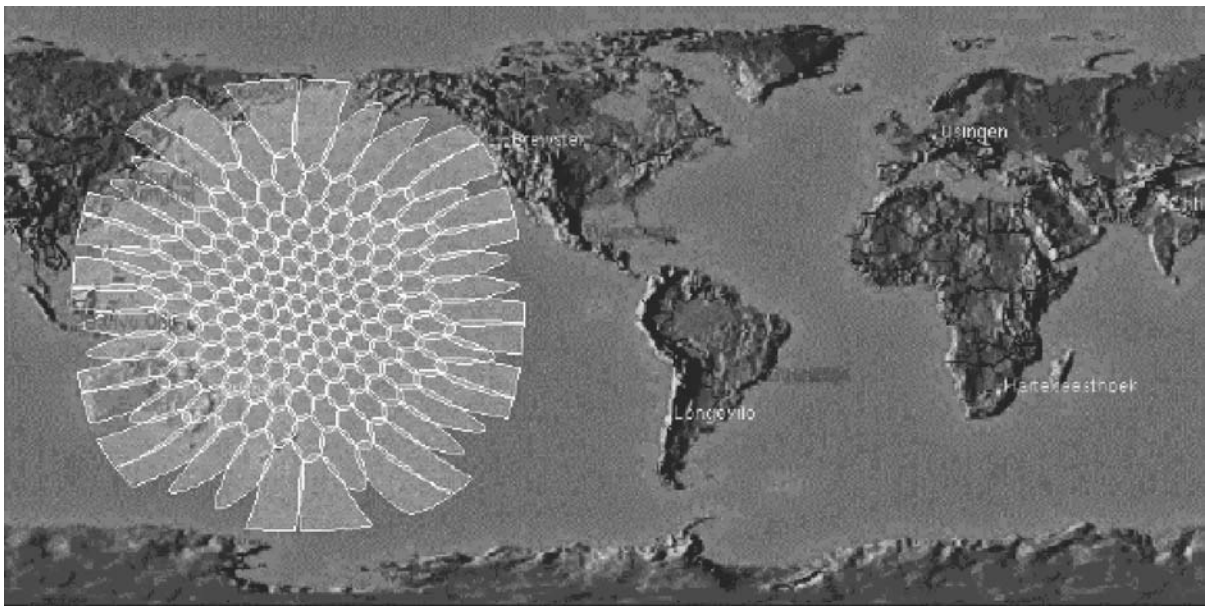

Fig. 13. Each ICO satellite has 163 service-link transmit and receive beams capable of supporting at least 4,500 digital telephone channels using time-division multiple access (TDMA) multiplexing. This illustration shows the movement of an ICO satellite's footprint of spot beams as it moves across the world. (*Animations by Raytheon Systems Company for ICO Global Communications*.)

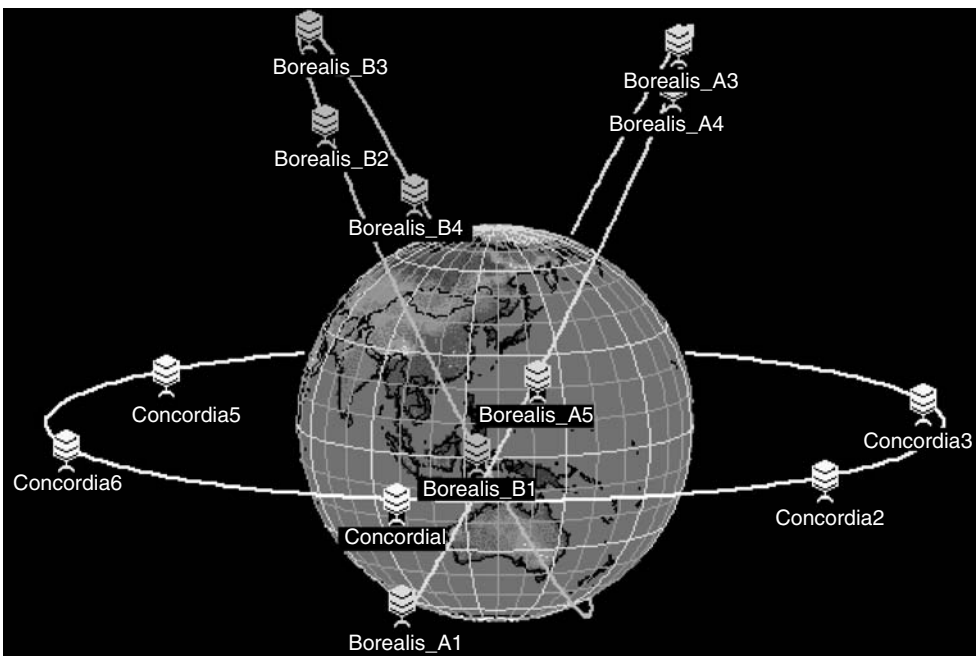

Fig. 14. A unique, patented elliptical orbit configuration for the Ellipso project will use two complementary sub-constellations with a total of 17 satellites plus a spare when it is activated in 2001. Four active satellites (and a spare) in each of the two Borealis elliptical orbits will soar higher (up to 4,725 miles or 7,605 kilometers) in the northern latitudes so they will have a larger "footprint" in the great continental areas, and drop to an altitude of only 393 miles (633 kilometers) while passing "under" the Earth. The smaller land masses in the tropical and southern latitudes will be served by six active satellites (and a spare) in the equatorial Concordia orbit at an altitude of about 5,000 miles (8,050 kilometers). Ellipso is intended to bring affordable fixed, mobile and airborne voice and data telecommunications to new markets worldwide, according to Boeing. (*Courtesy of The Boeing Company*.)

that the digital signals will be encoded using code-division multiple access (CDMA) technology rather than the frequency-division multiple access/time-division multiple access favored by many other satellite digital circuits. The project will support direct satellite links to pay phone stations equipped with *Globalstar* antenna, radio unit and optional digital telephone, but locally provided by an in-country service provider. In addition, the system includes vehicle-mounted car kits and handheld terminals. In use, the terminals will first try to connect with an existing cellular infrastructure; if that attempt fails, the units change to the satellite system. The call is then relayed via satellite down to a gateway antenna station for routing through the existing national terrestrial system to the end destination.

A unique, packets-only low-orbit system is operated by *ORBCOMM*, which placed two LEO satellites in orbit in April 1995 and reports having processed over 1.5 million messages that included personal communications and information on monitoring, positioning and tracking of commercial assets, environmental conditions and military resources on land and at sea. With 28 satellites in orbit (altitude: 508 miles or 818 kilometers) by September 1998, the company plans to have up to 36 small communication satellites launched by 1999, providing services in the USA and internationally. See Fig. 19. For launch, these compact spacecraft folded into a cylinder only 6-1/2 inches high and 41 inches in diameter and stacked eight high on a Pegasus rocket, which was launched from an aircraft at an altitude of 40,000 feet (12,200 meters). Each satellite has a mass

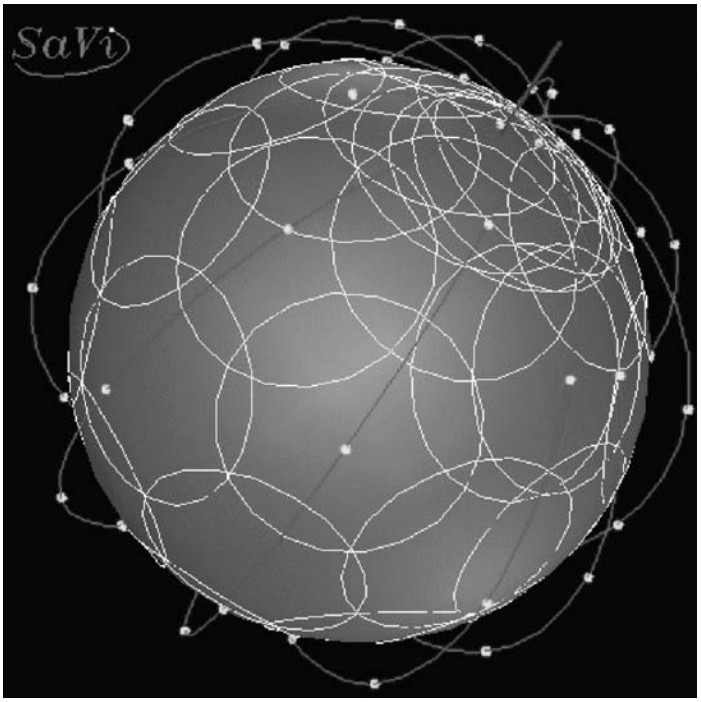

Fig. 15. Activated in late 1998, the Iridium constellation has six orbital planes, each equipped with 11 satellites, or a total of 66 active satellites in low-Earth orbits. (*Constellation views rendered by Lloyd Wood, using SaVi, the Satellite Visualization software created by Patrick Worfolk and Robert Thurman at the Geometry Center, University of Minnesota.*)

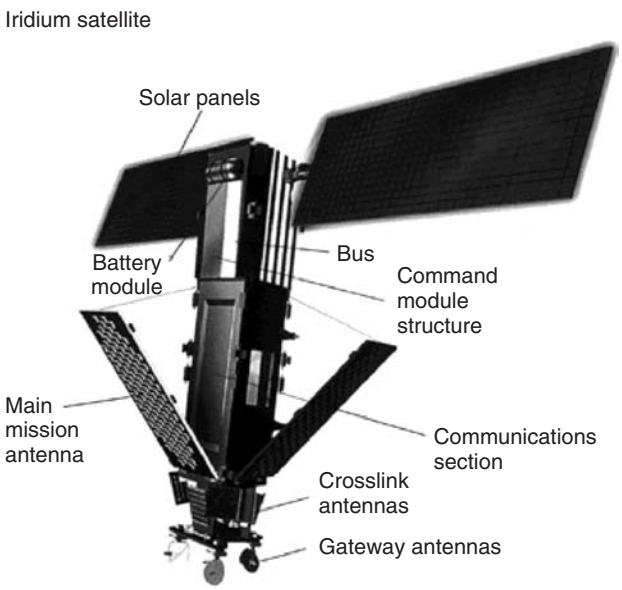

Fig. 16. Assembled in production lines rather than as custom-built units, the 66 active communication satellites of the Iridium constellation can signal each other as well as the system's earth stations and the individual user's special mobile telephone. (*Rendering courtesy of Motorola Corporation.*)

Fig. 17. The Iridium handheld telephone, costing more than $3,000, is capable of communicating with the Iridium satellites in low-Earth orbit as they pass overhead. (*Courtesy of Motorola Corporation.*)

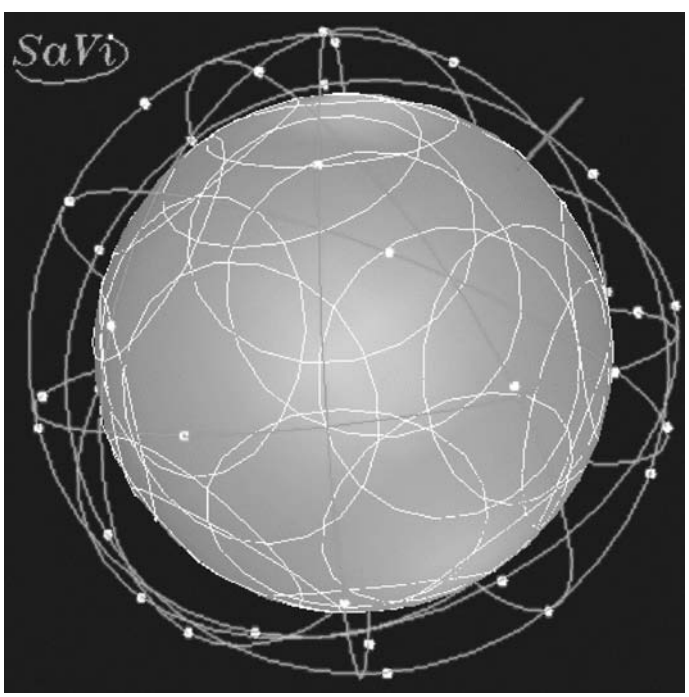

Fig. 18. The Globalstar constellation, scheduled for operation in late 1999, has eight orbital planes equipped with six active satellites in each plane, or a total of 48 active satellites (plus four on-orbit spares). (*Constellation views rendered by Lloyd Wood, using SaVi, the Satellite Visualization software created by Patrick Worfolk and Robert Thurman at the Geometry Center, University of Minnesota.*)

of only 90 pounds (40 kilograms). An *ORBCOMM* satellite is designed to send and receive two-way alphanumeric packets, similar to two-way paging or e-mail, but does not handle voice. The craft is described as an "orbiting packet router" that "grabs" small data packets from sensors in vehicles, containers, vessels or remote fixed sites, and relays the packets through a tracking Earth station to a gateway control center, from which the information is sent to the addressee. Using a new hand-held, two-way text messenger, subscribers can communicate with any Internet e-mail address, sending or receiving text messages of up to 2,000 characters. The device also integrates a *global positioning system* (GPS) receiver. This and other user devices, called "subscriber communicators," enable either monitoring of fixed, remote data assets, such as electric utility meters, oil or gas storage tanks, wells and pipelines and environmental projects, or

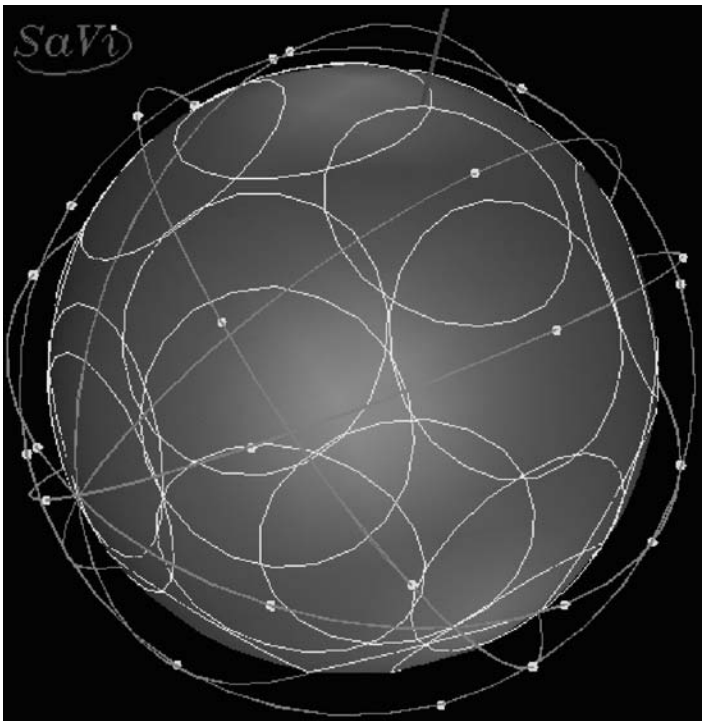

Fig. 19. The Orbomm satellite constellation has 36 active satellites in four planes of eight spacecraft each, and two higher-altitude planes of two spacecraft each. (*Constellation views rendered by Lloyd Wood, using SaVi, the Satellite Visualization software created by Patrick Worfolk and Robert Thurman at the Geometry Center, University of Minnesota.*)

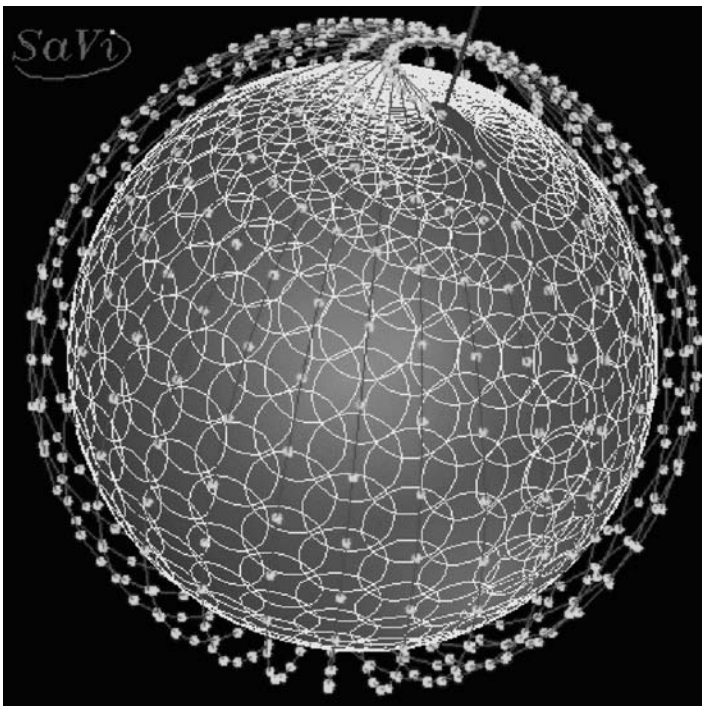

Fig. 20. The Teledesic project began with a mammoth proposal for 840 active satellites in 21 planes of 40 satellites each in low-Earth orbit. Boeing redesigned it to use 288 satellites in 12 planes of 24 satellites each. Target date for operations is 2003. (*Constellation views rendered by Lloyd Wood, using SaVi, the Satellite Visualization software created by Patrick Worfolk and Robert Thurman at the Geometry Center, University of Minnesota, and the Boeing Corporation.*)

mobile, two-way data and messaging communications. *ORBCOMM* operates in two frequency ranges: 137–138 megahertz and 400 megahertz, for transmissions down to mobile or fixed data communications devices, and 148–150 megahertz for uplinks.

Meanwhile, a much larger system involving more satellites than any other constellation system is being developed by a joint effort including Motorola, Lockheed Martin, The Boeing Company, cellular telephone pioneer Craig McCaw, Microsoft chairman Bill Gates, Saudi Prince Alwaleed Bin Talal, and Abu Dhabi Investment Company. Known as *Teledesic*, the system's initial design proposed a constellation of 840 satellites in 21 planes orbiting at an altitude of about 432 to 438 miles (695 to 705 kilometers), but this was eventually changed to 288 active satellites plus spares in 12 planes with 24 satellites per plane, and may be reconfigured again before it is implemented. See Fig. 20. The *Teledesic* network is promoted as a global, broadband "Internet-in-the-Sky™" system. Using advanced satellite technology, *Teledesic* and its partners are creating the world's first network to provide affordable, worldwide, "fiber-like" access to telecommunications services such as computer networking, broadband Internet access, interactive multimedia and high-quality voice. As of 2000, *Teledesic* service is targeted to begin in 2004.

Navigation Satellites

The various U.S. military forces have their own satellite operations offices within the Department of Defense. One of their most prominent installations is a navigation system–the *global positioning system* or *GPS*–completed in 1993. Developed and operated by the U.S. Department of Defense, it now serves thousands of civilian users as well as the armed forces. The fact that the U.S. military establishment controls *GPS* makes some European and Asian users nervous, so other systems are on the drawing boards.

The *GPS* satellites are operating in a medium orbit, about 12,000 miles or 20,200 kilometers high. At that altitude, at least four satellites are visible from any given spot on Earth at any time, day or night. *GPS* has a constellation of 21 *Navstar* satellites, plus three operational spares in orbit. The first satellite was launched in 1978; it and the next nine spacecraft were developmental. They were followed by the present 24 satellites, launched from 1989 to 1994. These are distributed in six planes inclined at 55 degrees. Each satellite circles the globe in 12 hours. The average life expectancy of each *GPS* satellite is about 7 or 8 years. *GPS* employs the 1984 Worldwide Geodetic System of coordinates, similar to the latitude and longitude lines on global maps.

The Russian military establishment also has a navigation satellite system, known as *GLONASS* (Global Orbiting Navigation Satellite System). Like the American *GPS* constellation, *GLONASS* consists of 24 satellites (in 1998, only 15 were considered operational), but they are distributed in three orbital planes at an altitude of about 11,870 miles (ca. 19,100 kilometers). Although the basic concept is similar, there are important differences between *GPS* and *GLONASS*, especially in their radio signals, which are incompatible. There are dual-system receivers available for people who want to access both systems, and there are good reasons for doing so, because the 10 degree higher orbital inclination of the *GLONASS* satellites places them in portions of the sky where *GPS* satellites are never visible. Besides, the composite receiver can select from twice as many satellites, significantly improving the geometry for improved, real-time accuracy in determining location. Also, the radio frequency system used by *GLONASS* is compatible with planned future navigation aids sponsored by other countries, such as the European Geostationary Navigation Overlay System (EGNOS), which would be available to users of composite receivers. Life expectancy of *GLONASS* satellites is about half that of the *GPS* satellites, but the Russian administrators contend that by 2002 the design life will be about equal.

The *GPS* satellites are used by U.S. and allied military personnel to pinpoint the locations of troops, vehicles, and targets, using signals broadcast in an encrypted P code on two frequencies from each satellite, providing Precise Positioning Service (PPS). Commercial users employ only one frequency from each satellite's downlinks, in which a C/A code provides Standard Positioning Service (SPS) signals, which are processed in special receivers available for purchase. More than 100 different receiver models were in use by 1998. Essentially, the receiver uses the signals from three satellites to pinpoint by triangulation a two-dimensional fix (latitude and longitude), or from four satellites to determine the commercial user's

location and altitude. These are shown in a display on the receiver–but only within a space of about a city block or circa 300 feet (100 meters). The Department of Defense deliberately blurred the accuracy of the system for non-military users, except in special cases, so as to prevent abuse of the system by enemies of the U.S. Despite this, the commercial customers for the *GPS* spent $1.6 billion for its services in 1997.

By 1998, the U.S. government reported that military purchases of *GPS* equipment represented just a fraction of industry sales. Worldwide *GPS* equipment sales reached $4 billion in 1998 and are expected to double in 2000. See Fig. 21. The growing enthusiasm among commercial customers is due in part to the introduction of new services provided by *Inmarsat*, *ORBCOMM*, and other commercial satellite networks, in which their customers have access to supplementary information that reportedly improves the accuracy of the *GPS* signals, in some cases, to the diameter of a golf ball. Among some of the more public applications of the *GPS* by the military was Operation Desert Storm, when Allied troops attacked Iraqi forces to liberate Kuwait in February, 1991, using 9,000 *GPS* receivers to guide them through trackless deserts. *GPS* receivers also are used by submarines, aircraft, and warships. A major civilian project was the digging of the rail tunnel under the English Channel, in which *GPS* receivers (set to the high-precision capability with permission of the Department of Defense) helped engineers to steer excavators as they simultaneously dug from the English and French coastlines, so they met in the middle. See also **Tunnel Engineering**. Automobile manufacturers are offering moving-map displays (some with voice direction as well) guided by *GPS* receivers as an option, and many expect these systems will eventually be standard equipment.

Fig. 21. One of many GPS handheld terminals, the Magellan GPS ColorTrak receiver has nine graphic navigation screens (five can be custom-set), stores up to 500 locations, or 20 routes with 30 legs. The satellite status screen displays which satellites are being used and their relative signal strength, as well as their position overhead. The plotter screen tracks where the user has been (in red) and the user's destination (in blue). (*Courtesy GPS Store*.)

Fleet vehicles such as delivery trucks and buses often are *GPS*-equipped as a method of monitoring their locations at all times, especially in conjunction with the *ORBCOMM* system. Land surveyors, mining companies construction contractors, and motion-picture photographers rely on *GPS* for economic and precise positioning of critical activities. When combined with tiny implanted transmitters, *GPS* receivers can be used to track wildlife in the Arctic or in jungles. They may be a means of protecting helpless Alzheimer's disease patients who tend to wander away and become lost–or locating escaped criminals.

As might be expected, there are many more organizations plotting different installations of geostationary, geosynchronous, medium-orbit and low-orbit satellites. Some of these will be successfully implemented and others may never make it into space, depending on their finances and the expertness of their engineering. But there is no doubt that the satellite population will increase year by year.

The electronic interference of satellite transmission circuits with radio astronomy, as well as visual interference with optical astronomy, has raised concerns among researchers. Optical astronomers have already been irritated by this phenomenon, since the antennas of the low-orbit *Iridium* satellites have produced sun reflections (called "flares") while passing through the night sky, interrupting telescope viewing–and sometimes they are even visible as brief flashes in the sky in daylight. As more low-orbit satellites join those already in the sky, that problem may become more significant. For additional information on communication satellites, see **Telephony (Telecommunications)**. Weather (meteorological) satellites are described in the article on **Weather Technology**. Scientific and reconnaissance satellites are described in the following article.

SATELLITES (Scientific and Reconnaissance). Satellites fall into three broad classifications: (1) commercially oriented missions, as represented by communication and navigation satellites described in the prior article; (2) scientifically dedicated satellites such as those found in space astronomy, cosmology, and earth sciences pertaining to the atmosphere, oceans, and terrain of the Earth; and (3) military-motivated missions. The latter are not described in this encyclopedia.

During the early years of satellite technology, rockets launched the orbiting vehicles. Many years later with the perfection of the space shuttle concept, orbiters within the handling capacity of the shuttle have been launched from that space vehicle. See also **Space Shuttle**. Power required for final orbit positioning, or when moving a given satellite to a new location, is accomplished by a power source (usually chemically propelled thrusters) that is built into the satellite by design. Control is managed by remote commands from ground stations on Earth.

Satellites generally orbit the Earth, although some satellites are research vehicles that have been designed to orbit a body other than Earth. Examples include the *Viking I* and *Viking II Orbiters*, which were designed to orbit the planet Earth, as opposed to *Viking I* and *Viking II Landers*, which actually set down on the surface of Mars. During the earlier Apollo lunar expedition, there was a lunar orbiter that was usedto keep in touch with the crew on the surface of the moon. Pictures of the blind side of the moon were taken for the first time from the lunar orbiter.

More recently, satellites also refer to manned space platforms that orbit the Earth called space stations. Examples include the U.S. built *Skylab* of the 1970's, the Russian built *Salyut* series of the 1970's and 1980's, the

Russian built *Mir Space Station* of the 1980's and 1990's and the multinationally owned and operated *International Space Station* which, as of late 1998, is under construction in space. See also **Space Stations**.

Satellite Sensing of Earth Resources

The earliest practical use of an Earth-orbiting satellite was simply that of viewing and studying Earth from the perspective that can only be achieved from a position in space far beyond that which can be attained by land-based aircraft. Weather satellites and land satellites, such as the *Landsat* program, share historical significance. The name *Landsat* was coined to differentiate the land surveillance satellite from a *Comsat* (communication satellite). Since its inception in 1965, the *Landsat* program has been highly successful in its scientific accomplishments and data collection. Remote sensing of numerous properties of Earth is central to the *Landsat* program, as well as to the Earth Science enterprise (formerly known as the *Mission to Planet Earth* program).

Early Remote Sensing Programs

Prior to the formal launching of the first earth resources technologysatellites (initially called *ERTS* and later named *Landsat*), the results of earth surveys from high-altitude aircraft and balloons greatly aided scientists and conservationists in charting the features of the Earth. (It is interesting to note that, beginning in the 1990's, weather services in various countries and the National Center for Atmospheric Research, headquartered in Boulder, Colorado, USA, made extensive use of aircraft and balloons). Earth resources experiments were on the testing agenda of several of the earlier *Gemini* and *Apollo* manned space flights. Images were made of the Earth both in the visible light range and the infrared (IR) and ultraviolet (UV) portions of the electromagnetic spectrum. The results were promising and indicated that such data, properly interpreted, could assist in a wide array of programs–agricultural planning, charting the movement of sea life, monitoring concentrations of air and water pollutants, and furnishing more fundamental knowledge of the Earth in terms of its geography, cartography, forestry, geology, and anhydrology.

The History of the Landsat Program

The original concept of an earth resources monitoring satellite is generally attributed to the United States Geological Survey during the 1960's, although scientists at the United States Department of Agriculture were also thinking along similar lines during that period. In 1968, the United States Department of the Interior, which oversees the Geological Survey, requested funds to build a new satellite, which it called *EROS* (earth resources observation satellite). The Department of the Interior accepted datahandling responsibility, and the National Aeronautics and Space Administration (NASA) agreed to develop and launch the satellite.

During the period that the first satellite was under development and construction, the name of the spacecraft was changed from *EROS* to *ERTS* (earth resources technology satellite). *The ERTS 1* was built into the same spacecraft frame as had been used for the *Nimbus* weather satellite of that period. As shown in Figs. 1 and 2, the spacecraft resembled an ocean buoy, equipped with two rectangular photovoltaic "wings" to capture solar energy. *ERTS 1* was launched by NASA on July 23, 1972, on a Delta Rocket from Vandenberg Air Force Base, California, into polar orbit, which took the satellite over any given location on earth once every 18days. Each day the satellite made 14 revolutions of the earth (about one every 103 minutes). Ground coverage proceeded westward until global coverage was completed. An active attitude control subsystem maintained the satellite's observing system within ± 0.7 degree of the local vertical. The two solar panels provided 500 watts of electrical energy. Altitude of the satellite was maintained at 900 kilometers. The payload included:

- Three television cameras (return beam vidicons) for photographing the earth in color. This system failed shortly after launch.
- A multispectral scanner (MSS) was included as a secondary system. The MSS had previously been tested at high altitude in an airplane, buthad not experienced orbital flight. The MSS became the primary system and performed well beyond expectations.

In addition to the viewing data, data was received from automatic data collection platforms located in the United States and Canada that concerned

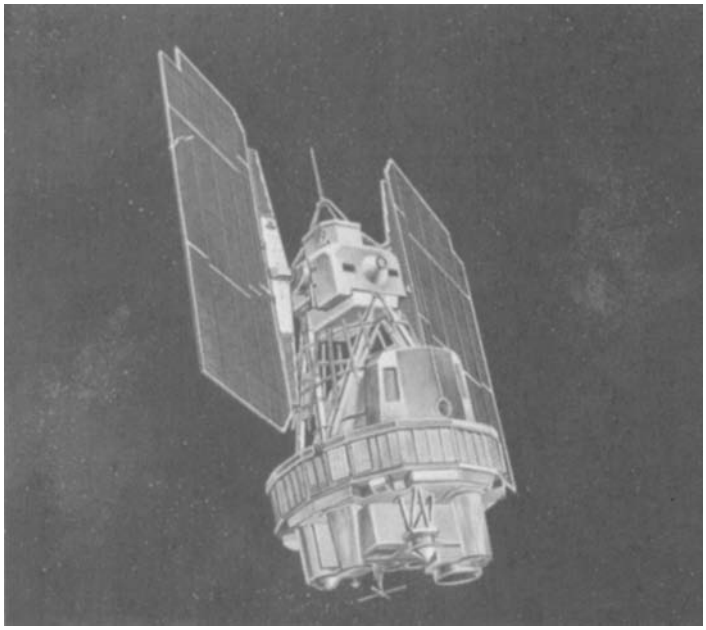

Fig. 1. The ERTS 1 (later named Landsat 1) earth resources technology satellite as it appeared in orbit after launching in 1972. The satellite operated in a polar orbit about 914 kilometers (about 570 miles) above the Earth. The orbiting observatory returned images from a multispectralscanner. A data collection system gathered environmental information from Earth-based platforms and relayed the information to a ground processing facility.

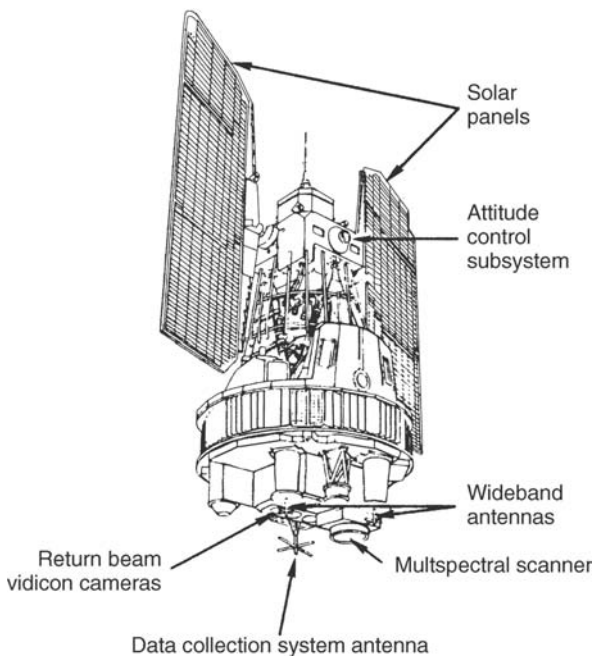

Fig. 2. Principal elements of the Landsat 1. Shortly after launching, the vidicon camera system failed. Thus, the satellite depended exclusively on the multispectral scanner (MSS), the results of which receivedwide scientific acclaim.

such local factors as stream flow, snow depth, and soil moisture. This information was relayed by the satellite to ground stations. Data from any platform was available to users within 24 hours from the time the sensor measurements were made. Data from the MSS were transmitted to tracking stations via dual wideband (2.2 giga-hertz) S-band data links for recording on magnetic tape. Narrowband telemetry provided for satellite housekeeping, the relay of data collection system data, and such payload-related data as attitude and timing. Telemetry, tracking, and command subsystems on board were compatible with tracking stations in NASA's space flight tracking and data network installed at that time.

As time permitted careful analysis of the data, users of the information showed considerable enthusiasm and the performance of *ERTS 1* was generally proclaimed a success. Thousands of images were collected and catalogued. The unusual colored views of features of the Earth were frequently seen in both the scientific and mainstream literature. Essentially, the first year of data gathering by the satellite was devoted by scientists in a variety of fields to learning how to use the data effectively, of literally coping with the immensity of the information, and in planning how to make the second satellite. Among the early accomplishments of the satellite were:

- Agriculture. Area coverage of Texas and Oklahoma categorized as to range and pasture land, forests and water; up to 11 types of crops identified for fields 20 acres (7 hectares) or larger for San Joaquin Valley and Imperial Valley, California.
- Cartography. Inaccuracies in map locations of Brazilian lakes and rivers discovered; unmapped lakes located in Iran. Geology. Nearly 50% additional unmapped faults found branching off the San Andreas Fault in California previously thought to be an accurately mapped seismologically active area.
- Hydrology. Shallow substrate water-bearing rocks detected in Nebraska, Illinois, and New York; polluted water drift charged off the coastof New Jersey; extent of Mississippi River flooding determined.
- Oceanography. Uncharted reefs detected off Bahaman Islands and Australian coast; navigation charts for Bahamas to depths of 4 to 8 meters (13 to 26 feet) produced more accurately than any prior maps.
- Urban Development. Dallas-Fort Worth images showed new roads, reservoirs, suburbs, and airports not on maps made three years prior.

A second satellite, *ERTS B*, was launched on January 22, 1975, and shortly thereafter was named *Landsat 2*. The original *ERTS 1* was renamed *Landsat 1*. A third satellite, *Landsat 3*, was launched on March 5, 1978. Design modifications were focused on improvements to the imaging system. By 1982, only one of the satellites, *Landsat 3*, remained active but the first of a second generation of surveillance satellites (*Landsat 4*, which was later renamed *Landsat D*) was launched that same year. The new satellite incorporated an improved multispectral scanner and a thematic mapper. See Figs. 3 and 4.

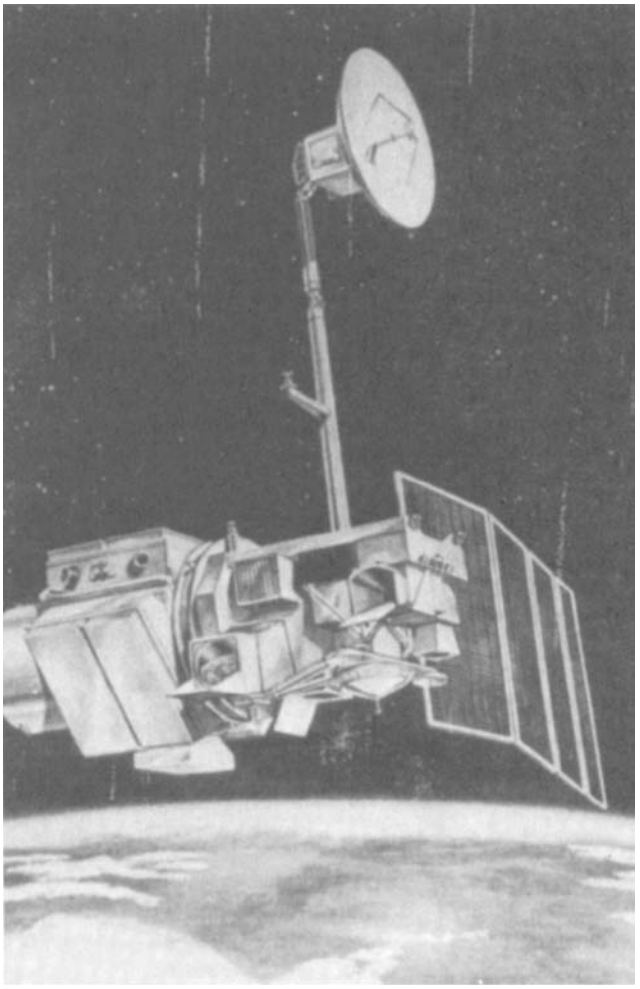

Fig. 3. View of Landsat D in orbit (artist's sketch). The satellite was launched into a sun-synchronous, polar orbit approximately 700 kilometers (435 miles) high in 1982. The satellite carried two remote sensing instruments as shown in Fig. 4. The satellite is sometimes referred to as Landsat 4. (*RCA Astro-Space Division, General Electric*.)

Landsat 1980–1998

Plans had been announced in the late 1970's for three additional *Landsat* satellites (*D*′,′′, and ′′′) to round out the second generation of vehicles. In the very early 1980's and particularly after a change in Administration in 1981, interest in the program by Congress and the Administration waned, although a number of strong supporters remained. The use of data by local and state governments, other governments worldwide, and by private groups did not measure up to earlier expectations. Also, there had been a series of technical difficultiesand disappointments. Much of the imagery of the world from space had been accomplished as witness the frequent use of images made by the earlier *Landsats*. Thus, with the exception of very specific projects, data alreadyon hand served many needs. Financial support for the program as derived from the sale of data did not appear to be forthcoming. But the principal deterrent to the program was the Administration's plan to turn to the program over to the private sector. Nevertheless, *Landsat D'* symbol, which hadbeen ready to launch for a considerable period, was indeed launched in March 1984.

In 1983, the Administration formally put the *Landsat* program out to bid to the private sector. A subsidy from the United States Governmentin the amount of $250 million to aid operating costs for a period of five years was an important part of the negotiations. In 1985, the Earth Observation Satellite Company (EOSAT), a partnership of Hughes Aircraft and RCA, was selected by the National Oceanic and Atmospheric Administration (NOAA) to operate the *Landsat* system under a ten year contract. Hughes announced in February 1986 that EOSAT would operate *Landsats 4* and *5*, (the latter formerly referred to as *D*') and would be the primary source for marketing, ordering, and distributing the data from the satellites. EOSAT would commence construction of *Landsats 6* and *7* vehicles. The latter would be built by RCA and would carry imaging devices built by Hughes. See Fig. 5.

By mid-1990, Hughes Aircraft announced that testing had commenced on the *Landsat 6* mapper sensor. The spacecraft would orbit the Earth

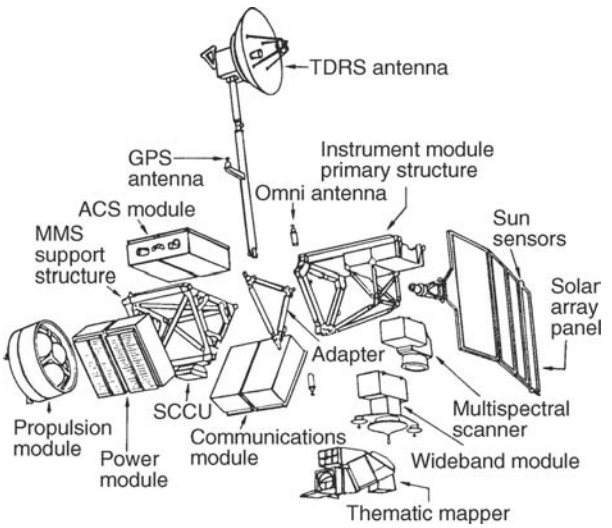

Fig. 4. Expanded view of Landsat D (or 4). The satellite carried a thematic mapper (TM), an experimental sensor of advanced design to provide scenes with 30-meter (about 100 feet) resolution. It is a 7-channel radiometer. Satellite also carried a multispectral scanner (MSS) with 4 channels, 80-meter (262.5-foot) resolution, which is identical to the sensors on Landsats 1 and 2. Landsat D had the capacity to generate 800 scenes per day (550 MMS; 250 TM) for all ground stations, as compared with 190 MSS scenes from Landsats 1, 2, and 3. (*National Aeronautics and Space Administration*.)

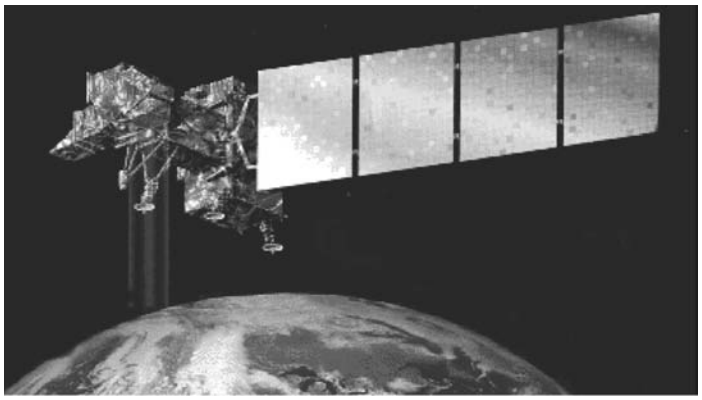

Fig. 5. Artist's concept of the Landsat satellite over Earth. (*NASA*.)

at the same altitude, inclination and equatorial crossing time as *Landsats 4* and *5*; however, the enhanced thematic mapper sensor would provide improved spatial resolution capable of discerning objects smaller than a tennis court.

In February 1992, the National Space Policy Directive No. 5, signed by President George Bush, formally recognized the importance of *Landsat* data. The Department of Defense (DoD) and NASA were instructed to develop and launch *Landsat 7* with performance capabilities at least equal to *Landsat 6*. In addition, DoD and NASA were instructed to define continuity requirements plus define a management plan that addressed future funding and operations responsibilities. The DoD accepted responsibility for the space segment, and NASA accepted responsibility for the ground segment. Later that year, the Land Remote Sensing Policy Act of 1992 recognized that commercialization of *Landsat* had not been successful. The *Landsat* Program Management team (LPM) was authorized to procure *Landsat 7* and to negotiate with contractors on data policy for Landsats *4–6*.

The DoD signed a contract with General Electric (now Lockheed Martin Missiles and Space) for the construction and launch of *Landsat 7*. *Landsat 7* successfully launched onboard a Boeing Delta II on April 15, 1999. The satellite will carry an Enhanced Thematic Mapper-Plus sensor. This will enable the satellite to seasonally monitor small but significant processes on a global scale, such as the annual cycles of vegetation growth; deforestation; agricultural land use; erosion and other forms of land degradation; snow accumulation and melt and the associated freshwater reservoir replenishment; and urbanization. NASA is responsible for the development and launch of the *Landsat 7* satellite and the development of the ground system. The *Landsat* Project at Goddard Space Flight Center manages these responsibilities. Hughes Santa Barbara Remote Sensing has contracted to build the sensor and Lockheed Martin Missiles and Space has contracted to develop the spacecraft. NOAA is responsible for operation and maintenance of the satellite, as well as the ground system for the life of the satellite. The United States Geological Survey (USGS), on behalf of NOAA, will capture, process, and distribute the data. The USGS is additionally responsible for maintaining an archive of *Landsat* data.

Landsat 7 is part of the global research program formerly known as NASA's *Mission to Planet Earth*, now called the *Earth Science enterprise*, which is a long-term program that is studying changes in Earth's global environment. The mission of the Earth Science enterprise is to study and expand the knowledge of the total Earth system and the effects of change, both natural and human-induced, on the global environment.

Additional Remote Sensing Technologies

High-Altitude Aircraft. These are still used, using X-band, 3-centimeter, and L-band, 25 centimeter radar, as well as thermal infrared multispectral scanners. An 8-channel scanner has been used effectively to gather mineral signature information at wavelengths between 8 and 12 micrometers. Results indicate that igneous rock units can be identified from their free silica content and that carbonate as well as clay-bearing units are readily separable on digitally processed images. Considerable use of this tool has been made in the Death Valley region of California and the Cuprite area of Nevada.

Orbiting Laboratories. This type of craft known as space stations, for example the *Mir Space Station*, and the *International Space Station* (*ISS*), which is currently under construction, can be highly useful. See also **Space Stations**. Earth sciences research in land, ocean and atmospheric processes can be performed to document transient and long-term natural and human-induced changes in the global environment. The data collected on the *Mir*, and later on the *ISS*, will add to the documentation of atmospheric conditions, ecological, and seasonal changes over long time periods. During long-duration missions, astronauts and cosmonauts perform routine observations and photography of Earth. The data collected augments the 35-year database of Earth imagery gathered by the *Landsat* programs. Unlike the *Landsat*, which covers the globe completely, space station coverage is site specific. Site selection is based on joint US/Russian activity and long-term planning which has identified known regions of interest. Within those parameters, coverage is based on the trajectory and attitude of the space vehicle, current events, and weather patterns. Ad hoc photography of special, unpredictable events, such as tropical storms, floods, forest fires, volcanic eruptions and dust storms, can be requested of the crew real-time. A specific focus of current missions is to document the aftereffects of the 1998 El Niño event.

The Space Shuttle. An ocean color experiment (OCE), designed to map ocean features with an 8-channel scanning radiometer, was installed on one of the early Shuttle excursions. The primary aim of the OCE was to detect phytoplanktonic algae on a global basis and to determine the chlorophyll pigment concentrations. The OCE was set up to focus mainly on deep-water areas in contrast with coastal waters. Ocean images were obtained at three widely separated locations: Yellow Sea, Gulf of Cadiz, and Grand Bahama Bank. The researchers agreed that the method of using chlorophyll concentrations as a tracer may be applied in large areas. Plankton patches are natural drifters and can be tracked by satellites. Thus the color scanner proved its utility in studies of both ocean circulation and biological processes. See also **Space Shuttle**.

The database of the Space Shuttle Earth Observations Project (SSEOP) contains location records and descriptions of over 250,000 of the photographs that the astronauts took of Earth. These photographs show:

1. volcanic eruptions,
2. transatlantic duststorms,
3. continental-scale smoke palls,
4. deforestation grids in the rain forests of Brazil,
5. the bleeding of Madagascar's red soil out the Betsiboka Estuary,
6. plankton blooms tens of miles long,
7. the rise of the Great Salt Lake,
8. the fall of the Aral Sea, and
9. the effects of El Niño from droughts in Australia to floods in California.

For representative pictures of topographical conditions, see Figs. 6, 7 and 8.

Ocean-Atmosphere Specific Satellites. The Remote Ocean Sensing System (NROSS) was a United States Navy program of the early 1990's which was designed to provide information on ocean waves and eddies, as well as research data on surface winds. *TOPEX/Poseidon* was a joint United States-France mission that was launched during the same time period. See Fig. 9. The goal of *TOPEX/Poseidon* was to monitor global ocean circulation over a number of years in order to discover the relationships between the oceans and atmosphere, and improve climate predictions on a global scale. The *TOPEX/Poseidon* satellite remains in operation today. Every 10 days it measures global sea level with unparalleled accuracy. This satellite was designed to carry a high-precision altimeter to measure the topography of the ocean surface, which results from the combined effects of wind, currents, and gravity. *TOPEX/Poseidon's* radar altimeter provided very precise measurements of sea surface heights, and the satellite data indicates that during 1994–95, sea levels increased. Although the data is not conclusive, continued increases in sea levels could worsen the effects of hurricanes and other storms, threatening coastal regions.

The combined data from *NROSS* and *TOPEX/Poseidon* yielded for the first time a comprehensive global description of oceanic circulation. A third and fourth satellite focusing on biology and geodesy, respectively,

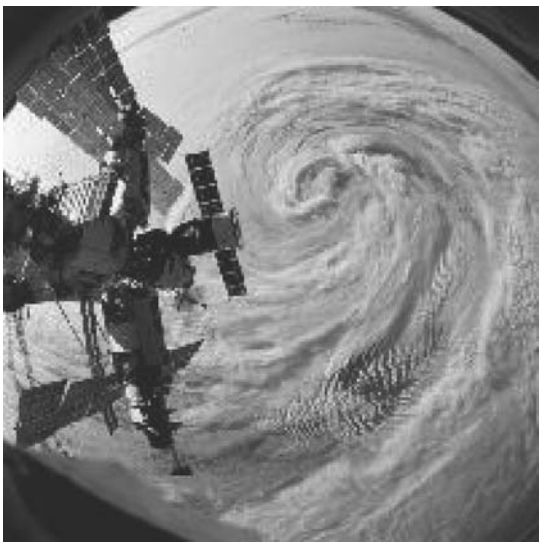

Fig. 6. SSEOP — The Mir over Indian Ocean low pressure system. (*NASA*.)

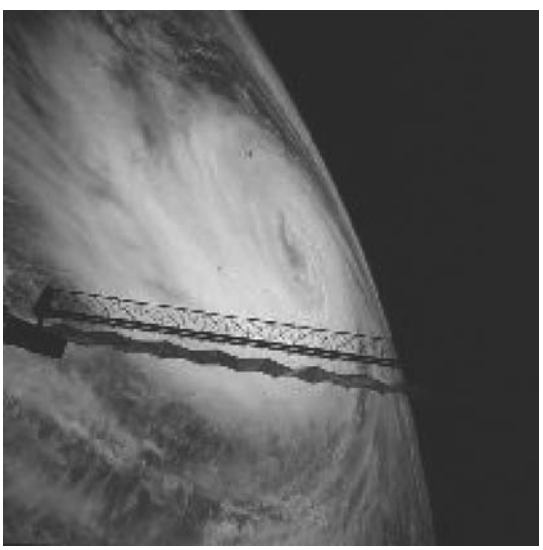

Fig. 7. SSEOP — Typhoon Violet, W. Pacific Ocean. (*NASA*.)

extended these studies. A later satellite, *Seasat*, equipped with synthetic aperture L-band radar, furnished important oceanographic information. See also **Ocean**.

The instrument operated in 2 channels, at approximately 0.5 to 1.1 micrometers (visible and near-infrared) and 10.5 to 12.5 micrometers (infrared), providing measurements of reflected solar energy and equivalent black-body temperatures.

Heat Capacity Mapping. A satellite of the same name (*HCMM*) performed heat capacity mapping. It provided thermal and visible images for mapping the thermal inertia of surface materials. See Figs. 10 and 11. Scientists from severalcountries including Australia, Canada, France, Germany, Italy, Morocco, Spain, Switzerland, and the United Kingdom, participated in investigations involving the *HCMM*. The satellite was used in connection with:

1. Urban heating patterns;
2. Freeze damage assessment with development of planting date advisories;
3. Evapotranspiration rates;
4. Soil moisture assessment
5. Thermal mapping for discrimination of geologic units and energy or mineral resource areas, and evaluation of thermal modeling and satellite mapping techniques;

Fig. 8. SSEOP — North American and Pacific Tectonic Plates: An exceptional southeastward view of the boundary between the North American and Pacific tectonic plates in central California. On the west are the forested Sierra Nevada and the Central Valley, which formed during collision of the two plates about 90 million years ago. The collisional margin evolved to a transform one about 30 million years ago; the San Andreas fault isthe best-known element of that transform fault system. Lake Tahoe and Mono Lake are visible in the eastern Sierra Nevada, beyond which extends the Basin and Range province of stretched continental crust. (*NASA*.)

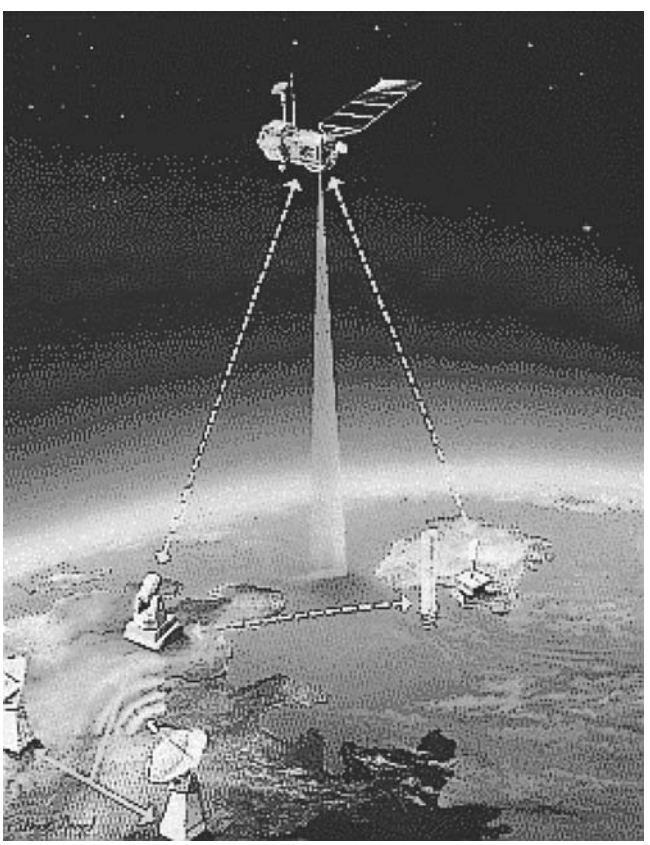

Fig. 9. Mission to Planet Earth (1995) TOPEX/Poseidon is an altimeter-type satellite; the illustration shows how such satellites, working with tide-gauge networks and land-based and orbital geodetic location systems can enable accurate, long-term, continuous monitoring of climate and sea level. (*NASA*.)

6. Detection of high potential groundwater pollution;
7. Studies of snow hydrology programs;
8. Studies of estuarine currents;

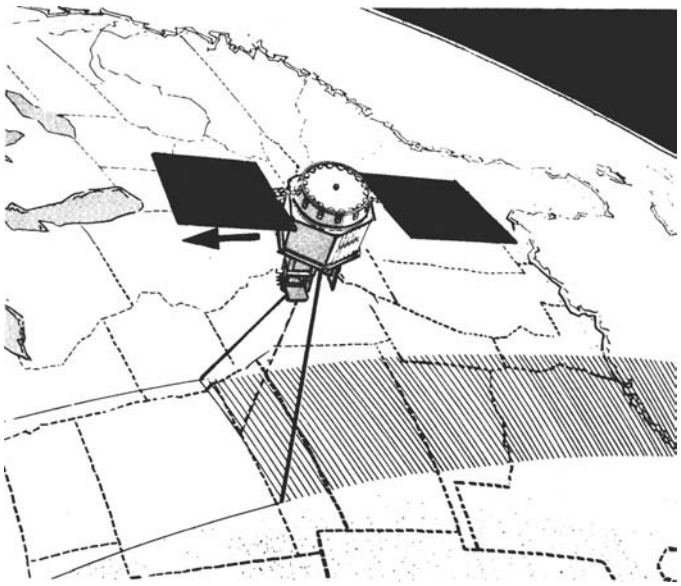

Fig. 10. *HCMM* (Heat Capacity Mapping Mission), the first spacecraft built to test the feasibility of measuring variations in the earth's temperature was launched on April 26, 1978. Purpose of mission–to produce thermal maps for discrimination of rock types, mineral resources, plant temperatures, soil moisture, snow fields, and water runoff. The experimental satellite traveled in a circular, sunsynchronous, 620-kilometer (385-mile) orbit that allowed for measuring mid latitude test areas of the earth's surface for their minimum temperatures and then measuring those same areas for maximum temperatures about 11 hours later. (*National Aeronautics and Space Administration.*)

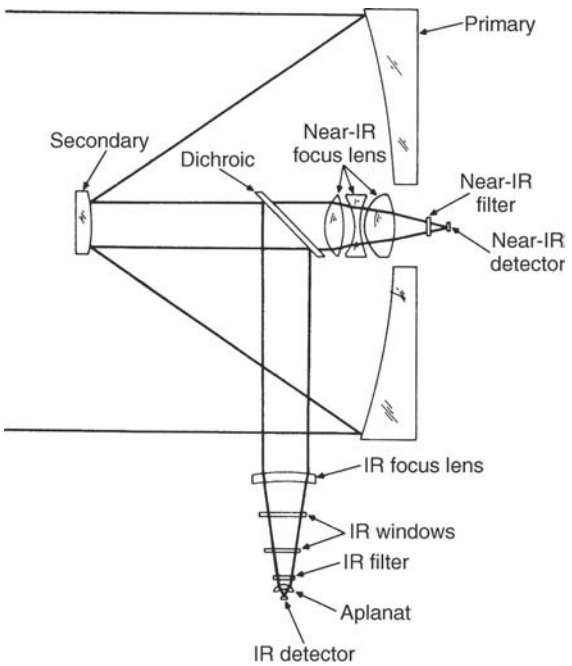

Fig. 11. Optical system of *HCMM* spacecraft. The instrument module was located on the spacecraft so that the Heat Capacity MappingRadiometer (HCMR) was earth-pointing. The base radiometer instrument was a modified spare Surface Composition Mapping Radiometer similar to that flownon Nimbus 5. The HCMR had a small geometric field of view (less than 1 (1 milliradians), high radiometric accuracy, and a wide enough swath coverage on the ground so that selected areas could be covered within the 12-hour period corresponding to maximum and minimum temperatures.

9. Topoclimatological and snow-hydrological survey of various countries, such as Switzerland;
10. Monitoring of large-scale pollution effects in the North Sea among several others.

Earth Radiation Budget Satellite

The *Stratospheric Aerosol and Gas Experiment II* (*SAGE II*) is situated on the Earth Radiation Budget *Satellite* (*ERBS*). The mission objective of the SAGE II instrument is to determine the vertical distribution of stratospheric aerosols, ozone, nitrogen dioxide, and water vapor on a global scale. Specific objectives are:

- To develop a viable, satellite-based, remote sensing technique for measuring stratospheric aerosols, nitrogen dioxide, water vapor, and ozone;
- To utilize these measurements to study global circulation, transient stratospheric phenomena, sources and sinks, and long term trends of individual species;
- To investigate aerosol optical properties from the four wavelength aerosol extinction measurements.

The Mission to Planet Earth/Earth Science Enterprise

The title "Mission to Planet Earth" originated over a decade ago in a report on the U.S. civil space program by a commission led by former astronaut Dr. Sally Ride. The term summarized the concept of looking at Earth as NASA looks at other planets, with a focus on ecosystems. In 1998, the name *Mission to Planet Earth* (*MTPE*) was changed to *Earth Science enterprise* (*ESE*) to signify the long-term commitment by NASA to understanding the global implications of natural and human-induced changes to the environment. The *ESE* effort involves extensive interagency andinternational cooperation. Among the international participants are the U.S./France satellite *TOPEX/Poseidon*, discussed earlier, and the Russian satellite, *Meteor-3*, which carries the *ESE* instrument known as the *Total Ozone Mapping Spectrometer* (*TOMS*). The *ESE* uses satellites and other tools to generate data about the ecosystem of the Earth. *ESE* studies are expected to provide improved weather forecasts, along with tools for managing agriculture and forests (with particular attention to the rain forests), as well as information for the fishing industry and coastal planners.

Upper Atmosphere Research Satellite. The *Upper Atmosphere Research Satellite* (*UARS*) is considered the first major element in NASA's Earth Science enterprise. The *UARS* was deployed from the shuttle Discovery into a 585 kilometer, 57 degree inclination orbit on September 15, 1991. Its mission was to carry out the first systematic, comprehensive study of the stratosphere, as well as to furnish new data on the mesosphere and thermosphere. The Earth's upper atmosphere, beginning only 10–15 kilometers above the surface, remains a frontier largely unexplored from space.

The *UARS* provides simultaneous, coordinated measurements of the internal structure of the atmosphere including trace constituents, physical dynamics, radiative emission, thermal structure, and density. Additionally, the *UARS* provides measurements of the external influences that canact upon the upper atmosphere such as solar radiation, tropospheric conditions, and electric fields. The combination of orbit and instrument design will provide nearly global coverage. See Figs. 12 and 13.

The UARS mission objectives include the study of: Upper atmosphere energy input and loss, Upper atmosphere global photochemistry, Upper atmosphere dynamics, Coupling among these processes, and The coupling between the upper and lower atmosphere.

A significant accomplishment of the *UARS* project was the mapping of an ozone-destroying radical, Chlorine Monoxide (ClO), within the Arctic region. The extent of ClO formation and its close association with polar stratospheric cloud formation was demonstrated. This was an important confirmation of earlier aircraft results, but it also showed the extent of the region with elevated ClO. Since these initial observations, *UARS* has continued to monitor both the late winter-spring ozone depletions in both the Arctic and Antarctic regions. *UARS* data showed that the Northern Hemisphere depletion in January-March 1996 was the largest ever recorded. Data fromthe *UARS* provided conclusive evidence that human-produced chemicals, including chlorofluorocarbons, are breaking down in the stratosphere and causing depletion of ozone over the Antarctic.

Shuttle-Based Tools. The Shuttle-based *Space Radar Laboratory* (*SRL*), which flew two 1994 missions, is another *ESE* tool that enabled an international team of scientists to observe shifting boundaries between temperate

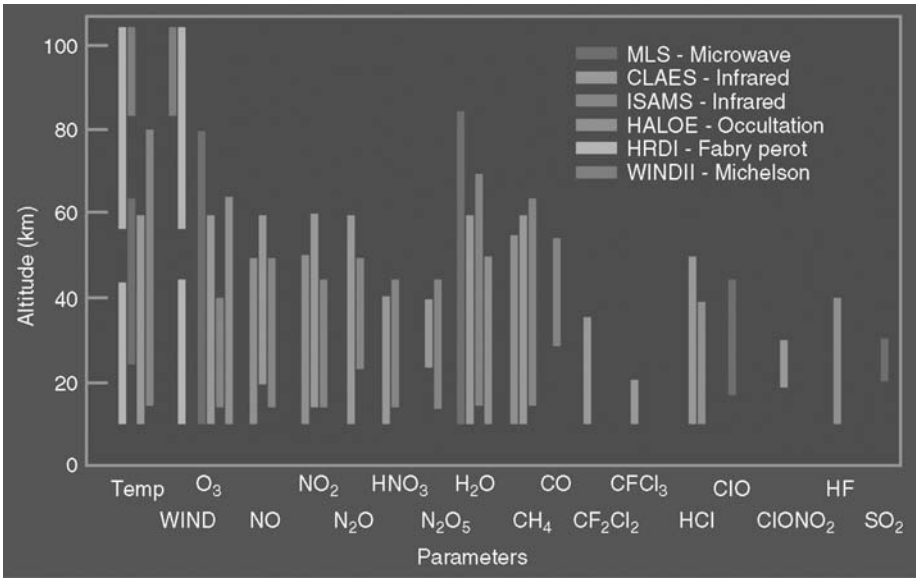

Fig. 12. The Upper Atmosphere Research Satellite (UARS) contains chemistry and dynamics sensors that make measurements of temperature, pressure, wind velocity, and gas species concentrations in the altitude ranges shown in the figure above. (*NASA*.)

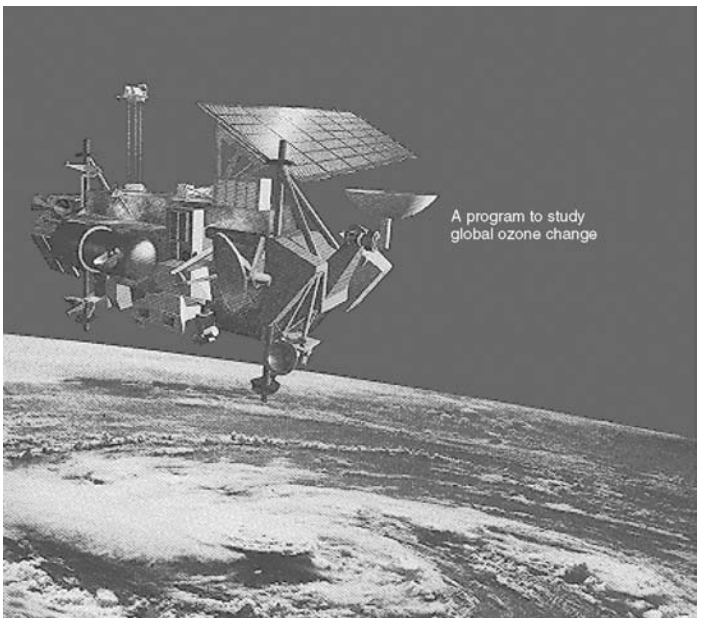

Fig. 13. The Upper Atmosphere Research Satellite (UARS) mission is to study global ozone change. (*NASA*.)

and boreal (northern) forests. These scientists analyzed the observations to study how such changes might affect changes in the climate. Results of the observations and analysis are also being used for map-making, study and interpretation. *SRL* data, along with aircraft and ground data, was also utilized by U.S. and Canadian scientists for the Boreal Ecosystem/Atmosphere Study of northern forests, a large scale investigation into how the forests and the atmosphere interchange energy, heat, water, carbon dioxide and other trace gases.

SeaStar Satellite. Orbital Imaging, a private U.S. company, launched the *SeaStar* satellite carrying the *Sea-viewing Wide Field-of-view Sensor* (*SeaWiFS*), in August 1997. See Fig. 14. The *SeaWiFS project* is animportant part of NASA's *Earth Science enterprise*. Its goal is to obtain quantitative data on global ocean bio-optical properties over a 5-year period to aid researchers in the Earth science community. The *SeaWiFS project* will develop and operate a research data system that will process and distribute data received from an Earth-orbiting ocean color sensor. Subtle changes in ocean color are indicative of the presence of various types and quantities of marine phytoplankton, microscopic marine plants. The measurement of color, and its analysis, will enable researchers to determine the chlorophyll content of the ocean. Ultimately, scientists will be able to assess the productivity of the world's oceans. Goddard Space Flight Center (GSFC) will develop the data processing and archiving and has primary responsibility for the integrity of the final products. See also **SeaStar Satellite**; and **Sea-Viewing Wide Field-of-View Sensor (SeaWiFS)**.

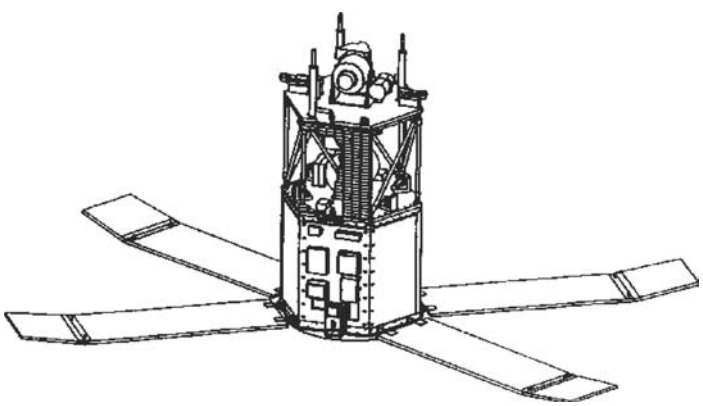

Fig. 14. SeaStar Satellite, with its solar panels deployed, on which the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) ocean color sensor willbe deployed. (*NASA*.)

The *Earth Science enterprise* will be an on-going effort for the foreseeable future as Phase II gets underway in 1999. The *ESE* strivesto understand all earth systems, including its physical, chemical and biological components. To achieve this goal, the comprehensive *Earth Observing System* (*EOS*) is being developed. See Fig. 15. It consistsof sensors being flown on a number of foreign and domestic satellites. *EOS* is the first integrated satellite/surface research system for observing how the Earth's parts (air, water, land and life) interact with each other. The *Earth Sciences enterprise* also includes the *EOS* Data and Information System (EOSDIS) and an active research and analysis program. The existing *Mir space station* complex affords several unique capabilities that will not be available from the *EOS* platforms. The moderate inclination orbit of 51.6 degrees of the *Mir* does not allow for the same global coverage as a polar orbit, but it does permit frequent revisits (approximately 3 days out of 4) to selected sites at mid-latitudes. It is anticipated that the *International Space Station* will provide the same excellent opportunities for earth science study.

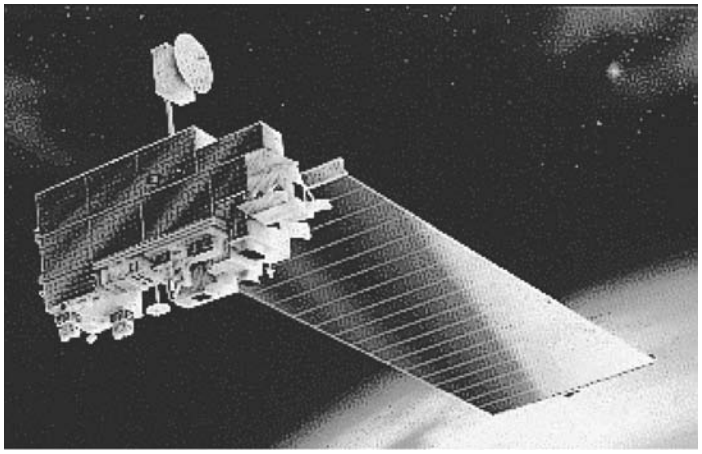

Fig. 15. Phase II of the Mission to Planet Earth, now called Earth Science enterprise, will begin in 1999 with the launch of the first Earth Observing System (EOS) spacecraft, EOS AM-1. (*NASA*.)

SATURATED COMPOUND. See **Organic Chemistry**.

SATURATED EDIBLE OILS. See **Vegetable Oils (Edible)**.

SATURATED VAPOR. A vapor whose temperature corresponds to the boiling temperature at the pressure existing on it. A vapor is saturated when its temperature is a function of its pressure alone. A saturated vapor may be wet or dry; the term does not necessarily imply a wet vapor. A vapor of 100 percent quality, having no superheat, is said to be dry and saturated.

The physical attributes of saturated steam are pressure, temperature, volume, enthalpy, and entropy. These are always given for steam that is dry and saturated, leaving the reader to apply the quality factor when it occurs. The increase of volume on vaporization and the latent heat of evaporation are present in wet steam to the extent of the percent dryness of the steam. One of the important entries in the saturated steam table is that for atmospheric pressure. At 14.7 psi (1 atmosphere) absolute pressure, the saturation temperature of steam is 212 °F (100 °C). The heat contained in it as a boiling liquid is 180 Btu (45.4 kilogram-calories) (above 32 °F (0 °C)), and its latent heat of evaporation is 970.2 Btu/pound (539.1 kilogram-calories/kilogram).

SATURATION. The state of being satisfied, or replete, or the action of bringing about that state. Following are specific uses of this term, some applying to single substance, entity, or region, and others to relations between more than one:

1. The condition in which the partial pressure (i.e., the pressure of a single component of a gaseous mixture, according to Dalton's Law) of any fluid constituent is equal to its maximum possible partial pressure under the existing environmental conditions, such that any increase in the amount of that constituent will initiate within it a change to a more condensed state. In molecular-kinetic terms, saturation is attained when the rate of return of molecules of a substance from the dissolved liquid or vapor phase to the more condensed parent phase is exactly equal to the rate of escape of molecules from the parent phase. In meteorology, the condition in which vapor pressure is equal to the equilibrium vapor pressure over a plane surface of pure liquid water, or sometimes ice.
2. The term applied to the maximum current that will pass through a gas under definite conditions of ionization.
3. The attribute of any color perception possessing a hue, that determines the degree of its difference from the achromatic color perception most resembling it.
4. In a nuclear reactor, the maximum activity obtainable by activation in a definite flux.
5. The maximum magnetization (or the maximum permanent magnetization) of which a body or substance is capable.
6. The process or condition of dissolving in a solvent all of a solute that the solvent can absorb, under equilibrium conditions at a given temperature.
7. The complete neutralization of an acid or base.

SATURATION (Atmospheric). See **Precipitation and Hydrometeors**.

SATURATION CURRENT. The ionization current that results when the applied potential is sufficient to collect all ions; the maximum current that will pass through a gas under definite conditions of ionization. The saturation current is a measure of the charge carried by the ions produced in each second, and hence may be used as a measure of the radioactivity of a substance.

SATURATION DEFICIT. 1. The amount by which the water vapor in the air must be increased to achieve saturation without changing the environmental temperature and pressure. The saturation deficit may be expressed in terms of a vapor pressure deficit, an absolute humidity deficit, or a relative humidity deficit. 2. The physiological saturation deficit: "The difference between the amount of vapor actually present in the air (i.e., the absolute humidity) and amount that saturated air at body temperature contains (viz., about 45 gm per cubic m)."

AMS

SATURATION EQUIVALENT POTENTIAL TEMPERATURE. A thermodynamic variable θ_{es} defined as

$$\theta_{es} = \theta + \left(\frac{L_v \theta}{C_p T}\right)^{r_{sat}}$$

where θ is potential temperature, L_v is the latent heat of vaporization, C_p is specific heat at constant pressure, T is absolute temperature, and r_{sat} is the theoretical value of the saturation mixing ratio of water in air of temperature T at pressure p. Compare with **Equivalent Potential Temperature**; and **Saturation Static Energy**.

AMS

SATURATION LEVEL. The altitude (and its corresponding pressure P_{sat}) to which an air parcel must be lifted dry-adiabatically or lowered moist-adiabatically to be just saturated (100% relative humidity with no liquid water present).

For unsaturated air, this is commonly known as the lifting condensation level. Saturation level is a conserved variable that does not change during adiabatic lifting or lowering of saturated or unsaturated air and can thus be used as a tracer for that air parcel. When paired with the corresponding saturation air temperature at that altitude, the result is a saturation point that can be represented on a thermodynamic diagram.

AMS

SATURATION MIXING RATIO. A thermodynamic function of state; the value of the mixing ratio of saturated air at the given temperature and pressure. This value may be read directly from a thermodynamic diagram. Without specific qualification, the saturation mixing ratio refers to saturation with respect to a plane surface of pure water. Saturation mixing ratios may also be specified with respect to a plane ice surface.

See also **Thermodynamic Diagram**.

AMS

SATURATION POINT. A point on a thermodynamic diagram representing the state of the air defined by a pair of variables: P_{sat} and T_{sat}, where P_{sat} is the saturation pressure and T_{sat} is the saturation temperature. These latter variables are the pressure and temperature of an air parcel that was raised dry-adiabatically or lowered moist-adiabatically until it was just at saturation. The saturation point is a conserved variable for adiabatic motion and thus serves as a tracer for the air parcel on a thermodynamic diagram.

See also **Thermodynamic Diagram**.

AMS

SATURATION STATIC ENERGY. A thermodynamic variable s_{es} defined as

$$s_{es} = C_p T + gz + L_v r_{sat}$$

where g is gravitational acceleration, z is height above some reference level (often taken as the height where the pressure is 100 kPa), L_v is the latent heat of vaporization, C_p is specific heat at constant pressure, T is absolute temperature, and r_{sat} is the theoretical value of saturation mixing ratio of water in air of temperature T at pressure p.

AMS

SATURATION VAPOR PRESSURE. 1. The vapor pressure of a system, at a given temperature, for which the vapor of a substance is in equilibrium with a plane surface of that substance's pure liquid or solid phase; that is, the vapor pressure of a system that has attained saturation but not supersaturation. The saturation vapor pressure of any pure substance, with respect to a specified parent phase, is an intrinsic property of that substance, and is a function of temperature alone. For water vapor, the saturation pressure over supercooled liquid differs appreciably from that over ice. 2. Same as equilibrium vapor pressure. See also **Equilibrium Vapor Pressure**.

AMS

SATURN. Sixth planet from the Sun, Saturn is unique in the solar system in that it is the only planet lighter than water, with a density of about 0.7 gram per cubic centimeter. Saturn is the second largest planet in the solar system, with a volume 815 times that of Earth, but with a mass only 95.2 times greater. Like Jupiter, Saturn's rapid rotation has caused the planet to be flattened at its poles. The equatorial radius is 60,330 kilometers (37,490 miles), while the polar radius is smaller — 54,000 kilometers (33,554 miles). The surface gravity of Saturn is 1.14 (Earth = 1.0). Saturn requires 29.46 Earth-years to complete one orbit around the Sun. Although a Saturnian year is long, its days are short, lasting only 10 hours, 39 minutes, 24 seconds, as first determined by *Voyager 1* and later reconfirmed by *Voyager 2*. See also **Voyager Missions to Jupiter and Saturn**.

In its slow orbit around the Sun, Saturn is perturbed by the other planets, notably Jupiter, so that its orbital path is not strictly elliptical. The planet wavers in its distance from the Sun in a region of between 9.0 AU and 10.1 AU. (One AU or astronomical unit equals distance from Sun to Earth, i.e., 149,597,860 kilometers; 92,955,806.8 miles.)

Saturn receives only about one-hundredth as much sunlight as is received by Earth. Like the three other gas giants (Jupiter, Neptune, and Uranus), Saturn does not have a solid surface comparable to that found on the terrestrial planets. Rather, it is a huge, multilayered globe of gases, notably a mixture of about 11% (mass) of helium, with nearly all the rest being hydrogen. There may be a small core predominantly of iron and rocky material. Gravity field analyses and temperature-profile measurements suggest that Saturn's core may extend out from the center by about 13,800 kilometers (8,575 miles), making it twice the size of Earth, but extremely small in relation to the huge size of the planet. It has been estimated that the core is probably so compressed that it may contain from 15 to 20 times the mass of Earth. It has been postulated that a layer of electrically conductive metallic hydrogen may surround the core. This form of hydrogen has not been observed on Earth because of the immense pressure required to produce it. The interaction between this inner atmosphere and the outer layers (hydrogen and helium) may explain Saturn's emission of heat. Both Saturn and Jupiter release about twice the amount of energy they receive from the Sun. But scientists observe that the two planets probably produce their energy in different ways. Whereas it is postulated that Jupiter emits energy left over from the gravitational contraction that occurred when the planet was formed (estimated about 4.6 billion years ago), it is suggested that Saturn's heat production may be the result of the separation of hydrogen and helium in the outer layer, with heavier helium sinking through the planet's liquid hydrogen interior. Other statistics are given in the entry on **Planets and the Solar System**. See Figs. 1, 2, and 3.

Missions to Saturn. To date, the environs of Saturn have been explored by three U.S. spacecraft, and by the Hubble Space Telescope, as described in the next several paragraphs. Most of the progress made during the past several years has been the analysis of massive amounts of data sent back to Earth from the Hubble Space Telescope and the former missions.

Saturn has been a frequent target of the Hubble Space Telescope, which has produced stunning views of long-lived hurricane-like storms in Saturn's atmosphere. The world's major telescopes, including Hubble, were recently trained on Saturn to observe the phenomenon known to astronomers as a Saturn ring plane crossing. The rings seen edge-on from the Earth's perspective on May 22, 1995, August 10, 1995, and February 11, 1996. Ring plane crossings provide astronomers with unique views of the Saturnian system. The Hubble Space Telescope more recently discovered "Great White Spot" that appears to be representative of periodic disturbances in the planet's atmosphere. This is described toward the end of this article. Considerable research from Earth also has gone forward with microwave radar imaging and is discussed later. See also **Hubble Space Telescope (HST)**.

The latest mission to Saturn and the most ambitious effort in planetary space exploration ever mounted. The *Cassini* spacecraft, was launched from Cape Canaveral, Florida, USA on October 15, 1997. *Cassini* is an international mission resulting from the joint efforts of NASA, the European Space Agency (ESA) and the Italian Space Agency, Agenzia Spaziale Italiana (ASI). *Cassini* is sending a sophisticated robotic spacecraft to orbit the ringed planet and study the Saturnian system. *Cassini*

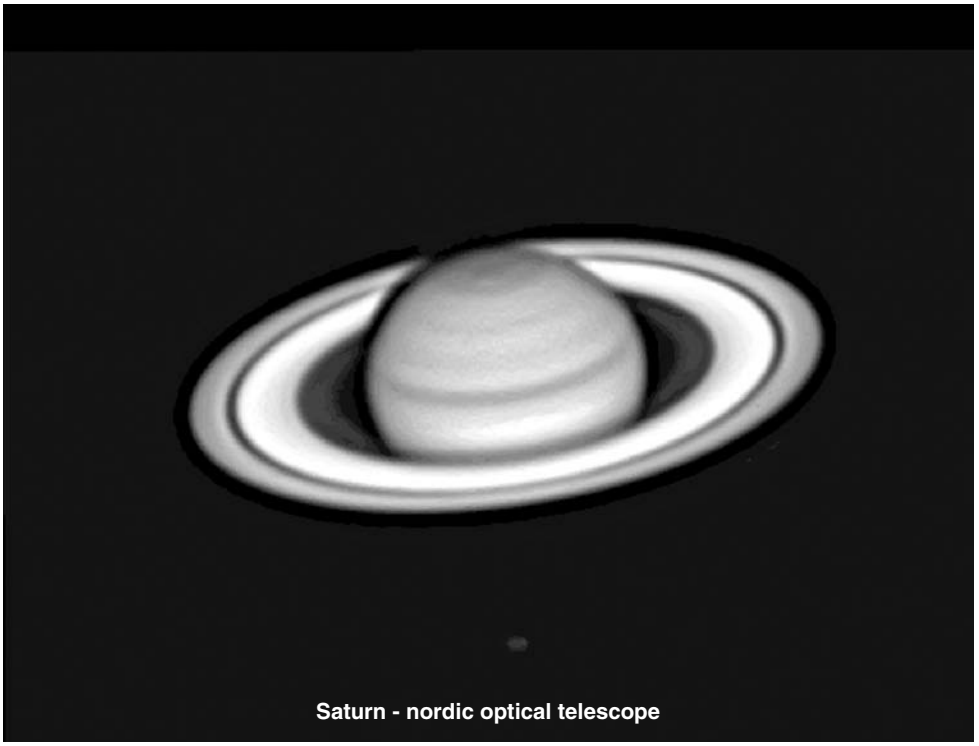

Fig. 1. View of Saturn as seen with an Earth-based telescope (100 inch; 254 centimeters). (*Jet Propulsion Laboratory, National Aeronautics And Space Administration*.)

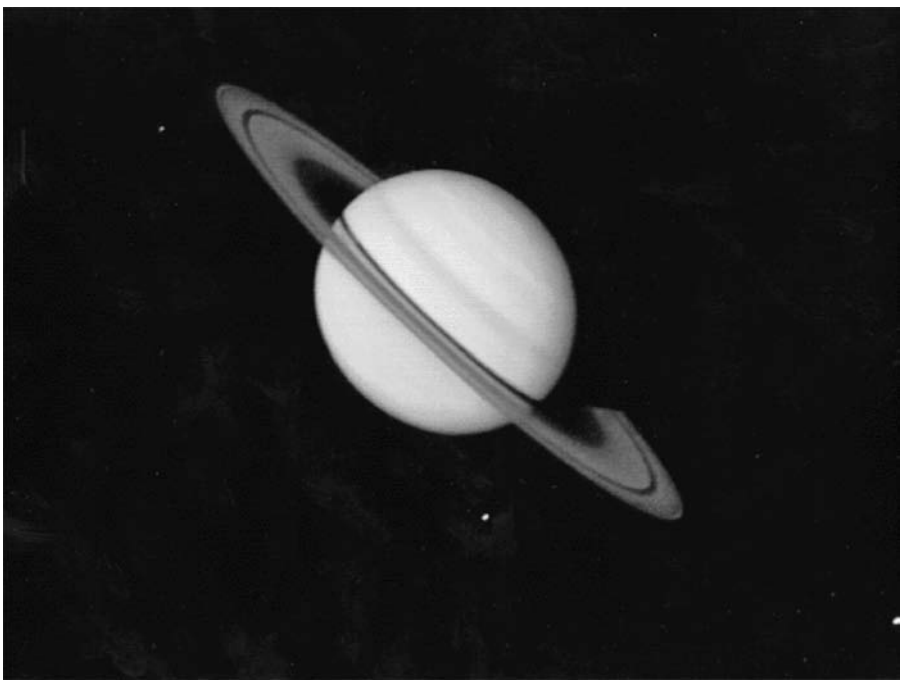

Fig. 2. Image of Saturn showing three of its moons, Enceladus, Dione, and Tethys, that was taken by Voyager 1 on July 24, 1980 from a distance of 106 million kilometers (63.6 million miles). North is at 1 : 30. Bands can be seen in the Northern Hemisphere and structure can be identified in the rings, including the Cassini Division, toward the outer edge of the rings. The satellites, which can be seen in this image, are Enceladus, near the left edge of the rings, Dione, below Saturn, and Tethys, at the right edge of the frame. Saturn is 120,000 kilometers (72,000 miles) in diameter. (*Jet Propulsion Laboratory, National Aeronautics And Space Administration*.)

successfully performed a flyby of the planet Venus on April 26, 1998 coming about 284 kilometers (176 miles) from the Venusian surface. The flyby gave the *Cassini* spacecraft a boost in speed of about 7 kilometers per second (about 4 miles per second), which will help the spacecraft reach the planet Saturn as projected in July 2004. In its long trajectory to Saturn, *Cassini* will perform another flyby of Venus in June 1999, one of Earth in August 1999, and one of Jupiter in the year 2000. All of the flybys impart more speed to the spacecraft, which will enable it to reach its final destination of the Saturnian system. This flight pattern is referred to as a VVEJGA (Venus-Venus-Earth-Jupiter Gravity Assist) trajectory. It is anticipated that *Cassini* will enter orbit around Saturn in 2004 and remain in orbit for a minimum of four years. The goal of the *Cassini* mission primarily consists of delivering *Huygens*, a scientific probe, to Titan, Saturn's largest moon, and then remaining in orbit around Saturn

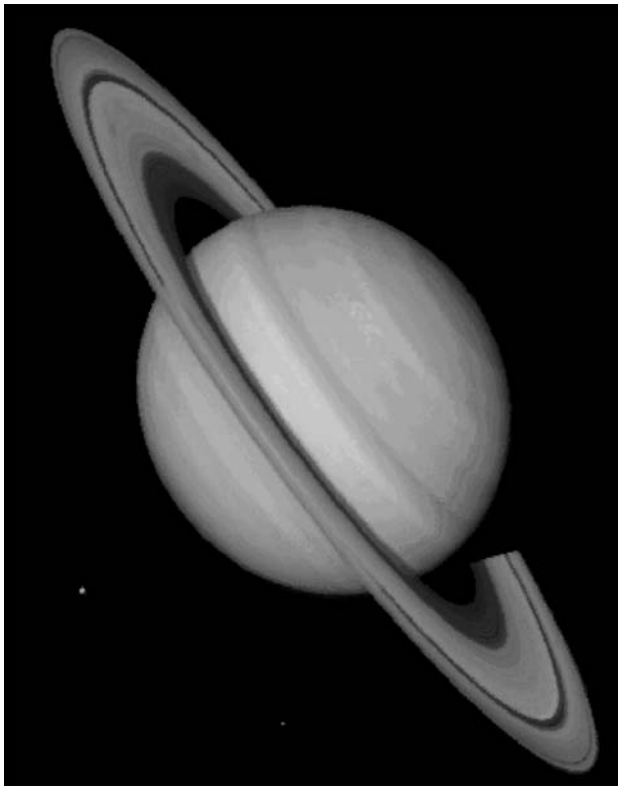

Fig. 3. Several dark spoke-like features can be seen across the broad B ring (left of planet). The moons Rhea and Dione appear as dots below and below left of Saturn, respectively. This photo was taken July 21, 1981, when *Voyager 2* was 33.9 million kilometers (21 million miles) from the planet. The spacecraft made its closest approach to Saturn on August 25, 1981. (*Jet Propulsion Laboratory, National Aeronautics And Space Administration*.)

to conduct detailed studies of the planet and its rings and satellites. The principal objectives are to:

1. determine the three-dimensional structure and dynamical behavior of the rings;
2. determine the composition of the satellite surfaces and the geological history of each object;
3. determine the nature and origin of the dark material on Iapetus' leading hemisphere;
4. measure the three-dimensional structure and dynamical behavior of the magnetosphere;
5. study the dynamical behavior of Saturn's atmosphere at cloud level;
6. study the time variability of Titan's clouds and hazes; and,
7. characterize Titan's surface on a regional scale.

Cassini's instrumentation consists of: a composite infrared spectrometer, a CCD imaging system, a cosmic dust analyzer, a magnetospheric imaging instrument, an ion/neutral mass spectrometer, a magnetometer, a plasma spectrometer, a radar mapper, a radio and plasma wave experiment, an ultraviolet imaging spectrograph, and a visible/infrared mapping spectrometer. Telemetry from the communications antenna and other special transmitters will be used to make observations of the atmospheres of Titan and Saturn. They will also be used to measure the gravity fields of the planet Saturn and its satellites. See also **Cassini Mission to Saturn**.

Past U.S. missions to Saturn include:

(1) *Pioneer 11*, in 1979, flew past the planet and on September 5 of that year, scientists reported the discovery of Saturn's 11th moon orbiting the planet and two more rings of debris encircling the planet. The space probe swept within 13,000 miles (20,917 kilometers) of the planet and then flew by Titan, Saturn's largest moon. Scientists had feared that the spacecraft would be damaged by some of the debris around the planet, but *Pioneer 11* passed through several potential trouble spots unharmed and beamed back

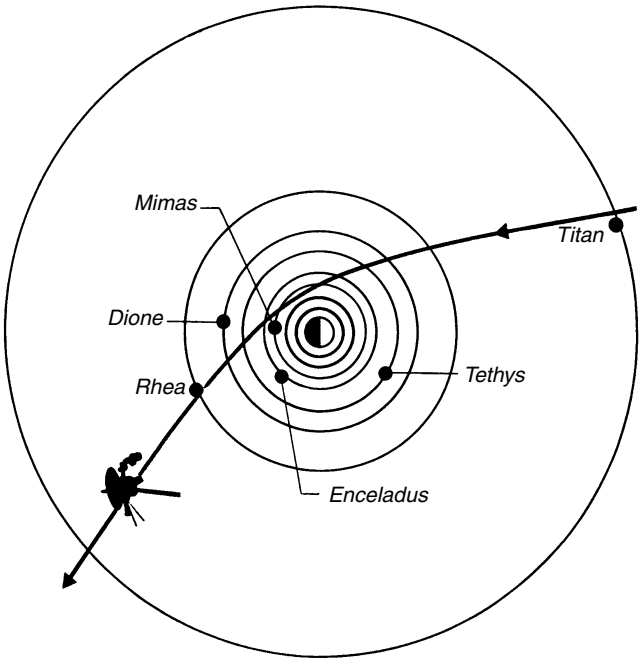

Fig. 4. Trek of *Voyager I* as it swept past Saturn in the fall of 1980. (*Jet Propulsion Laboratory*.)

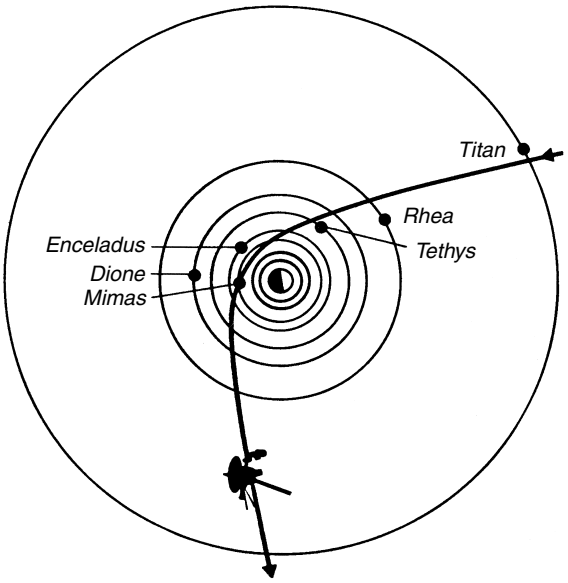

Fig. 5. Trek of *Voyager 2* as it swept past Saturn in late-summer of 1981. (*Jet Propulsion Laboratory*.)

a wealth of data to Earth. Much of the information supported the image of Saturn as had been previously determined by Earth-based observations.

(2) *Voyager 1*, in the fall of 1980, viewed the planet after the spacecraft had visited Jupiter early in the spring of 1979. Early pictures of the planet taken during the summer of 1980, as the spacecraft approached Saturn, were almost featureless with exception of the three classic rings that had been studied for years from Earth. As *Voyager 1* approached more closely, it appeared that there were not just three rings, but scores, then hundreds, and finally thousands of thin ringlets. It would turn out that they were not individual rings separated by gaps; some of the variations were caused by the gravitational attraction of nearby satellites pulling millions of particles into motion, spiraling outward across the rings like waves in an ocean. The photos from *Voyager 1* also revealed other puzzling phenomena — dark features that resembled spokes in the bright B-ring. As *Voyager 1* zeroed in on Saturn, more satellites were seen, until a total of six had been found — three from Earth observations and three by *Voyager*. Two

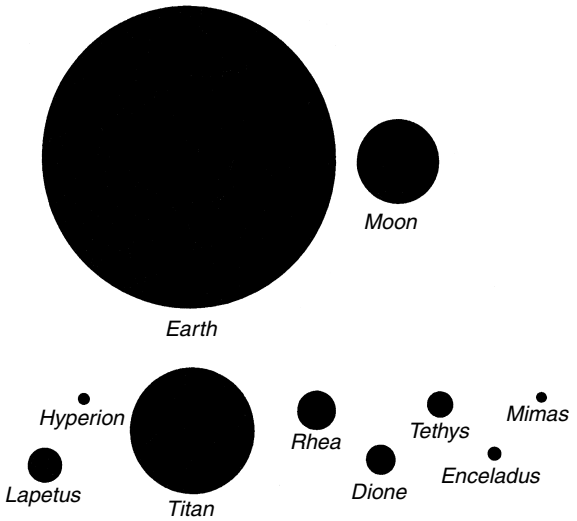

Fig. 6. Size comparison (diameter) of Saturn's major satellites with Earth and its moon. (*Jet Propulsion Laboratory*.)

that were discovered in *Voyager* images appeared to shepherd the narrow F-ring. Two more, discovered from Earth, had appeared to share the same orbit. Inspection of *Voyager* photos, however, showed that the satellites' orbits are about 31 miles (50 kilometers) apart. A little more calculation yielded the astonishing prediction that, as the two satellites approached each other in January 1982, they would trade orbits and continue on their way, to resume their game of "musical chairs" the next time they approached. A day before *Voyager 1* swept by Saturn, it flew within 2500 miles (4000 km) of the huge satellite Titan and passed directly behind it, making what scientists had predicted would be extremely important observations. Titan was shrouded by a thick, opaque haze that completely obscured its surface from the cameras. But the infrared instrument and the spacecraft radio probed the atmosphere to measure the diameter of the satellite and the thickness, temperature, and composition of its atmosphere. Once beyond Titan, *Voyager 1* flew past Saturn and briefly disappeared behind it. En route to the Earth, the radio signals penetrated Saturn's atmosphere and passed through the rings. Measurements of the way the atmosphere altered the signals, and the rings scattered them, would tell much about the atmosphere and help determine the sizes of particles that make up the rings. *Voyager 1* swept past its targets and took a new course upward from the plane in which the planets orbit the Sun, outward toward the edge of the solar system. Its cameras and its UV and IR instruments were turned off, but other instruments still probe for galactic cosmic rays, the edge of the solar system, and the beginning of interstellar space. The trek of *Voyager 1* is depicted in Fig. 4.

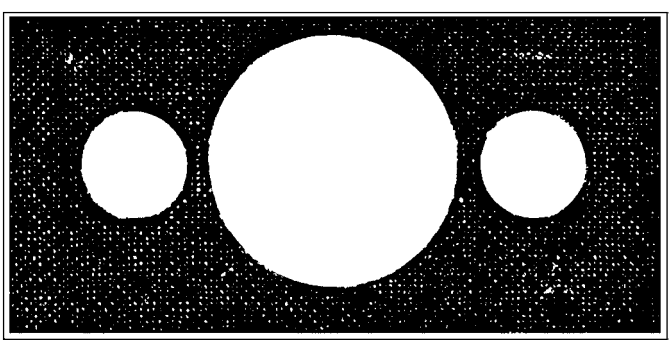

Fig. 7. Sketch of Saturn by Galileo (1610). When Galileo first focused his telescope on Saturn, he realized that the appearance of the planet was unusual, but he did not ascertain its real character because the power of his telescope was far too low. He believed he was looking at three globes, one large and two small, which seemed to change slowly in appearance. In 1655, Huygens, after years of observing the planet, finally realized that these projections were actually a flat ring slightly separated from the main globe.

(3) *Voyager 2*, in late summer 1981, made it possible to view Saturn for a second time. Having had an opportunity to study the images taken by *Voyager 1*, scientists decided to arrange the second encounter for a closer study of the planet's rings and its satellites, other than Titan. As the summer of 1981 approached, scientists, having gained experience from *Voyager 1*, were able to set their camera exposures at more exact levels, to cope with the low light levels and the general blandness of Saturn. On this approach, Saturn presented alternating dark and bright bands of clouds and high-speed jet streams. Swirling cloud patterns, which were smaller versions of the large and intense storms seen on Jupiter, were also visible through Saturn's haze layer. *Voyager 2's* cameras zeroed in on the rings, and scientists searched for small satellites in the rings that might cause the multi-ringed appearance. Those moonlets, some scientists believed, might sweep up material in the rings, creating gaps. *Voyager 2* would soar closer to the rings, and the improved resolution of the pictures should show structures as small as 0.6 mile (1 km) in diameter. One of *Voyager's* most important experiments involved an instrument called a photopolarimeter, which measures light intensity. As *Voyager 2* passed above Saturn, the photopolarimeter detected changes in the starlight's intensity as it was altered by changes in the thickness of the rings. Quick analysis of data showed that the rings' structure was far different from what it appeared to be in the photos.

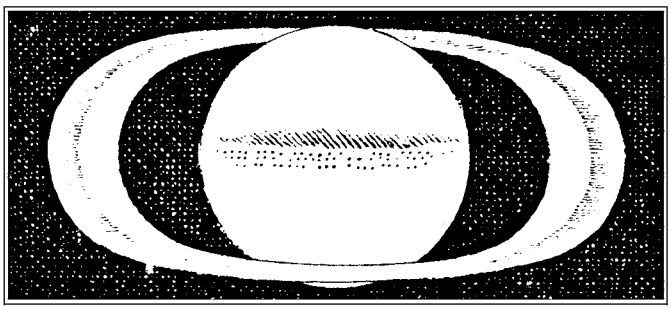

Fig. 8. Sketch of Saturn by Cassini (1675). Cassini found the first breach in the supposedly solid, rigid, and opaque ring when he discovered that it was divided into two parts by a dark line, now known as Cassini's division. In later years, Cassini also detected some of Saturn's moons. The earliest successful photograph of Saturn was taken in 1883 by Andrew Common. In 1895, James Keeler suggested that the rings are in fact a swarm of particles in near-independent orbits.

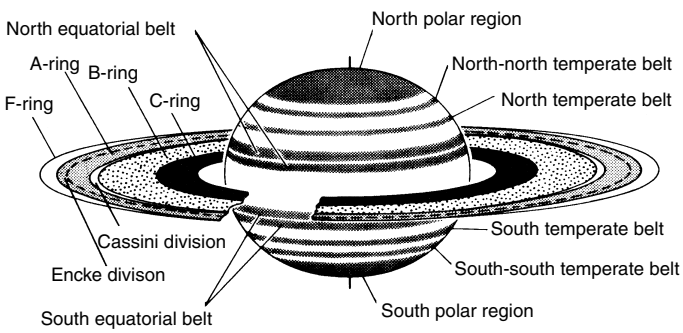

Fig. 9. Principal visual features of Saturn.

No region was totally empty of ring particles. The members of the photopolarimeter team have 800,000 samples, each one a 330-foot (100-meter) slice of the rings. Years will be required to complete this analysis. *Voyager 2* also photographed and measured all of the planet's satellites that were then known, a number that had expanded to 17. Upon completion of the sweep by Saturn, *Voyager 2* proceeded on toward Uranus and Neptune. See separate articles on these planets. The trek of *Voyager 2* past Saturn is depicted in Fig. 5.

Highlights of Voyager's Scientific Findings. After studying the volumes of data returned by the two *Voyager* spacecraft, although analyses are still in progress, scientists at NASA (National Aeronautics and Space Administration), and Jet Propulsion Laboratory (JPL), with over 30,000 photos of the Saturn system, have selected the following highlights:

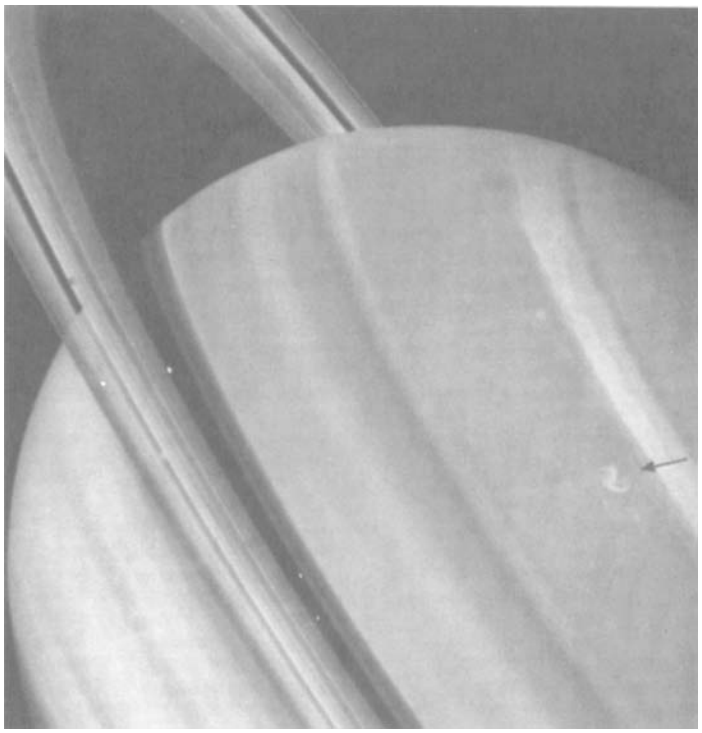

Fig. 10. View of Saturn and its ring system returned by *Voyager 2* on August 11, 1981 when the spacecraft was 13.9 million kilometers (8.6 million miles) away from the planet and approaching it at about 1 million kilometers (620,000 miles) per day. The ring system's shadow is clearly cast in the equatorial region. Storm clouds and small-scale spots in the mid-latitudes are apparent. The so-called "ribbonlike" feature in the white cloud band marks a high-velocity jet at about 47°N. At this location, the westerly wind speeds are about 150 meters per second (330 miles per hour). The banding on Saturn extends toward both poles. (*Jet Propulsion Laboratory*.)

1. There is less helium in the top of Saturn's atmosphere than in Jupiter's.
2. Subdued contrasts and color differences (Jupiter and Saturn) are primarily a result of either more horizontal mixing or less production of localized colors on Saturn than on Jupiter.
3. Winds blow at extremely high speeds on Saturn. Near the equator, the *Voyagers* measured winds of about 500 meters per second (1100 miles per hour). The winds blow primarily in an eastward direction.
4. The Voyagers found aurora like ultraviolet emissions at mid latitudes on Saturn, and auroras at higher latitudes.
5. The *Voyagers* discovered radio emissions from the planet with which they determined the length of Saturn's day to be 10 hours, 39 minutes, 24 seconds.
6. The complicated structure in Saturn's rings appears to be caused, at least in part, by density waves, which are created by gravitational interactions with several of the inner satellites. Few clear gaps exist anywhere in the rings.
7. Radial, spoke-like features were discovered in the rings and remain poorly understood.
8. Titan, Saturn's largest satellite, has an atmosphere composed of nitrogen, methane, and several organic compounds, including hydrogen cyanide.
9. Titan's surface atmospheric pressure is 1.6 bars (60% greater than the surface pressure on Earth).
10. The temperature at the surface of Titan is 95 K (−288°F; ∼−172°C). Methane, therefore, possibly plays much the same role on Titan as water does on Earth.
11. Saturn's regular satellites appear to be composed primarily of ice. Phoebe, the outermost, is believed to be a captured asteroid.
12. Many new satellites have been discovered at Saturn, some from Earth-based observations, others by the two *Voyagers*. There may be over twenty. Scientists expect to find more. As indicated by Fig. 6, Saturn's satellites, with exception of the huge Titan, are smaller than Earth's moon.
13. The size of Saturn's magnetosphere, like Jupiter's, is controlled by external pressure of the solar wind.

More details of some of the foregoing observations are developed in this article.

Observations of Saturn by Early Astronomers. To the naked eye, Saturn appears like one of the brighter stars, but with the absence of twinkling. In a telescope, the planet itself has a belted appearance quite similar to that of Jupiter, but without as many distinctive surface features as are seen on the larger planet. Although Galileo realized that the planet had some unusual features, he did not live to know that what he saw was a ring system. Galileo's sketch, made in 1610, is shown in Fig. 7. Huygens first described the rings with reasonable accuracy for this period in 1650. Cassini, by 1675, identified a ring system that was divided into two parts by a dark line (now known as the *Cassini division*). Cassini also noted some belt or zone demarcations, as indicated by his sketch shown in Fig. 8. The first successful photo of Saturn, clearly showing the ring system, was not made until 1883. In 1895, Keller suggested that the rings were a swarm of particles in nearly independent orbits. Bond, in the late 1800s, found a second division of the rings and a third or "crepe" ring close to the planet itself.

Atmosphere of Saturn

Saturn has cloud bands similar to those of Jupiter, although they are more difficult to see and contrast less with the planetary disk. Images of Saturn confirm its rather bland appearance. The blandness may be a result of lower temperatures and reduced chemical and meteorological activity compared with Jupiter; or the presence of a relatively permanent and uniform high-altitude haze. As shown by Fig. 9, the principal features of Saturn's visible surface are stripes that parallel the equator. There are dark belts and light zones that have been seen continuously over two centuries of observation. Although *Voyager 1* saw only a few markings, *Voyager 2* saw many, including long-lived ovals, tilted features in east-west shear zones and others similar to, but smaller than, the features on Jupiter. One white oval on Saturn was noted to be 7000 by 5000 kilometers (4000 by 3000 miles), with a 100-meter-per-second (200-mile-per-hour) circumferential wind. See Fig. 10. Winds appear to blow at extremely high speeds on Saturn. Near the equator, the *Voyagers* measured winds about 500 meters per second (1100 miles per hour). The winds blow primarily in an easterly direction. The strongest winds are found near the equator, and velocity falls off uniformly at higher latitudes. At latitudes greater than 35°, the winds alternate eastward and westward as the latitude increases. The marked dominance of eastward jet streams indicates that winds are not confined to the cloud layer, but must extend inward at least 2000 kilometers (1240 miles). Furthermore, measurements by *Voyager 2* showing a striking north-south symmetry has led some scientists to suggest that the winds may extend from north to south clear through the interior of the planet.

When *Voyager 2* flew behind Saturn, its radio beam penetrated Saturn's atmosphere, measuring the upper-atmosphere temperature and density. Minimum temperatures of about 82 Kelvin (−312°F; −191°C) were measured at the 70-millibar level (surface pressure on Earth is about 1000 millibars). The temperature increased to 143 K (−202°F; −130°C) at the deepest levels probed — about 1200 millibars. Temperatures near the north pole were about 10°C (18°F) colder at the 100-millibar level than temperatures at mid-latitudes. Scientists believe the difference may be a seasonal effect.

The *Voyagers* found auroralike ultraviolet emissions of hydrogen at mid-latitudes (above 65°). Scientists have suggested the high-latitude auroral activity leads to formation of complex hydrocarbon molecules that are carried toward the equator. The mid-latitude auroras, which normally

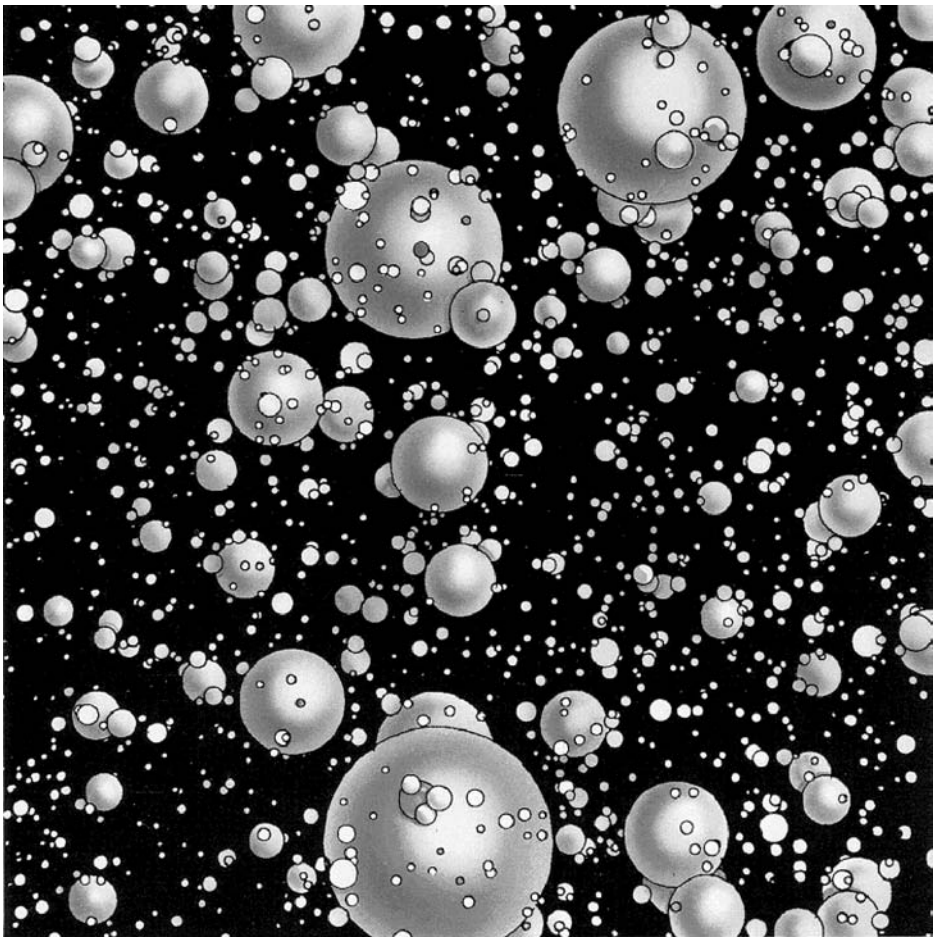

Fig. 11. A computer-simulated view of particles ranging in size from marbles to beach balls, populating a 3 meter (10 foot) square section of Saturn's A Ring. This picture was constructed to illustrate the size distribution of ring particles based on Voyager Radio Science occultation data. In reality the particles are not smooth spheres, but their depiction here as spheres is representative of the properties often assumed (implicitly or explicitly) in mathematical models of the rings. (*NASA*.)

Fig. 12. This enhanced color image shows the outer half of Saturn's main ring system. The dark Cassini Division near the middle divides the outer A Ring from the B Ring. The Cassini Division was once thought to be empty, but this view shows that it contains several fainter ring structures. The most prominent structure in the A Ring is the Encke Gap, about one-third of the way from the ring's outer edge. This gap is "shepherded" open by the tiny embedded moon Pan. The B Ring is more densely packed with material than the A Ring (i.e., higher in optical depth) so it shows up as brighter in this image at a low phase angle. Several faint "spokes" are visible as dark streaks across the B Ring. At lower right, you can see the outer tip of the much fainter C Ring. (*NASA*.)

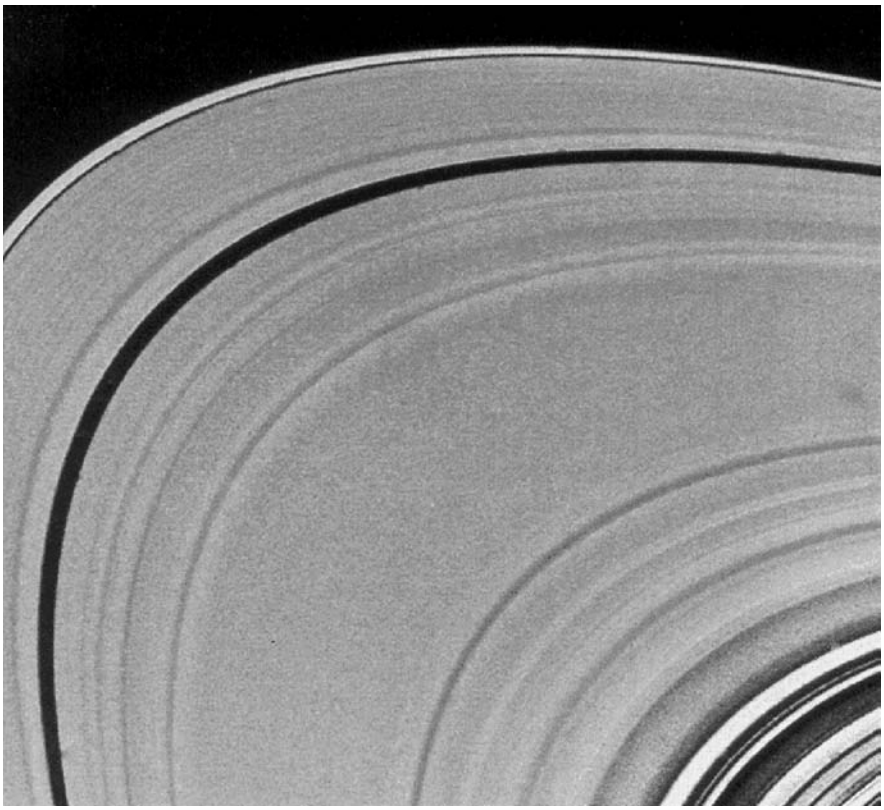

Fig. 13. Saturn's outer A Ring in false color, constructed from Voyager 2 green, violet, and ultraviolet frames. The Cassini Division (lower right) is distinctly less red than the A Ring. Also visible, as a sequence of dark features in the outermost A Ring, is a series of orbital resonances with Saturn's inner moons. The 325 kilometer (195 mile) wide Encke Division (upper left center) contains the tiny moon Pan. However, the cause of the narrower Keeler Gap (closer to the outer edge of the A Ring) and the gaps in the Cassini Division is not known. (*NASA*.)

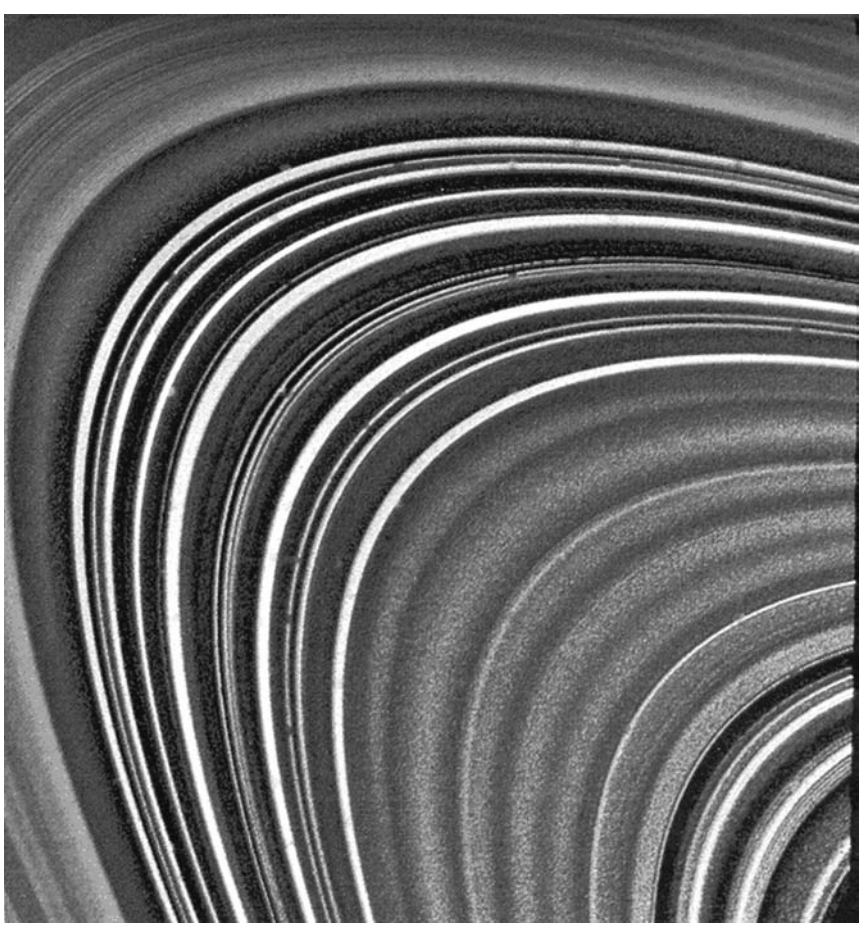

Fig. 14. The outer part of Saturn's C Ring (blue) and the inner part of the B Ring (yellow) are shown here in false color. The color difference blurs over the boundary between the rings. The Maxwell Gap and its eccentric ringlet, which appears yellow due to image misalignment, are in the left center of this frame. (*NASA*.)

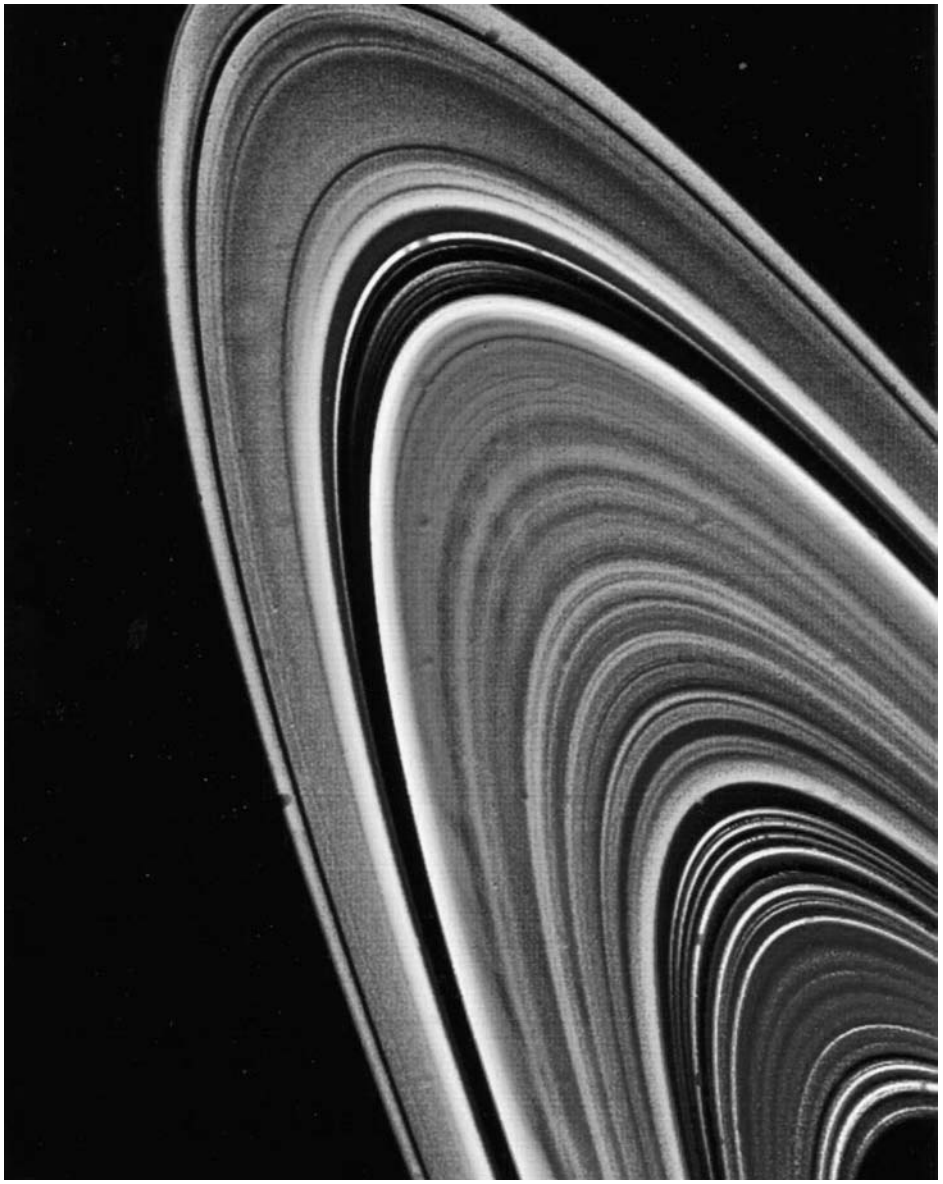

Fig. 15. To illustrate the chemistry of the rings, this highly enhanced false color view of Saturn's rings was assembled from clear, orange and ultraviolet images. Possible variations in chemical composition from one part of Saturn's ring system to another are visible as subtle color variations. In addition to the previously known blue color of the C Ring and the Cassini Division, the picture shows additional color differences (red-green) within and between the A and B Rings. The distance to Saturn was 8.9 million kilometers (5.5 million miles). (*NASA*.)

occur only in sunlit regions, remain a puzzle; bombardment by electrons and ions, known to cause auroras on Earth, occurs primarily at high latitudes.

Saturn's Ring System

The alphabetical letter designations of Saturn's rings (Fig. 9) are based upon the chronology of discovery. The letters do not consistently relate to their positions relative to the planet. The A ring is the outermost ring visible with small telescopes. The B ring, the brightest ring, lies inside the A ring and is separated from it by Cassini's division. The C ring, barely visible with small telescopes, lies inside the B ring. The Cassini division between the B and A rings is the most prominent gap between the rings and is easily visible with Earth-based telescopes. A thin space within the outermost edge of the A ring is the Encke division. This was first identified by *Pioneer* spacecraft. The average thickness of the rings is estimated at no greater than 16 kilometers (10 miles).

Perhaps the greatest surprises and the most perplexing puzzles encountered by the *Voyagers* are the rings. *Voyager 1* found a great deal of unexpected structure in the classical A, B, and C rings. One suggestion was that the structure might be unresolved ringlets and gaps. Ring photos by *Voyager 1* were of lower resolution than those of *Voyager 2*, and scientists at first suggested that gaps might be created by tiny satellites orbiting within the rings and sweeping out bands of particles. One such large gap was detected at the inner edge of the Cassini division.

Cameras and instruments of much greater resolution than used in the past will be required on future missions to glean greater information pertaining to the variety and characteristics of particles actually making up what appears to be hundreds of thousands of rings. As some scientists believed, *Voyager* observations no longer support the concept that the gravity of small moonlets within the rings channel the trillions of ice chunks that compose the rings into so many narrow traffic lanes. The only moonlets of this nature detected were the "shepherds" discovered by *Voyager 1* which appear to maintain the thin outer F ring in place. As pointed out by Loudon (1981), there is more matter associated with the rings than would be expected from data that are converted into photographs. As the *Voyager 2* streaked through the ring system's thin 500-foot (150-meter) thick outer extension at a relative speed of 8 miles (13 kilometers) per second, the craft was bombarded by thousands of dust-sized particles not for 500 feet, but for about 1000 miles (1600 kilometers).

As observed by the Stanford University radio science team when *Voyager 1* passed behind Saturn and a radio signal was beamed to Earth through the rings, useful information was gained concerning the ringlets

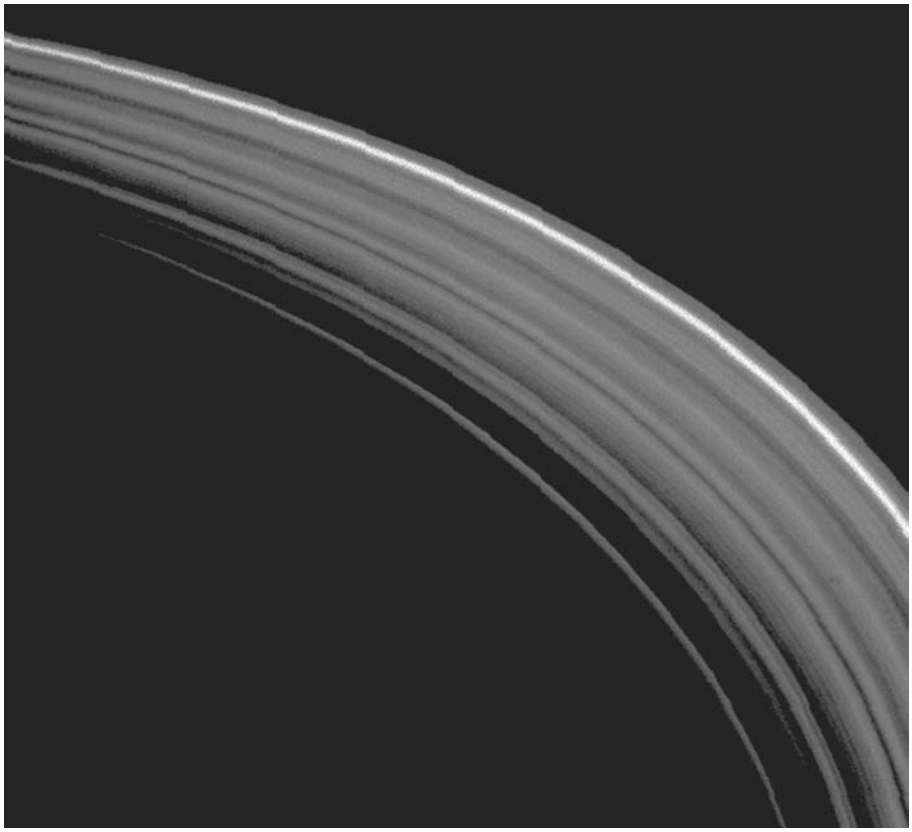

Fig. 16. Saturn's F Ring. The Voyager 2 PPS (Photopolarimeter) instrument performed a stellar occultation experiment at Saturn. Because of the instrument's high sensitivity and the small apparent size of the star used, delta Scorpii, structure was observed on a much finer scale — hundreds of meters — than would otherwise be possible. For comparison, the finest resolution obtained by the Voyager cameras was about 10 kilometers (6 miles). These synthetic images have been generated by "smearing out" sections of the one-dimensional occultation profile into two-dimensional pseudo-images. Regions of higher optical depth appear brighter in the images. These synthesized images show the very fine structure of Saturn's F Ring, including a dense outer core and a diffuse set of inner strands. Note that the uniformity and lack of kinks or knots here are only artifacts of the occultation experiment, which takes a single narrow slice of the rings. (*NASA*.)

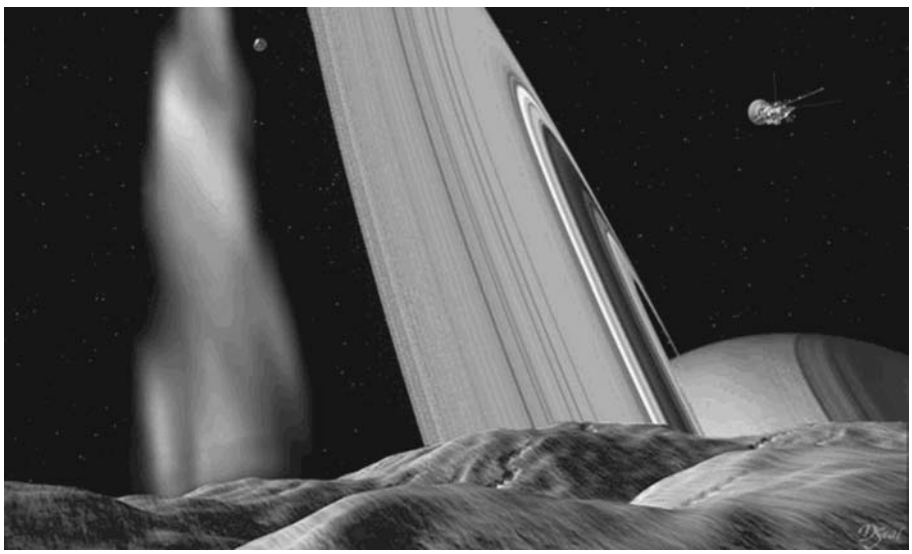

Fig. 17. This artist's rendering simulates Saturn's rings as seen from the surface of Pandora, one of the shepherds of the F Ring. The clumpy, wispy F Ring crosses the image from top to bottom, and the F Ring's other shepherd can be seen in the interior of the F Ring near the top. (*Courtesy of Dave Seal, JPL.*)

and the distribution of particle sizes within the ringlets. It was observed that in some ringlets, the fine particles are denser on the inner and outer edges than they are in the middle. The rings appear to consist of a tenuous background sheet of material, with empty gaps and denser ridges superimposed on it. It was noted that a typical ridge has a very sharp edge. The investigators, by comparing the attenuation of the microwave signal at two wavelengths, were able to estimate the size distribution of ring particles. It was found that there are about 120 to 200 particles per square kilometer in the size range of 9 to 11 meters. Very few larger particles were detected. The numbers as well as uncertainties increased rapidly with diminishing size. It was found in the 3- to 5-meter particle range, that there are from 1700 to 6000 particles per square kilometer. The investigators noted that there may be millions that are smaller than that; or there may be none; the radio data are consistent with either interpretation. See Fig. 11.

Voyager 2 measurements provided much of the data required for an understanding of structure. Higher-resolution photos of the inner edge

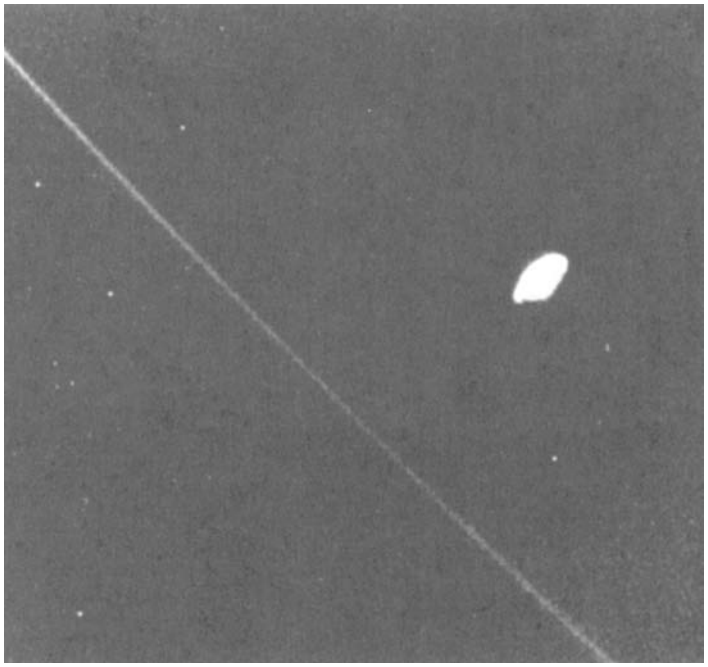

Fig. 18. Saturn's F ring and its inner shepherding satellite (1980S27) are pictured in this closeup *Voyager 2* image acquired on August 25, 1981 from a range of 365,000 kilometers (227,000 miles). Features as small as 6 kilometers (3.7 miles) are visible. The satellite is elongated and irregular, with its longest axis pointing toward the center of Saturn (toward upper right of view). As seen here, the F ring is thin and does not show the multiple, braided structure noted by Voyager 1 in 1980. There is no indication of a band or kink in the ring at its closest point to the shepherd; such a feature would be consistent with some of the theories advanced on the formation of the braids. (*Jet Propulsion Laboratory*.)

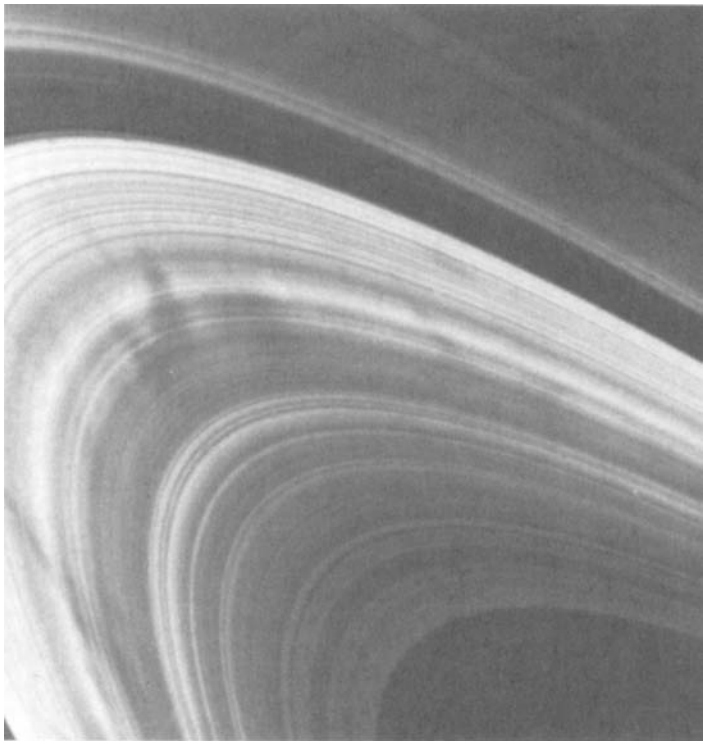

Fig. 19. *Voyager 2* obtained this high-resolution picture of Saturn's rings on August 22, 1981 when the spacecraft was 4 million kilometers (2.4 million miles) distant from the planet. Evident here are the numerous "spoke" features in the B ring; their very sharp, narrow appearance suggests short formation times. Some scientists believe that electromagnetic forces are responsible in some way for these features, but no detailed theory has been formulated. Pictures such as this and analyses of *Voyager* 2's spoke motion pictures may reveal additional clues about the origins of these complex structures. (*Jet Propulsion Laboratory*.)

of the Cassini division showed no sign of satellites down to about 5–9 kilometers (3–6 miles). No systematic searches were conducted in any of the other ring gaps. *Voyager 2's* photopolarimeter provided more surprises. The instrument measured changes in starlight from Delta Scorpii as the spacecraft flew above the rings when the starlight passed through the rings. The photopolarimeter was capable of resolving structure smaller than 300 meters (1000 feet). The star-occultation experiment showed that few clear gaps exist anywhere in the rings. The structure in the B ring instead appears to be variations in density of ring material, probably caused by traveling density waves or other, stationary forms of waves. The gravitational effects of Saturn's satellites form density waves. They propagate outward from positions where the ring particles orbit Saturn in harmony with the satellites. Resonant points are locations where a particle orbits Saturn in one-half or one-third the time required by a satellite, such as Mimas. For example, at the 2:1 resonant point with the satellite 1980 S1, a series of outward propagating density waves has characteristics that indicate there are about 60 grams of material per square centimeter of ring area and that the velocity of the particles relative to one another is about one millimeter per second. The small-scale structure of the rings may therefore be largely transitory, although larger-scale features, such as the Cassini and Encke divisions, appear to be more permanent. The edges of the rings where the few gaps exist are so sharp that the ring must be less than about 200 meters (650 feet) thick at such points. See Figs. 12–17.

In almost every case where clear gaps do appear in the rings, eccentric ringlets are found. These seem to show variations in brightness. In some cases, the differences are due to clumping or kinking; in others to nearly complete absence of ring material. Some scientists believe the only plausible explanation for the clear regions and kinky ringlets within them is the presence of nearby, yet undetected moonlets.

Two separate, discontinuous ringlets were found in the A-ring gap, about 73,000 kilometers (45,000 miles) from Saturn's cloud tops. At high resolution, at least one of these ringlets was noted to have multiple strands.

Pioneer 11 discovered Saturn's F ring in 1979. Photos of that ring taken by *Voyager 1* showed three separated strands that appeared twisted or braided. *Voyager 2* found five separate strands in a region that had no apparent braiding, but did reveal apparent braiding in another region. The photopolarimeter found that the brightest of the F-ring strands was subdivided into at least ten strands. The twists in the F ring are believed to originate in gravitational perturbations caused by the two shepherding satellites, 1980 S26 and 1980 S27. See Fig. 18.

Clumps of material in the F ring appear fairly uniformly distributed around the ring every 9000 kilometers (5600 miles), a spacing that coincides with the relative motion of F-ring particles and the shepherding satellites in one orbital period. By analogy, scientists suggest that similar mechanisms may be operating for irregular ringlets that exist in gaps in the main ring system.

The spokes found in the B ring appear only at radial distances between 43,000 kilometers (27,000 miles) and 57,000 kilometers (35,000 miles) above Saturn's clouds. Some spokes, those that are narrow and have a radial alignment, may be recently formed. The broader, less radial spokes appear to have formed earlier than the narrow examples and seem to follow Keplerian orbits — individual areas rotate at speeds governed by distances from the center of the planet. In some cases, scientists suggest that they see evidence that new spokes are reprinted over older ones. Formation of the spokes is not restricted to regions near the planet's shadow. As both *Voyagers* approached Saturn, the spokes appeared dark against a bright ring background. As the spacecraft departed, the spokes appeared brighter than the surrounding ring areas, indicating they backscatter the reflected sunlight more efficiently. See Fig. 19.

Spokes are also visible at high phase angles in light reflected from Saturn on the unilluminated underside of the rings. This suggests, according to some scientists, that charging of the small particles by photoionization alone may not be responsible for levitating them above the bulk of the ring material.

Another challenge faced by investigators is an understanding of the observation that even general dimensions of the rings do not seem to remain true at all positions around the planet. The distance of the B ring's outer edge, near a 2:1 resonance with Mimas, varies by at least 140 kilometers (87 miles). Furthermore, the elliptical shape of the outer edge does not follow a Keplerian orbit, since Saturn is at the center of

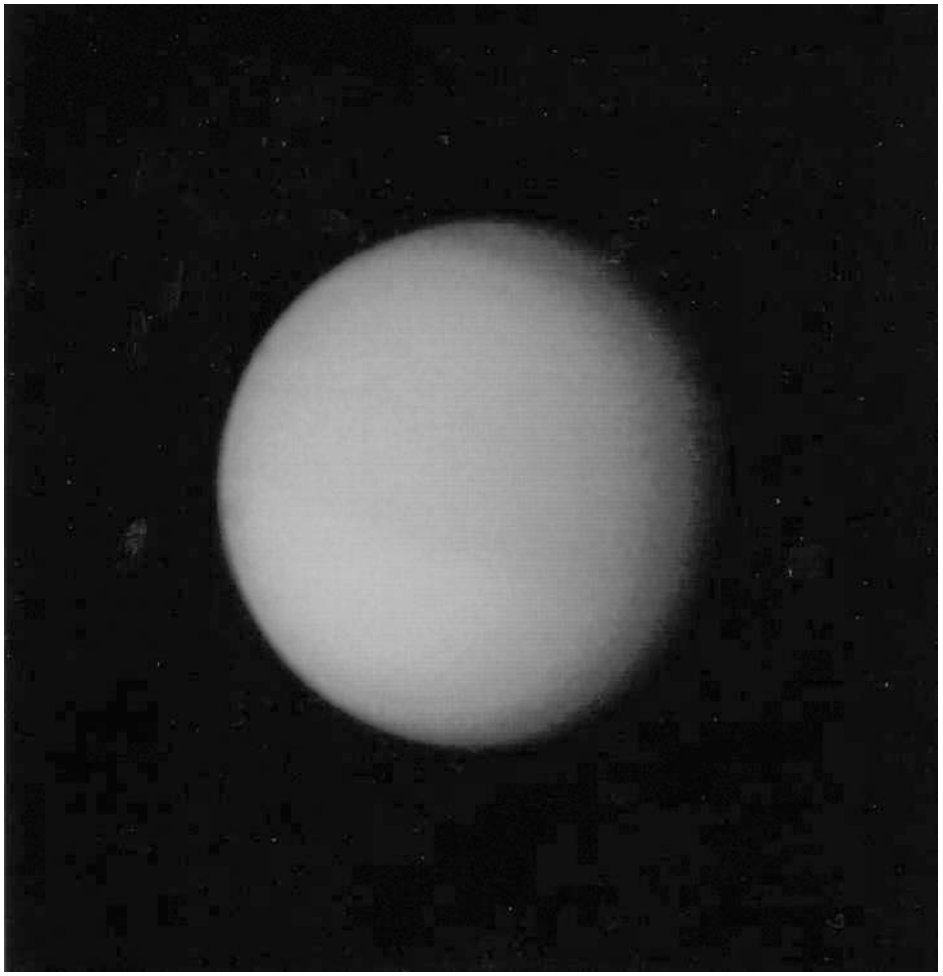

Fig. 20. On August 25, 1981, *Voyager 2* obtained this view of Titan, Saturn's largest satellite, from a range of 4.5 million kilometers (2.7 million miles). Separate violet, blue and green frames were combined to make this photograph, in which cloud features of diameter greater than 85 kilometers (50 miles) are visible. Seen here are the bright Southern Hemisphere and the dark North Polar Region. At this resolution, Titan appears to be completely shrouded by a thick atmosphere; visible features consist of cloud bands parallel to the equator. There is the suggestion of a Northern Hemisphere feature diagonal to the equator, but this is the result of a loss of data in one of the images used to compose this photograph. The *Voyager* Project is managed for NASA by the Jet Propulsion Laboratory, Pasadena, Calif. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

the ellipse, rather than at one focus. Although the gravitational effects of Mimas are most likely responsible for the elliptical shape, present theory predicts a somewhat smaller magnitude than that which was observed.

Voyager 1 measured radio waves that originate in sporadic electric discharges. The source of these discharges is still unknown. It is possible that they may originate in the rings. *Voyager 2* measured similar discharges, but at a rate only 10% that of the findings of *Voyager 1*, and with a different polarization.

Magnetosphere

The size of Saturn's magnetosphere is determined by external pressure of the solar wind. When *Voyager 2* entered the magnetosphere, the solar wind pressure was high and the magnetosphere extended only 19 Saturn radii (1.1 million kilometers; 712,000 miles) in the Sun's direction. Several hours later, however, the solar wind pressure dropped and Saturn's magnetosphere ballooned outward over a six-hour period. It apparently remained inflated for at least three days, since it was 70% larger than when *Voyager 2* crossed the magnetic boundary on the outbound leg.

Unlike all other planets whose magnetic fields have been measured, Saturn's field is tipped only about one degree relative to the rotation poles. That rare alignment was first measured by *Pioneer 11* in 1979 and was later confirmed by *Voyager 1*.

Several distinct regions have been identified within Saturn's magnetosphere. Inside about 400,000 kilometers (250,000 miles), there is a torus of H^+ and O^+ ions, probably originating from water ice sputtered from the surfaces of the satellites Dione and Tethys. These ions are positively charged atoms of hydrogen and oxygen that have lost one electron. Strong plasma-wave emissions appear to be associated with the inner torus.

At the outer regions of the inner torus, some ions have been accelerated to high velocities. In terms of temperatures, such velocities correspond to 400 to 500 million degrees Kelvin.

Outside the inner torus is a thick sheet of plasma that extends out to about 1 million kilometers (620,000 miles). The source for material in the outer plasma may be Saturn's ionosphere, Titan's atmosphere, and the neutral hydrogen torus that surrounds Titan between 500,000 kilometers (300,000 miles) and 1.5 million kilometers (1 million miles).

Radio emissions from Saturn had changed between the encounters of *Voyager 1* and *2*. *Voyager 2* detected Jupiter's magnetotail as it approached Saturn in the winter and early spring of 1981. Soon afterward, when Saturn was believed to be bathed in the Jovian magnetotail, the ringed planet's kilometric radio emissions were also undetectable.

During portions of *Voyager 2's* Saturn encounter, kilometric radio emissions again were not detected. The observations are consistent with effects caused by Jupiter's magnetotail, although *Voyager* scientists admit of no direct evidence that the shutdown of Saturn's natural radio signals was caused by Jupiter's magnetotail.

Satellites of Saturn

Titan. The largest of Saturn's satellites is Titan and, in fact, is the second largest satellite in the solar system. It is the only satellite known to have a dense atmosphere. Some scientists believe that Titan may prove to be the most interesting body in the solar system, i.e., from a terrestrial perspective. For almost two decades, space scientists have

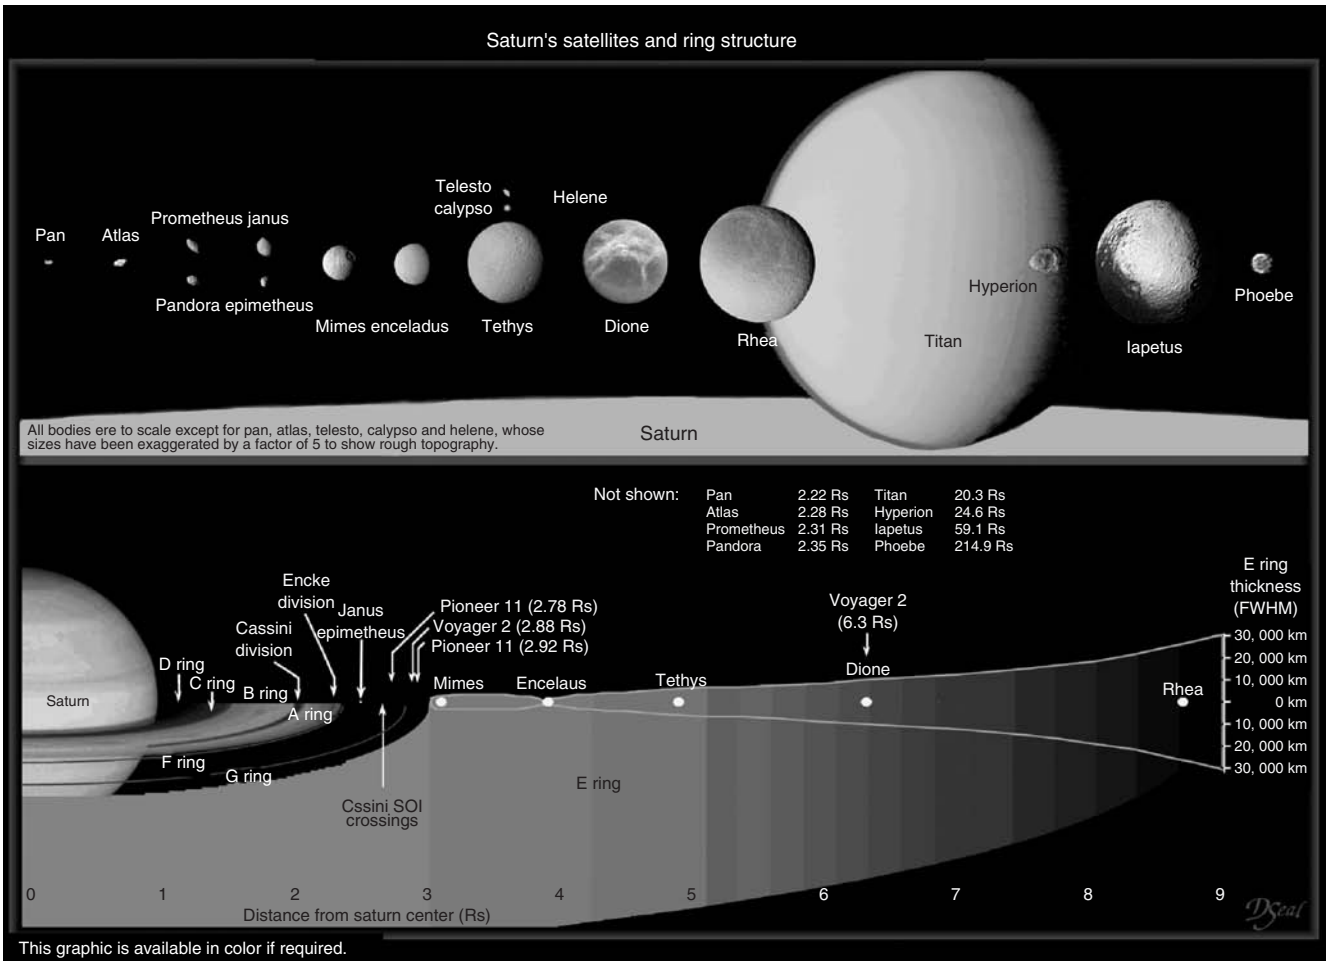

Fig. 21. Saturn has 18 named satellites, more than any other planet. There may very well also be several small ones yet to be discovered. Of those moons for which rotation rates are known, all but Phoebe and Hyperion rotate synchronously. The three pairs Mimas-Tethys, Enceladus-Dione and Titan-Hyperion interact gravitationally in such a way as to maintain stable relationships between their orbits: the period of Mimas' orbit is exactly half that of Tethys, they are thus said to be in a 1:2 resonance; Enceladus-Dione are also 1:2; Titan-Hyperion are in a 3:4 resonance. In addition to the 18 named satellites, at least a dozen more have been reported and given provisional designations. (*JPL, NASA*.)

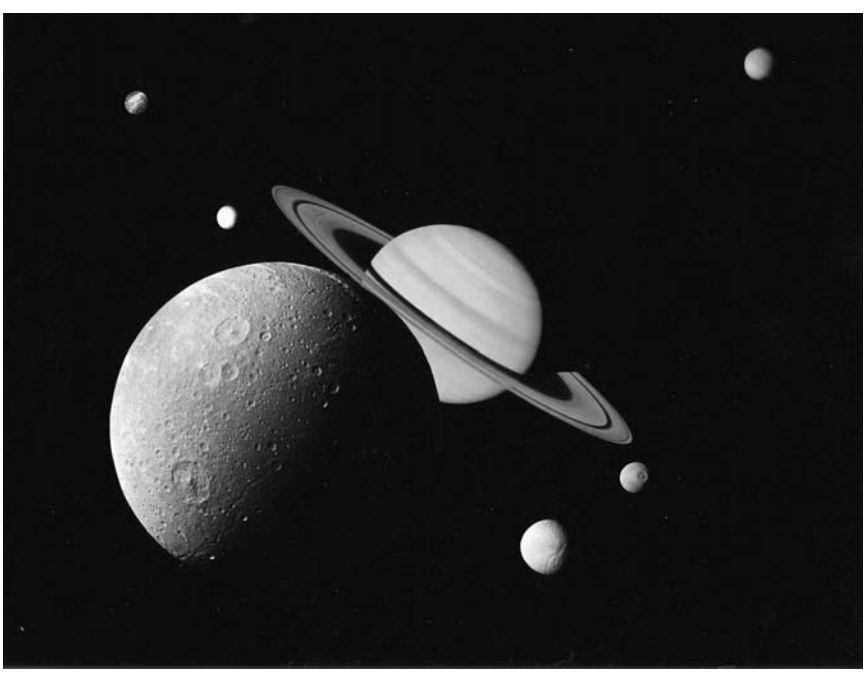

Fig. 22. This montage of images of the Saturnian system was prepared from an assemblage of images taken by the *Voyager 1* spacecraft during its Saturn encounter in November 1980. This artist's view shows Dione in the forefront, Saturn rising behind, Tethys and Mimas fading in the distance to the right, Enceladus and Rhea off Saturn's rings to the left, and Titan in its distant orbit at the top. The *Voyager* Project is managed for NASA by the Jet Propulsion Laboratory, Pasadena, California. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

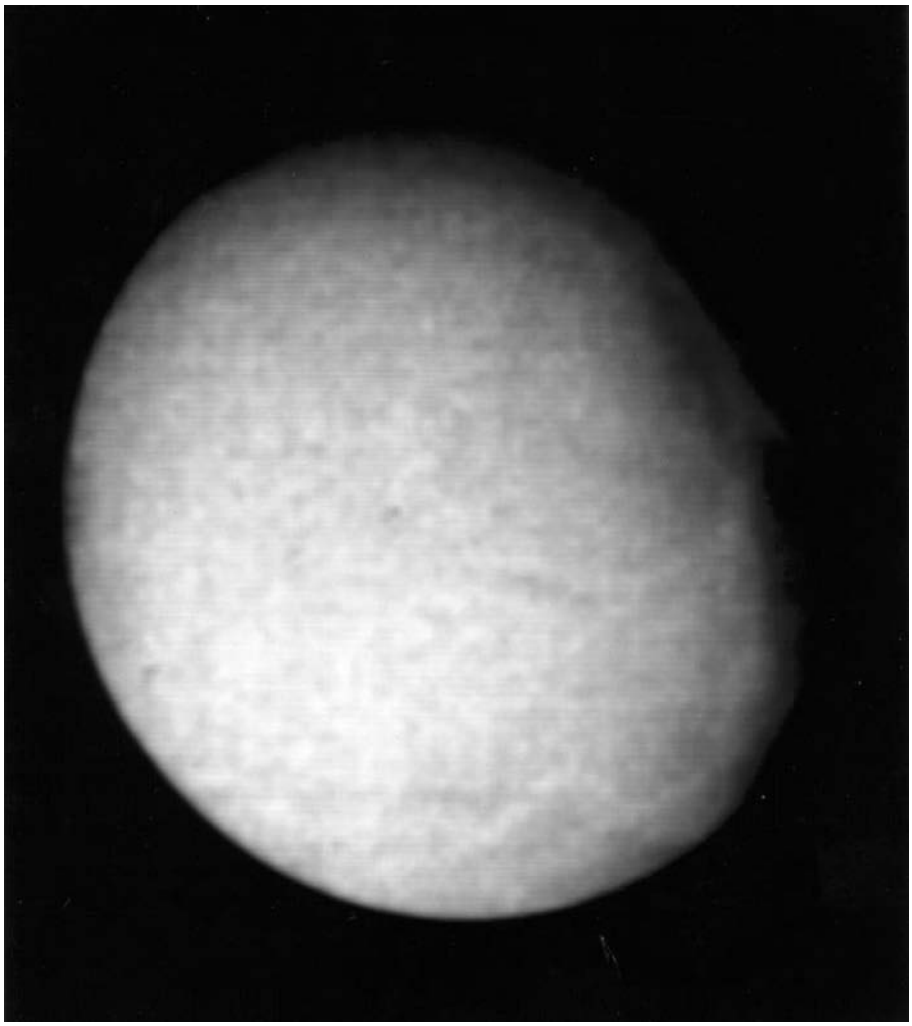

Fig. 23. Little detail is visible on the surface of Saturn's satellite Enceladus in this color-enhanced image taken by NASA's *Voyager 1* on November 12, 1980 from a distance of 655,000 kilometers (393,000 miles). The lack of visible surface detail on the satellite indicates that Enceladus' surface is dramatically different from the surfaces of the other larger Saturnian moons. The *Voyager* Project is managed for NASA by the Jet Propulsion Laboratory, Pasadena, California. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

searched for clues to the primeval Earth. The chemistry taking place in Titan's atmosphere may be similar to that which occurred in the Earth's atmosphere several billion years ago.

Because of its thick, opaque atmosphere, astronomers for some years believed that Titan was the largest satellite in the solar system. Their measurements were necessarily limited to measurements at the cloud tops. *Voyager 1's* close approach and diametric radio occultation showed, however, that Titan's surface diameter is only 5050 kilometers (3200 miles), which is slightly smaller than Ganymede, Jupiter's largest satellite. Both these satellites are larger than the planet Mercury. Titan's density appears to be about twice that of water ice. It has been suggested that it may be composed of nearly equal amounts of rock and ice.

Titan's surface was not seen in any of the *Voyager* photos. The surface is hidden by a dense, optically thick photochemical haze whose main layer is about 50 kilometers (30 miles) thicker in the southern hemisphere than in the northern hemisphere. Several distinct, detached haze layers can be seen above the visibly opaque haze layer. See Fig. 20. These haze layers merge with the main layer over the north pole of Titan, forming what scientists first thought was a darkened hood. The hood was found, under the better viewing conditions of *Voyager 2*, to be a dark ring around the pole. The southern hemisphere is slightly brighter than the northern hemisphere, possibly the result of seasonal effects. When the Voyagers flew past, the season on Titan was the equivalent of April on Earth; or early spring in the northern hemisphere and early autumn in the southern hemisphere.

The atmospheric pressure near Titan's surface is about 1.6 bars or 60% greater than that on Earth. The atmosphere is mostly nitrogen, also the major constituent of the Earth's atmosphere.

The surface temperature appears to be about 95 K ($-288\,^{\circ}$F; $-180\,^{\circ}$C), only 4 K above the triple-point temperature of methane. Methane, therefore, quite possibly plays the same role on Titan as water does on Earth — as rain, snow, and vapor. Rivers and lakes of methane may exist under a nitrogen sky. Clouds may drop liquid-methane precipitation. Titan's methane, through continuing photochemistry, may be converted to ethane, acetylene, an ethylene and, when combined with nitrogen, hydrogen cyanide. HCN is an especially important molecule, since it is a building block of amino acids. Titan's low temperature probably inhibits more complex organic chemistry.

Titan has no intrinsic magnetic field. Therefore, it has no electrically conducting and convecting liquid core. Its interaction with Saturn's magnetosphere creates a magnetic wake behind the satellite. Titan also serves as a source for both neutral and charged hydrogen atoms in Saturn's magnetosphere.

In later studies of Titan data (from *Voyager*), B.L. Lutz, C. de Bergh, and T. Owen reported discovery of carbon monoxide in the atmosphere of the satellite. The researchers reported that the 3-O rotation-vibration band of CO in the near-IR spectrum of Titan had been identified, and a reflecting layer model mixing ration of CO to molecular N of 6×10^{-5} had been determined. This result supported the earlier probable detection of CO_2 and strengthened possible analogies between the atmosphere of Titan and conditions on primitive Earth.

Eshelman, Lindal, and Tyler in post-*Voyager* data analysis, reported that Titan's dense and cold nitrogen atmosphere contains a small amount of methane under conditions at least approaching those at which one or both constituents would condense. The possibility of methane and nitrogen rain

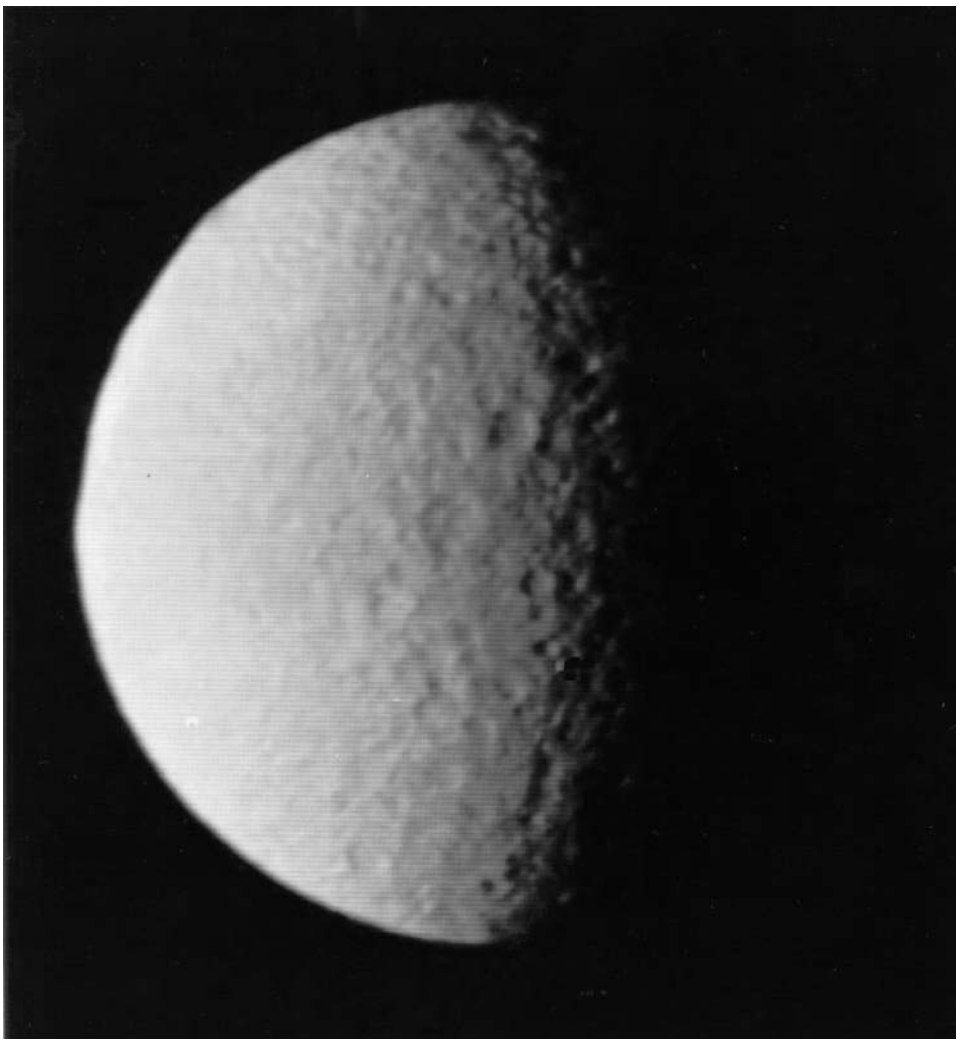

Fig. 24. A heavily cratered surface is apparent in this photo of Saturn's satellite Tethys, taken November 12, 1980 by *Voyager 1* from a distance of 570,000 kilometers (354,000 miles). Other photos of Tethys showed the opposite hemisphere, dominated by what appears to be a large impact crater or hill. Tethys is about 1,000 kilometers (600 miles) in diameter and is composed largely of ice. *Voyager 1* made its closest approach to Saturn on November 12, 1980. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

clouds and global methane oceans has been discussed widely. However, researchers report that, from specific features of radio occultation and other *Voyager* data, they have concluded that nitrogen does not condense on Titan, and that the satellite has neither global methane oceans nor a global cloud of liquid methane droplets. The investigators further observed that certain results indirectly support the conjecture that methane does not condense at any location. However, other considerations favor a methane ice haze in the troposphere, and liquid and solid methane may exist on the surface and as low clouds at polar latitudes.

F.M. Flaser (Goddard Space Flight Center), working on the same problem, observed that if global oceans of methane exist on Titan, the atmosphere above them must be within 2% of saturation. The two *Voyager* radio occultation soundings, made at low altitudes, probably occurred over land, since they imply a relative humidity & 70% near the surface. Oceans might exist at other low-altitude locations if the zonal wind velocities in the lowest 3 km are & 4 centimeters per second.

As a point of contrast, Lunine, Stevenson, and Yung (California Institute of Technology), from studies of Voyager data, suggested that Titan is covered by an ocean one to several kilometers deep consisting mainly of ethane. They report that if the ocean is in thermodynamic equilibrium with an atmosphere of 3% (mole fraction) methane, then its composition is roughly 70% ethane, 25% methane, and 5% nitrogen. Photochemical models predict that ethane is the dominant end product of methane photolysis so that the evolving ocean is both the source and the sink for continuing photolysis. The coexisting atmosphere is compatible with *Voyager* data.

As pointed out by D.O. Muhleman and colleagues, Division of Geological and Planetary Sciences, California Institute of Technology, "The present understanding of the atmosphere and surface conditions on Saturn's largest moon, Titan, including the stability of methane, and an application of thermodynamics leads to a strong prediction of liquid hydrocarbons in an ethane-methane mixture on the surface." These scientists utilized the Very Large Array radio telescope in New Mexico as the receiving instrument. Statistically significant echoes were obtained that show that Titan is not covered with a deep, global ocean of ethane, as previously thought. The researchers conclude their mid-1990 paper with, "The VLA/JPL (Very Large Array/Jet Propulsion Laboratory) radar measurements will be repeated as often as possible during the closest passages of Titan to the Earth. However, most of the questions concerning the Titan surface will not be answered until the *Cassini* spacecraft reaches the Saturn system. It is quite likely that such a spacecraft would have an imaging radar and altimeter that will reveal much of the surface structure and will be very important for the study of Titan's geology, but will not be able to measure the surface reflectivity with an accuracy near to that of even current Earth-based radars."

Inner Satellites. Those Saturnian satellites which range in distance outward from the planet between 99,760 kilometers (62,000 miles) and 482,700 kilometers (300,000 miles) are known as *inner* satellites. These include Janus, Mimas, Enceladus, Tethys, Dione, and Rhea. These satellites are approximately spherical in shape and appear to be composed mostly of water ice. Enceladus reflects almost 100% of the sunlight that strikes it. These satellites represent a size of satellite not previously explored during

pre-*Voyager* missions. Mimas, Tethys, Dione, and Rhea are all heavily cratered; Enceladus features fewer craters. See Figs. 21 and 22.

Enceladus. This satellite appears to have by far the most active surface of any satellite in the Saturnian system. At least five types of surface-terrain elements have been identified. Although craters can be seen across portions of its surface, the lack of craters in other areas implies an age less than a few hundred million years for the youngest region on the surface. See Fig. 23. It seems likely that portions of the surface of Enceladus are still undergoing change, since there are areas that are covered by ridged plains with no evidence of cratering down to the limit of resolution of *Voyager 2* cameras (2 kilometers; 1.1 miles). Other areas are criss-crossed by a pattern of linear faults. It is unlikely that a body so small could contain enough radioactive material for the modification to have been produced internally. A more likely source of heating appears to be tidal interaction with Dione — similar to the action between Jupiter and its satellite, Io. For Enceladus' present orbit, however, current theories of tidal heating do not predict generation of sufficient energy to explain all the heating that must have occurred. Because the satellite reflects so much sunlight, Enceladus' current surface temperature is only 72 K (−330 °F; −201 °C).

Tethys. Photos of Tethys taken by *Voyager 2* show an enormous impact crater nearly one-third the diameter of the satellite and larger than Mimas. The crater appears to have formed when Tethys was relatively fluid because nearly the original shape of the satellite was restored after impact. A gigantic fracture covers three-fourths of Tethys' circumference. See Fig. 24. Scientists suggest that the fracture can be explained if Tethys were once fluid and its crust hardened before the interior. Freezing and consequent expansion of the interior could have caused a surface fracture about the size of that observed. However, expansion would not be expected to cause only one large crack. The canyon has been named Ithaca Chasma. Tethys' current surface temperature is about 86 K (−305 °F; −187 °C).

Mimas. Photos of Mimas show a huge crater. The crater is about one-third the diameter of the satellite. This crater has greater surface relief, implying that Mimas was much more rigid at the time the cratering event occurred. See Fig. 25.

Dione. The terrain of this satellite is described as "wispy," probably consisting of numerous cracks rimmed with ice. As shown in Fig. 26, a

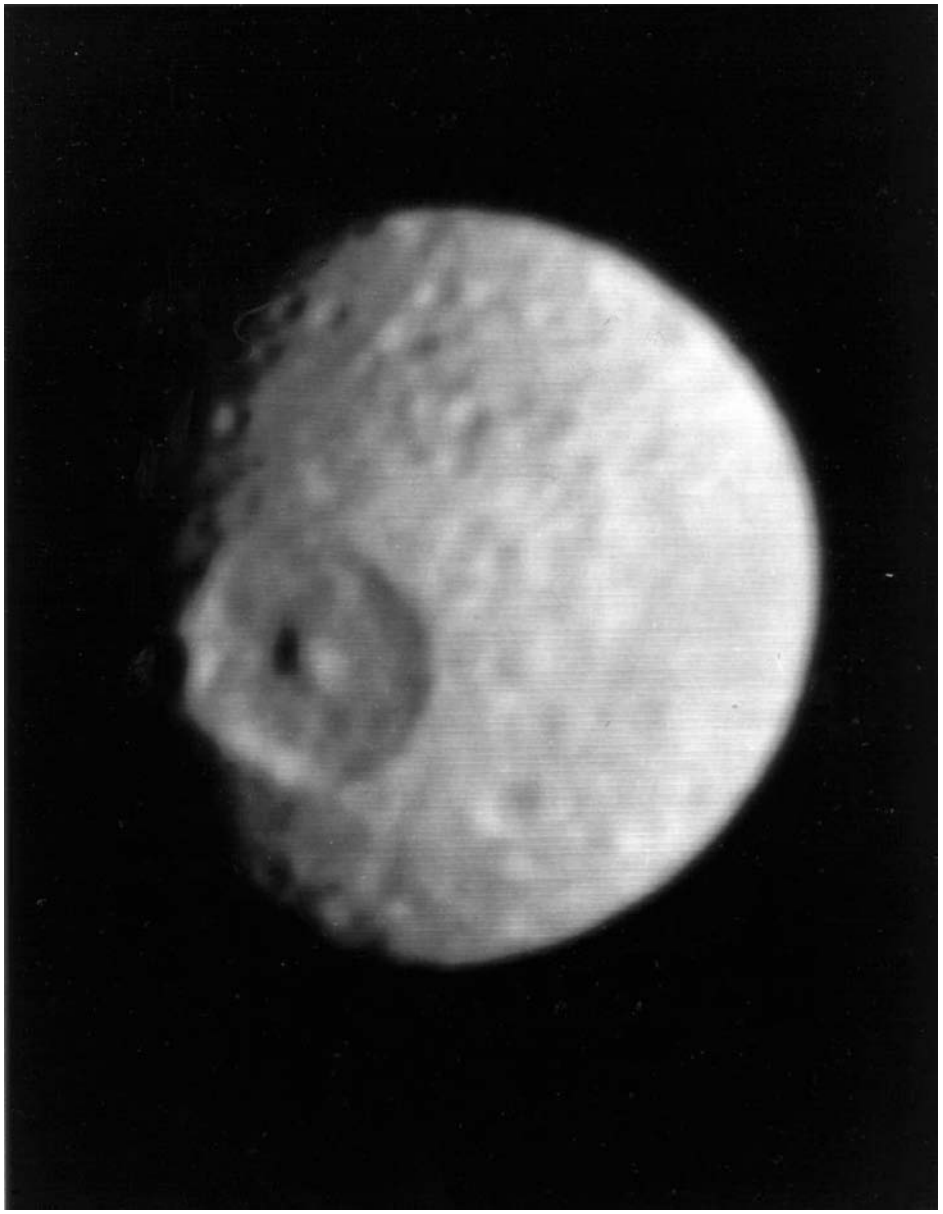

Fig. 25. The conspicuous crater on the surface of Saturn's moon Mimas is seen in this image taken by NASA's *Voyager 1* on November 12, 1980 when the spacecraft was 540,000 kilometers (324,000 miles) from the satellite. The massive crater, whose proportionate size (approximately 100 kilometers or 60 miles) is about one-quarter of the satellite's diameter (390 kilometers or 235 miles) is without precedent among the explored objects of the solar system. The impact that formed the crater was probably almost large enough to shatter Mimas into two or more fragments. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration.*)

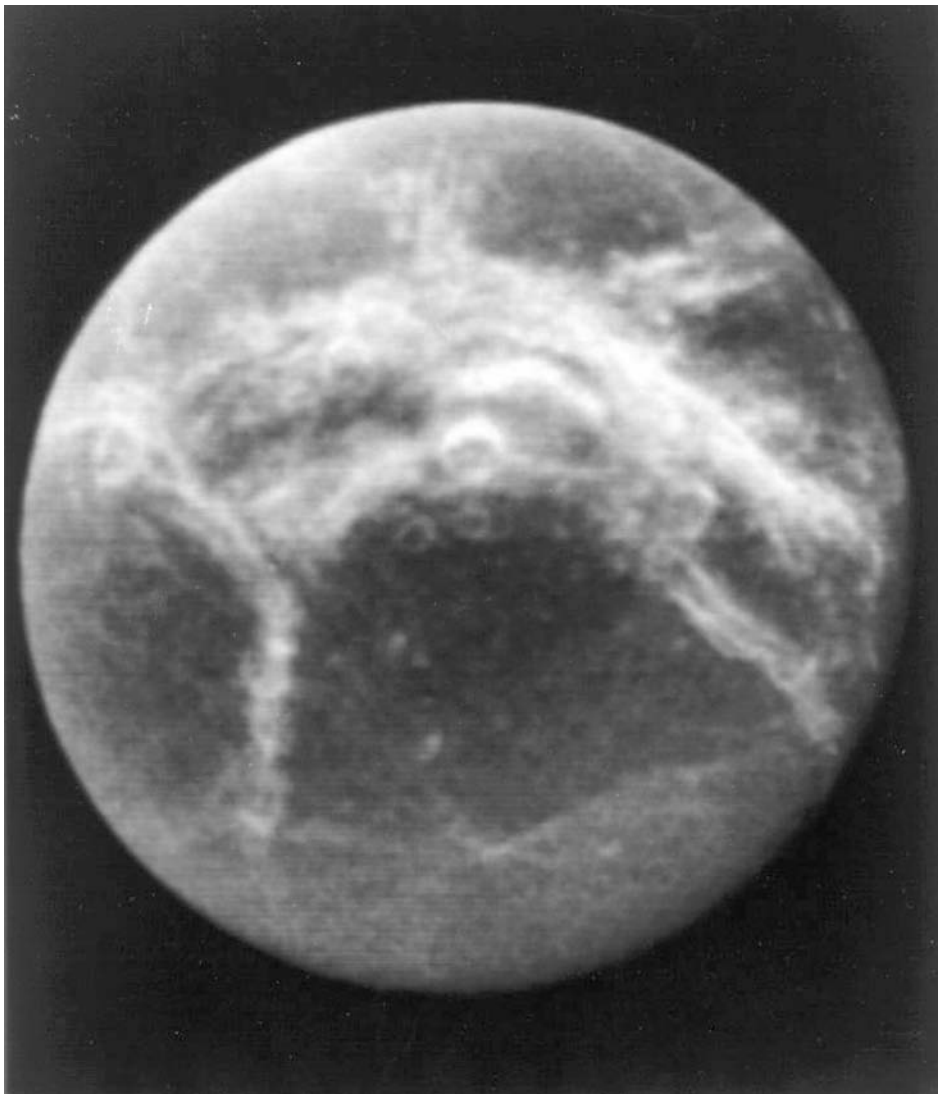

Fig. 26. Large bright streaks are seen to cross the face of Saturn's moon Dione in this photograph taken by NASA's *Voyager 1* on November 12, 1980 from a distance of 695,000 kilometers (417,000 miles). Higher resolution views of Dione taken by *Voyager 1* show some of these streaks to be grooves that may be the result of fracturing in the satellite's surface. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

very large and wide fracture is noted in the southern hemisphere of the body. The wispy streaks stand out vividly against an already bright surface.

Rhea. This is a crater-saturated body, possibly impacted by many short-period comets. This is one of the better mapped satellites of Saturn. See Fig. 27.

Outer Satellites. In addition to Titan, previously described, the outer satellites of Saturn include Hyperion, Iapetus, and Phoebe. The outer satellites range in distance outward from the planet between about 1.15 million kilometers (720,000 miles) and 12.9 million kilometers (8 million miles).

Iapetus. This satellite has long been known to have large differences in surface brightness. Brightness of the surface material on the trailing side has been measured at 50%, while the leading-side material reflects only 5% of the sunlight that strikes it. Most of the dark material is distributed in a pattern directly centered on the leading surface, causing conjecture that the material was swept up as it spiralled inward, presumably from Phoebe. The trailing face of Iapetus, however, has several craters with dark floors. That implies that the dark material originated in the satellite's interior. It is possible that the dark material came both from Phoebe and from Iapetus' interior. See Fig. 28.

Hyperion. This satellite shows no evidence of internal activity. Its irregular shape and evidence of bombardment by meteoritic material makes it appear to be the oldest surface in the Saturnian system. Hyperion is shaped like a hamburger and is probably not in a gravitationally stable position. It is possible that one or more meteorites jostled Hyperion out of position and that the satellite will eventually swing back. See Fig. 29.

In studies of *Voyager* data, J. Wisdom and S. Peale (University of California, Santa Barbara) and F. Mignard (Research Center for the Study of Geodynamics and Astronomy, Grasse, France), reported that Hyperion tumbles chaotically, not just end over end, but first one way and then another, slowing down and then speeding up. These theorists believe that Saturn's gravity would synchronize Hyperion's rotation if the satellite were not of such an odd shape ($115 \times 145 \times 190$ km) and in an elongated, eccentric orbit. It is suggested that as Hyperion follows its eccentric orbit, Saturn tugs on different parts of the satellite with differing effects, sending it into chaotic tumbling. There is also the gravitational effect of Titan on the small satellite. Unfortunately, a difference of 18 months in the timing of observations is the basis of the current conclusions.

Further studies by Thomas (Cornell University) and colleagues of the brightness of Hyperion indicate a regular 13-day period of rotation during the 61 days of *Voyager 2's* encounter with Saturn. The case of Hyperion's rotation has not been solved conclusively.

Phoebe. This satellite was photographed by *Voyager 2* after the spacecraft passed Saturn. Phoebe orbits in a retrograde direction in a plane much closer to the ecliptic than to Saturn's equatorial plane. *Voyager 2* found that Phoebe is roughly circular in shape and reflects about 6% of the sunlight. It is also quite red in color. Phoebe rotates on its axis about once in nine hours. Thus, unlike the other Saturnian satellites, it does not always

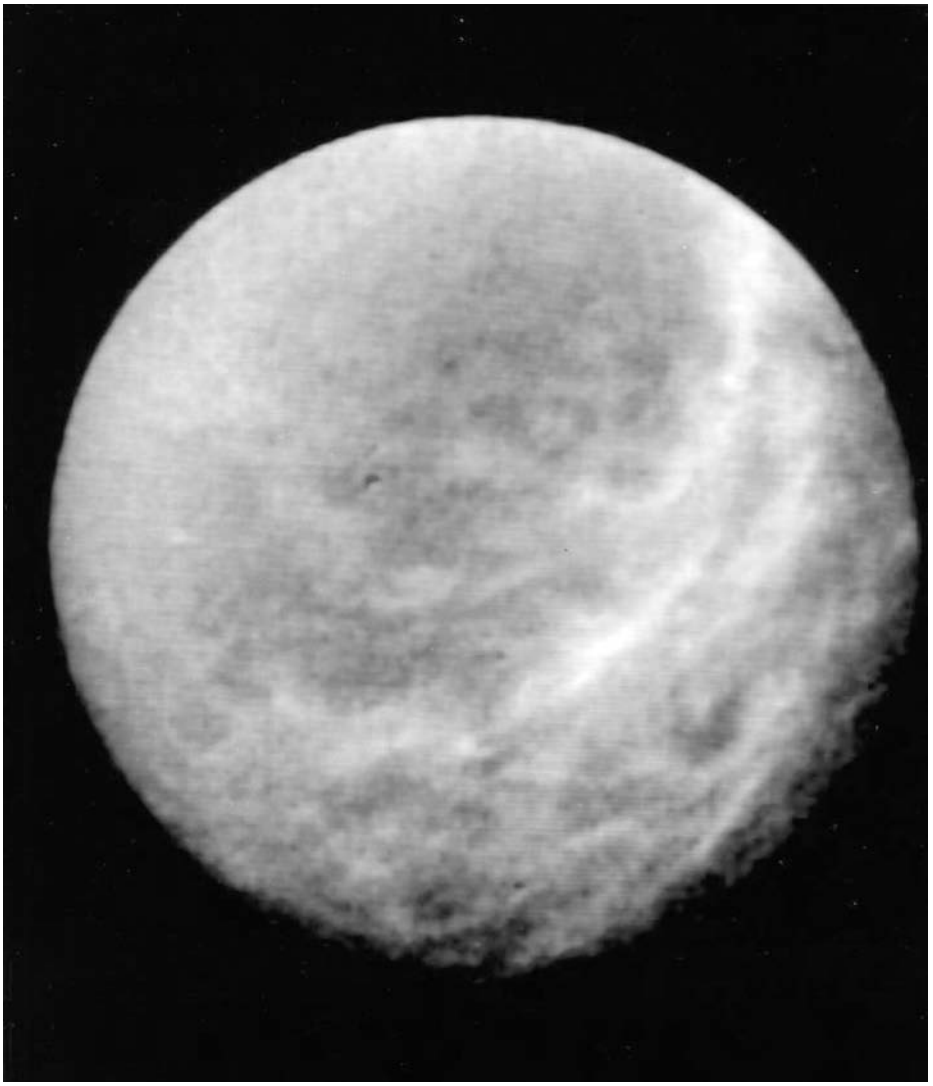

Fig. 27. Special computer processing was used to enhance subtle color and brightness variations in this photo of Saturn's satellite, Rhea, taken by Voyager 1 on November 12, 1980, at a distance of 1.3 million kilometers (808,000 miles). Rhea's surface is composed mostly of ice, so is very reflective, and presents an almost uniformly white appearance. Of particular interest to Voyager scientists are the bright streaks that can be seen crossing Rhea's face. Scientists believe the streaks may be caused by fresh ice ejected from beneath the satellite's surface. (*Jet Propulsion Laboratory, California Institute Of Technology, National Aeronautics And Space Administration*.)

show the same face to the planet. If, as scientists suggest, Phoebe is a captured asteroid with its composition unmodified since its formation in the outer solar system, it is the first such object that has been photographed.

Newly Discovered, Very Small Satellites. A total of seven very small satellites was observed by *Voyagers 1* and *2*. See Fig. 30. These satellites are irregularly shaped bodies that have been highly cratered by the impact of cosmic debris. The irregularity is probably due to fracturing by large impacts and is sustained by the rigidity of the bodies. These objects range from about ten to several hundred kilometers across. Included are the two F-ring shepherding satellites, first seen by *Voyager 1* in 1980.

Post-Mission Analyses

Based upon the masses of information collected from prior Saturn missions, numerous scientists establish continuing programs of data analysis to refine prior concepts of the characteristics of the planet. As one example, J.E. Klepeis and colleagues at the University of California, Lawrence Livermore National Laboratory, reported on their experiences by establishing models of Saturn and making comparisons with the conditions on Jupiter. The group has observed, "Models of Jupiter and Saturn postulate a central rock core surrounded by a fluid mixture of hydrogen and helium. These models suggest that the mixture is undergoing phase separation in Saturn, but not Jupiter. State-of-the-art total energy calculations of the enthalpy of mixing for ordered alloys of hydrogen and helium confirm that at least partial phase separation has occurred on Saturn and predict that this process also has begun on Jupiter."

Radar Imaging from Earth. The *Voyager* missions to Saturn did not end all Earth-based astronomical imaging of the planet. These would include imaging by the Hubble space telescope mentioned later. However, much greater progress has occurred in connection with radar imaging. For example, A.W. Grossman and colleagues at the Division of Geological and Planetary Science, California Institute of Technology, describe their use of high-resolution microwave imaging of the planet. In a 1989 paper, the researchers used this technology to study the ring systems of Saturn. The radio interferometric observations were made at the Very Large Array telescope in New Mexico at wavelengths of 2 and 6 centimeters. With this information, the investigators prepared maps that show an increase in brightness temperature of about 3 K from equator to pole at both wavelengths, while a map made with 6-meter radiation indicated a bright band at northern mid-latitudes. "These data are consistent with a radiative transfer model of the atmosphere that constrains the well-mixed, fully saturated, NH_3 mixing ratio to be 1.2×10^{-4} in a region just below the NH_3 clouds, while the observed bright band indicates a 25 percent relative decrease of NH_3 in northern mid-latitudes. Brightness temperatures for the classical rings also are presented in the paper. Ring brightness shows a variation with azimuth and is linearly polarized at an average value of about 5 percent. The variations in ring polarization suggest that at least 20 percent of the ring brightness is the result of a single scattering process."

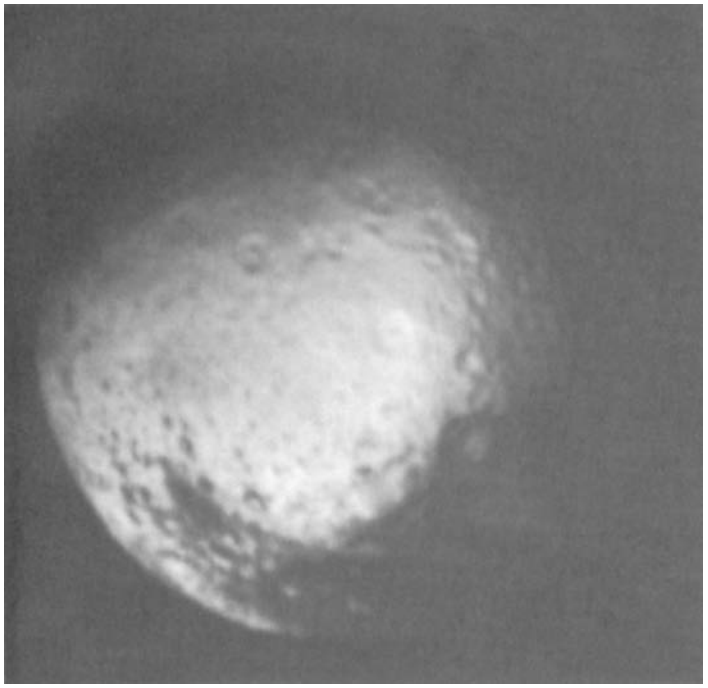

Fig. 28. View made by *Voyager 2* at time of its closest approach to lapetus, the outermost of Saturn's large satellites. Image was made on August 22, 1981 when the spacecraft was 1.1 million kilometers (680,000 miles) from the satellite. The camera resolution was about 21 kilometers (13 miles). This view, which is lit from above, primarily shows the heavily cratered northern hemisphere toward the bright trailing side of the satellite. The north pole itself is near the large central-peak crater seen partly in the shadow at the top of the image. Iapetus is noteworthy for the very dark material (lower and right-hand parts of this frame) that apparently covers the ice crust of the satellite primarily at its leading hemisphere. This dark material is red and reflects only about 5% of the incident sunlight; it may be of either external or internal origin. Study of its relationship with the underlying topography, for example, near the large crater at the border of the dark material, may help to resolve this mystery. (*Jet Propulsion Laboratory*.)

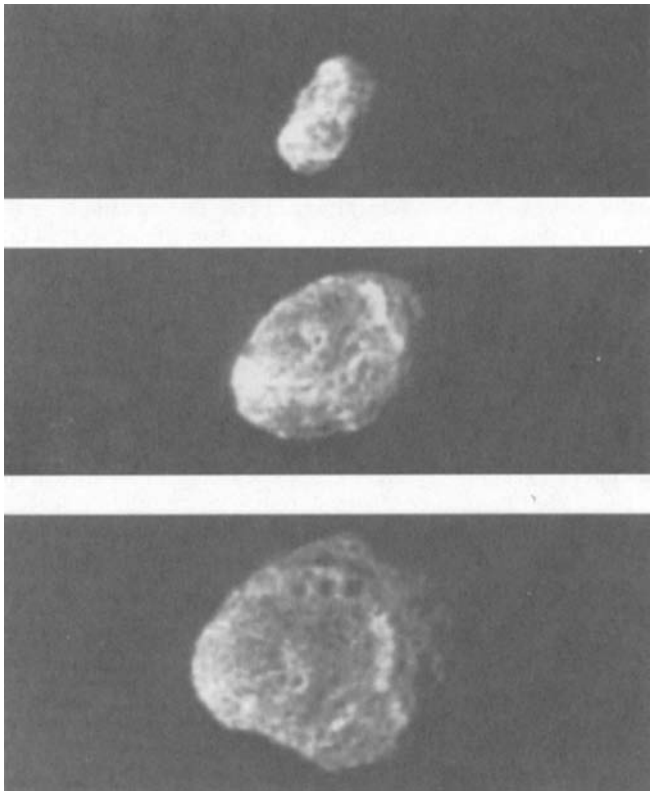

Fig. 29. Three views of Hyperion obtained as *Voyager 2* flew by this satellite. The views were taken: top view, on the morning of August 23, 1981 from a range of 1.2 million kilometers (740,000 miles); middle view, on the morning of August 24 from 700,000 kilometers (430,000 miles); lower view, at noon on August 24 from 500,000 kilometers (310,000 miles). Together, these views show the changing aspect of the satellite as *Voyager 2* moved in for closer views. Hyperion, roughly 360 by 210 kilometers (220 by 130 miles) and shaped like a hamburger, is probably not in a gravitationally stable position. Its surface is pock-marked with many meteorite-impact craters. The large indentation at the bottom limb (lower view) is one such crater (about 100 kilometers; 60 miles across). The smallest visible crater pit is about 10–20 kilometers (6–12 miles.)

The scientists conclude their paper, "The observations represent the ultimate in resolution and sensitivity obtainable from Earth-based radio telescopes. A vast improvement in our knowledge of Saturn's deep atmosphere and rings can be obtained from a Saturn-orbiting spacecraft instrument observing at radio wavelengths."

Great White Spot of Saturn. When the Hubble space telescope was pointed toward Saturn in late August 1990, the planet's image, after computer corrections to compensate for Hubble's disability, exhibited no surprises. The planet appeared calm and much as expected. However, in late September, a number of amateur astronomers reported the sudden development of a white spot reminiscent of a gigantic storm system. Larger, professional telescopes were turned to view Saturn, and these better images confirmed some unusual activity on the planet spread across Saturn's equatorial region. Scientists then interrupted Hubble's planned schedule for viewing Saturn. The white spot was reconfirmed. See Fig. 31. Some scientists liken the spot to the Great Red Spot of Jupiter. Because magma in the interior of Saturn had not been detected or even suspected, a volcanic eruption was quickly ruled out. There was a press conference on November 20, 1990, at which time a color image was released. The spot was described as a brick-colored hurricane. One scientist has observed that apparently massive amounts of energy, if not magmatic, well up from its interior (this energy remains from the period when the planet was formed) and that this heat, when it reaches the planet's thin atmosphere, periodically causes considerable turbulence.

NASA Hubble Space Telescope image of the ringed planet Saturn shows a rare storm that appears as a white arrowhead-shaped feature near the planet's equator. See Fig. 32. An upwelling of warmer air, similar to a terrestrial thunderhead generates the storm. The east-west extent of this storm is equal to the diameter of the Earth (about 13,167 kilometers or 7,900 miles). Hubble provides new details about the effects of Saturn's prevailing winds on the storm. The new image shows that the storm's motion and size have changed little since its discovery in September, 1994. The storm was imaged with Hubble's Wide Field Planetary Camera 2 (WFPC2) in the wide field mode on December 1, 1994, when Saturn was 1,506.7 million kilometers (904 million miles) from the Earth. The picture is a composite of images taken through different color filters within a six minute interval to create a "true-color" rendition of the planet. The blue fringe on the right limb of the planet is an artifact of image processing used to compensate for the rotation of the planet between exposures.

The Hubble images are sharp enough to reveal that Saturn's prevailing winds shape a dark "wedge" that eats into the western (left) side of the bright central cloud. The planet's strongest eastward winds (clocked at 1,000 miles per hour from analysis of *Voyager* spacecraft images taken in 1980–81) are at the latitude of the wedge. To the north of this arrowhead-shaped feature, the winds decrease so that the storm center is moving eastward relative to the local flow. The clouds expanding north of the storm are swept westward by the winds at higher latitudes. The strong winds near the latitude of the dark wedge blow over the northern part of the storm, creating a secondary disturbance that generates the faint white clouds to the east (right) of the storm center. The storm's white clouds are ammonia ice crystals that form when an upward flow of warmer gases shoves its way through Saturn's frigid cloud tops. This current storm is larger than the white clouds associated with minor storms that have been reported more frequently as bright cloud features. Hubble observed a similar, though larger, storm in September 1990, which was one of three

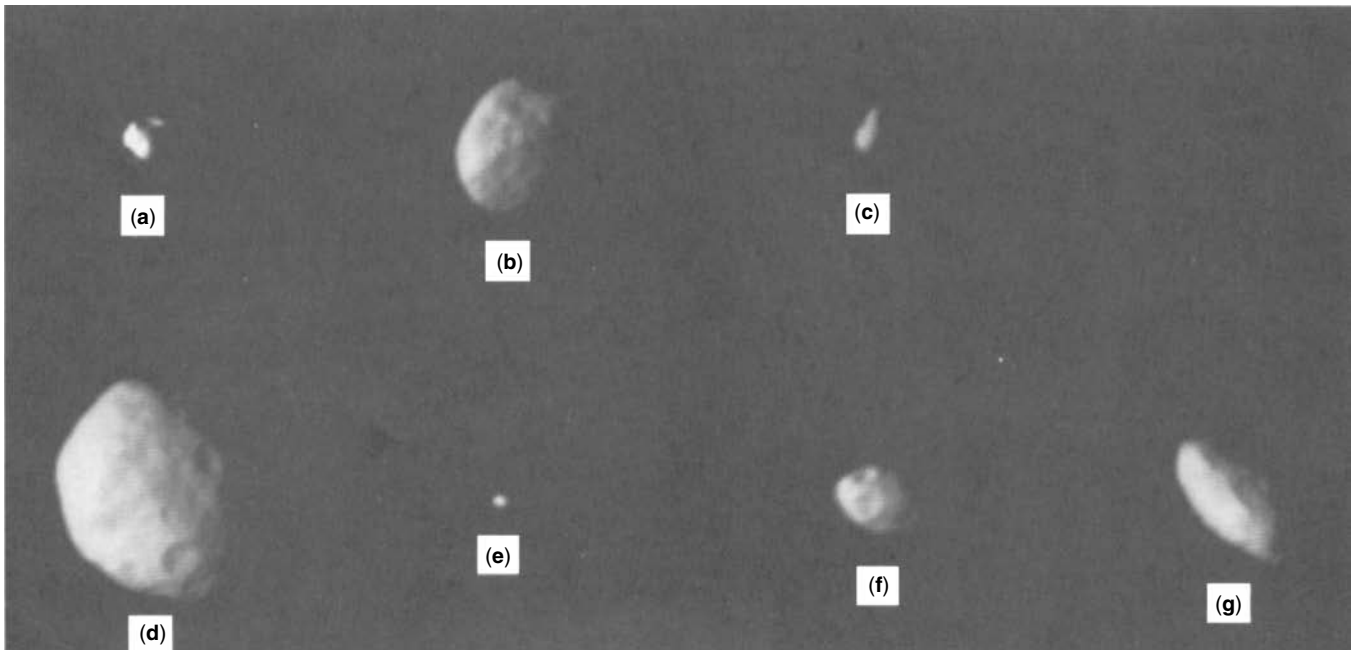

Fig. 30. Composite showing seven of the very small satellites of Saturn as photographed on August 25, 1981 by *Voyager 2*. (**a**) 1980S6 (Dione trojan); (**b**) 1980S3 (Trailing co-orbital); (**c**) 1980S25 (Trailing Tethys trojan); (**d**) 1980S1 (Leading co-orbital); (**e**) 1980S13 (Leading Tethys trojan); (**f**) 1980S26 (Outer F-ring shepherd); (**g**) 1980S27 (Inner F-ring shepherd). It should be noted that these views taken at differing distances from the various satellites, ranging from 248,000 kilometers (154,000 miles) to 667,000 kilometers (414,000 miles). (*Jet Propulsion Laboratory*.)

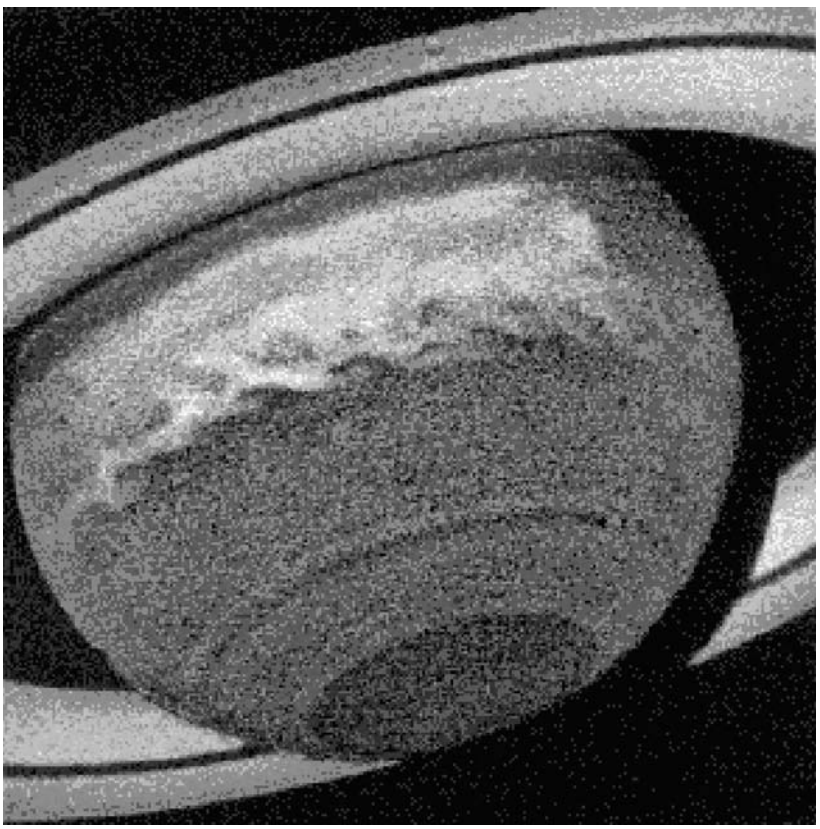

Fig. 31. Saturn's Great White Spot. On September 24, 1990, Stuart Wilber discovered a giant white spot on Saturn using a 10-inch reflector at Las Cruces, New Mexico. The Hubble Space Telescope took this image on November 9, 1990, and the white spot had spread out around the planet. This was the most spectacular eruption on Saturn since 1933. (*NASA*).

major Saturn storms seen over the past two centuries. Although these events were separated by about 57 years (approximately 2 Saturnian years) there is yet no explanation why they apparently follow a cycle — occurring when it is summer in Saturn's Northern Hemisphere. For additional photos of Saturn. See also **Hubble Space Telescope (HST)**.

SAUERKRAUT. See **Brassica**.

SAUGER. See **Perches and Darters**.

SAVANNAH. A tropical or subtropical region of grassland and other drought-resistant (xerophilous) vegetation. This type of growth occurs in regions that have a long dry season but a heavy rainy season, and continuously warm temperatures. Africa has the most extensive areas of savannah, but they are also widespread in South America (the *campos*), and, to a lesser extent, in India and southeast Asia, Australia, and Central America. See also **Biome**.

SAVORY (Summer Savory). See **Spices**.

SAWFISHES. See **Skates and Rays**.

SAWFLY *(Insecta, Hymenoptera)*. A plant-feeding member of this order, whose more familiar species are the ants, bees, and wasps. The sawflies have four wings, somewhat like those of the wasps, but the abdomen is broadly connected with the thorax, in contrast with the thin-waisted bodies of the other forms. See Fig. 1. They are named from the saw-like ovipositor with which slits are cut in the tissues of plants to receive the eggs. Some species are of economic importance. Since the larvae eat leaves they can be destroyed by a number of control chemicals. Cultural practices are also extremely important.

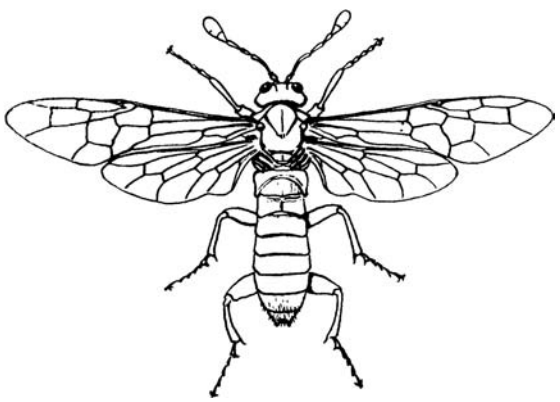

Fig. 1. Sawfly. (*USDA*.)

A native of North America, the *wheatstem sawfly* (*Cephus cinctus*, Norton) attacks wheat, as well as barley, spring rye, spelt, timothy, and a number of native grasses. The *European wheatstem sawfly* (*Cephus pygmacus*, Linne) is a closely related species. These insects are most damaging in the wheat-growing stages of the north and west of the Mississippi, although the European species is found mostly in the eastern states of New York and Pennsylvania. Without effective control measures, records indicate that in some years these insects have destroyed more than 50% of some crops. An infested field displays fallen straw (similar to the damage wrought by the hessian fly and jointworm). This is because the sawfly larvae have been feeding there. With the brown-headed, legless larva ($\frac{1}{3}-\frac{1}{2}$) inch; 8–12 millimeters long) will be straw cuttings that look like sawdust. This is the result of the cutting-type action characteristic of this insect. As the season progresses, the larva works their way down the stem and finally makes a V-shaped groove on the inside of the stem, causing the stem to break. The insect drops to the base of the plant and plugs up the opening, where it hibernates and ultimately pupates.

Control practices include turning the stubble shortly after harvest. Burning is not practical because the insects live close to ground level. Early cutting of grain, when possible, also reduces the damage. Rotation of crops, planting corn (maize), flax, alfalfa or sweet clover, is effective. Where the sawfly is a persistent problem, wheat varieties that are solid-stemmed should be selected.

The *raspberry sawfly* (*Monophadnoides geniculatus* or *Priophorus rubivorus*, Rowler) is sometimes abundant on raspberry leaves at a time in spring when the plant has reached its full foliage. The larva is a spiny, multilegged, pale-green worm that usually feeds along the edges of leaves. Unless controlled, the plant may be fully stripped of its leaves.

The *currant stem girdler* (*Janus integer*) is another economic species found in the United States.

Horntail flies are large sawflies (woodwasps) whose larvae bore in the trunks of trees. The adults have a cylindrical body; the female has a short, strong ovipositor which is the source of the name horn-tail. With this organ, holes are drilled into the wood of the tree for deposition of eggs. Among these is the species *Cimbex americana*, the *elm sawfly*.

The *pear slug* (*Caliroa cerasi*, Linne) is the olive to dark green or black larva of a shiny black sawfly. The larva resembles a snail or slug and ranges up to $\frac{1}{2}$ inch (12 millimeters) in length. The larva feeds on the upper surface of cherry, pear, and plum trees, retards growth and development of fruit, and generally weakens the tree. The pest is distributed throughout the United States. Chemical controls are the same as those for fruit curculios. See also **Curculio**. In small orchard operations, handpicking the larvae from the leaves and placing them in a pail containing kerosene is effective. Also, a few applications of lime diluted with water and applied to the leaves is effective. The slugs can be washed from the foliage with a strong stream of water and then destroyed at groundlevel.

Knerer and Atwood have made an extensive study of the polymorphism and speciation of *Diprionid* sawflies, and this is reported in *Science*, **179** (4078), 1090–1099 (1973). The *Diprionidae* represent only a small fraction of all the sawflies known, but they share the habits of most other leaf feeders. The family is interesting mainly because of the diversity of distinct races or physiological strains that are adapted to specific host plants, and because of the social behavior exhibited by the larvae in aggregations. Both phenomena illustrate various evolutionary mechanisms at work, simultaneously providing examples of newly emerging biologic units and of the origin of some of the most primitive social behavior found in insects. These factors are well summarized by Knerer and Atwood.

SAYBOLT UNIVERSIAL VISCOSITY. The efflux time in seconds (SUS) of 60 mL of sample flowing through a calibrated Universal orifice in a Saybolt viscometer under specified conditions.

See also **Viscosity**; and **Viscometer**.

SAYBOLT VISCOSIMETER. See **Viscosity**.

S-BAND. A frequency band used in radar extending approximately from 1.55 to 5.2 kilomegacycles per second.

SCABIES. See **Dermatitis and Dermatosis**.

SCAD *(Osteichthyes)*. Of the order *Percomorphi*, suborder *Percoidea*, family *Carangidae*, the scad is a species of fish common in the region of the West Indies. The scad is also called cigar fish or round robin. The big-eyed scad, goggler, or chicharro is related and although common in warmer waters, does range as far north as Cape Cod. The term *scad* also has been applied to the related horse mackerel, a European species occasionally taken on the Atlantic coast of North America.

SCALAR. Any physical quantity with a field that can be described by a single numerical value at each point in space. A scalar quantity is distinguished from a vector quantity by the fact that a scalar quantity possesses only magnitude, whereas a vector quantity possesses both

magnitude and direction. Thus, pressure is a scalar quantity and velocity is a vector quantity.

SCALAR FIELD. Consider the space reflection $x' \rightarrow;\ x;\ \mathbf{x}' = -\mathbf{x}$, $x'^{\mathrm{o}} = x^{\mathrm{o}}$. Define the transformation of a spinless field operator under space reflection such that

$$\phi'(x') = P\phi(x)P^{-1}$$
$$= \eta\phi(x')$$

Where η_{p} is a complex constant and P the unitary operator which induces the transformation. If the operator of space reflection is performed twice, we must revert to the original field so that $\eta_{\mathrm{p}^2} = 1$ or $\eta_{\mathrm{p}} = \pm 1$. A field which transforms with $\eta_{\mathrm{p}} = +1$ is called a *scalar field*, while one that transforms with $\eta_{\mathrm{p}} = -1$ is called a *pseudoscalar field*. The particles described by scalar (pseudoscalar) fields have an intrinsic parity $+1(-1)$.

SCALAR PRODUCT. See **Vector Multiplication**.

SCALAR QUANTITY. A number, either in the sense of the ratio between two quantities of the same kind, or as distinguished from other mathematical constructs, e.g., vectors, matrices, etc.

SCALD FISHES. See **Flatfishes**.

SCALE. Common uses of this term are:

1. A balance used for weighing. A **weighing scale** (usually just "scale" in common usage) is a device for measuring the weight of an object. These scales are often used to measure the weight of a person, and are also used in science to obtain the mass of an object, and in many industrial and commercial applications to determine the weight of things ranging from feathers to loaded tractor-trailers.

Weighing scales are also sometimes used to measure force rather than mass.

Balances. A **balance** (also **balance scale**, **beam balance** or **laboratory balance**) is used to measure the mass of an object. In its conventional form, this class of measuring instrument compares the sample, placed in a weighing pan (weighing **basin**) and suspended from one end of a beam with a standard mass or combination of standard masses in a scale pan (scale basin) suspended from the other end. To weigh an object in the measuring pan, standard weights are added to the scale pan until the beam is in equilibrium as closely as possible. Then a slider weight usually present is moved along a scale on or parallel to the beam (and attached to it) until fine balance is achieved. The slider position gives a fine correction to the mass value.

Spring Scales. Some weighing scales such as a **Jolly balance** (named after Phillipp Gustav von Jolly who invented the balance about 1874) use a spring with a known spring constant (see Hooke's law) and measure the displacement of the spring by any variety of mechanisms to produce an estimate of the gravitational force applied by the object, which can be simply hung from the spring or set on a pivot and bearing platform. Rack and pinion mechanisms are often used to convert the linear spring motion to a dial reading.

Spring scales typically measure force, which can be measured in units of force such as newtons or pounds-force.

Spring scales typically cannot be used for commercial applications unless their springs are temperature compensated or used at a fairly constant temperature. The spring scales which are legal for commerce can be calibrated for the accurate measurement of mass (the quantity measured for weight in commerce) in the location in which they are used. They can give an accurate measurement in kilograms or pounds for this purpose.

2. A series of markings at regular intervals which are used for measurement or computation.

3. A defined set of values in terms of which quantities of the same nature as those defined may be measured, e.g., temperature scale.

4. In music, a **scale** is a set of musical notes that provides material for part or all of a musical work. Scales are typically ordered in pitch, with their ordering providing a measure of musical distance. Scales differ from modes in that scales do not have a primary or "tonic" pitch. Thus a single scale can have many different modes, depending on which of its notes is chosen as primary.

The distance between two successive notes in a scale is called a "scale step." Composers often transform musical patterns by moving every note in the pattern by a constant number of scale steps: thus, in the C major scale, the pattern C-D-E ("doe, a deer") might be shifted up a single scale step to become D-E-F ("ray, a drop"). Since the steps of a scale can have various sizes, this process introduces subtle melodic and harmonic variation into the music. This variation is what gives scalar music much of its complexity.

Scales may be described according to the intervals they contain:

- for example: diatonic, chromatic, whole tone

or by the number of different pitch classes they contain:

- most common: pentatonic, hexatonic, heptatonic or five, six, and seven tone scales, respectively.
- used in prehistoric music: *ditonic* or two, *tritonic* or three, *tetratonic* or four
- most commonly in jazz and modern classical music: octatonic or eight.

Scales are often abstracted from performance or composition, though they are often used precompositionally to guide or limit a composition. One or more scales may be used in a composition, such as in Claude Debussy's *L'Isle Joyeuse*. Below, the first scale is a whole tone scale, while the second and third scales are diatonic scales. All three are used in the opening pages of Debussy's piece.

5. An important property of a map is the **scale**. It can be indicated by a scale bar and/or a ratio 1:n. This enables the map user to measure a distance on the map and determine the distance on the ground. These days maps are usually produced under the metric system which makes it easy to perform this task. Maps are usually produced at standard scale factors of (say) 1:10,000 or 1:50,000 or 1:100,000 and all you need to do is take a measurement on the map (in mm) and multiply that figure by the scale factor to determine the distance on the ground.

6. **Scale** in the computing field is used as a verb.

An algorithm, design, networking protocol, program, or other system is said to **scale** if it is suitably efficient and practical when applied to large situations (e.g. a large input data set or large number of participating nodes in the case of a distributed system). For example, the distributed nature of the Domain Name System allows it to work efficiently even when all hosts on the worldwide Internet are served, so it is said to "scale well".

7. In mathematics a **logarithmic scale** is a scale of measurement that uses the logarithm of a physical quantity instead of the quantity itself. Presentation of data on a logarithmic scale can be helpful when the data covers a large range of values; the logarithm reduces this to a more manageable range. Some of our senses operate in a logarithmic fashion (doubling the input strength adds a constant to the subjective signal strength), which makes logarithmic scales for these input quantities especially appropriate. In particular our sense of hearing perceives equal ratios of frequencies as equal differences in pitch. See also **Logarithm**.

Logarithmic scales are either defined for *ratios* of the underlying quantity, or one has to agree to measure the quantity in fixed units. Deviating from these units means that the logarithmic measure will change by an *additive* constant. The base of the logarithm also has to be specified, unless the scale's value is considered to be a dimensional quantity expressed in generic (indefinite-base) logarithmic units.

On most logarithmic scales, *small* values (or ratios) of the underlying quantity correspond to *small* (possibly negative) values of the logarithmic measure. Well-known examples of such scales are:

- Richter magnitude scale for strength of earthquakes and movement in the earth.
- bel and decibel and neper for acoustic power (loudness) and electric power;
- cent, minor second, major second, and octave for the relative pitch of notes in music;
- logit for odds in statistics;

- Palermo Technical Impact Hazard Scale;
- Logarithmic timeline;
- counting f-stops for ratios of photographic exposure;
- rating low probabilities by the number of 'nines' in the decimal expansion of the probability of their not happening: for example, a system which will fail with a probability of 10^{-5} is 99.999% reliable: "five nines".
- Entropy in thermodynamics.
- Information in information theory.

Some logarithmic scales were designed such that *large* values (or ratios) of the underlying quantity correspond to *small* values of the logarithmic measure. Examples of such scales are:

- pH for acidity;
- stellar magnitude scale for brightness of stars;
- Krumbein scale for grain size in geology.
- Kardashev scale for technological advance in physics.

8. An **architect's scale** is a specialized ruler. It is used in making or measuring from reduced scale drawings, such as blueprints. It is marked with a range of calibrated scales (ratios).

The scale was traditionally made of wood but for accuracy and longevity the material used should be dimensionally stable and durable. Today they are now more commonly made of rigid plastic or aluminum. Depending on the number of different scales to be accommodated architect's scales may be flat or shaped with a cross-section of an equilateral triangle.

In the United States, and prior to metrification in Britain, Canada and Australia, architect's scales are/were marked as a ratio of x inches-to-the-foot. For example one inch measured from a drawing with a scale of "one-inch-to-the-foot" is equivalent to one foot in the real world (a scale of 1:12) whereas one inch measured from a drawing with a scale of "two-inches-to-the-foot" is equivalent to six inches in the real world (a scale of 1:6).

Typical scales used in the United States are:

- Full scale, with inches divided into sixteenths of an inch

The following scales are generally grouped in pairs using the same dual-numbered index line:

- three-inches-to-the-foot (1:4)/one-and-one-half-inch-to-the-foot (1:8)
- two-inches-to-the-foot (1:6)/one-inch-to-the-foot (1:12)
- three-quarters-inch-to-the-foot (1:16)/three-eighths-inch-to-the-foot (1:32)
- one-half-inch-to-the-foot (1:24)/one-quarter-inch-to-the-foot (1:48)
- one-eighths-inch-to-the-foot (1:96)/one-sixteenths-inch-to-the-foot (1:192)

Metric Units. Architect's scale rulers used in Britain and other metric areas are marked with ratios without reference to a base unit. Therefore a drawing will indicate both its scale and the unit of measurement being used.

In Britain the standard units used on architectural drawings are the SI units millimetres (mm) and metres (m), whereas in France centimetres (cm) and metres are most often used.

In Britain, for flat rulers, the paired scales often found on architect's scales are:

- 1:1/1:100
- 1:5/1:50
- 1:20/1:200
- 1:1250/1:2500

and for triangular rulers:

- 1:1/1:10
- 1:2/1:20
- 1:5/1:50
- 1:100/1:200
- 1:500/1:1000
- 1:1250/1:2500

9. An **engineer's scale** is a ruler, a tool for measuring distances. It is commonly made of plastic and is just over twelve inches long, so that the measuring ticks at the edges do not become unusable by wear. It is used in making engineering drawings, commonly called blueprints, in scale. For example, "one-tenth size" would appear on a drawing to indicate a part larger than the paper itself. It is not to be used to measure the machined parts to see if these meet the specifications.

This scale is divided into decimalized fractions of an inch, but has a cross-section like an equilateral triangle, which enables the scale to have six edges indexed for measurement. One edge is divided into tenths of an inch, and the subsequent ones are directly marked for twentieths, thirtieths, fortieths, fiftieths, and finally sixtieths of an inch.

On a metric engineer's scale, common scales are 1:100, 1:200, 1:250, 1:300, 1:400, and 1:500.

The engineer's scale came into existence when machining parts required a greater precision than the usual, binary fractionalization of the inch as in the architect's scale for houses and furniture. They were used, for example, in laying out printed circuit boards with the spacing of leads from integrated circuit chips as one-tenth of an inch. In the twenty-first century, those which are commonly purchased in the US are actually made in Germany.

10. In Food sciences the **Zadoks scale** is a cereal development scale proposed by the Dutch phytopathologist Jan C. Zadoks that is widely used in cereal research and agriculture.

Knowing the stages of development of a crop is critical in many management decisions that growers make. They are represented on a scale from 10 to 92. For example, in some countries, nitrogen and herbicide applications must be completed during the tillering stage. In France, the recommendation for the first nitrogen application on wheat is 6 weeks before Z30, with the second application on Z30. Wheat growth regulators are typically applied at Z30. Disease control is most critical in the stem extension and heading stage (Z31, Z32, Z35), in particular as soon as the flag leaf is out (Z37). The crop is also more sensitive to heat or frost at some stages than others (for example, during the meiosis stage the crop is very sensitive to low temperature). Knowing the growth stage of the crop when checking for problems is essential for deciding which control measures should be followed.

Examples of typical stages:

- during tillering
  - Z10: one leaf
  - Z21: tillering begins
- during stem extension
  - Z30: ear is one centimeter long in wheat
  - Z31: first node visible
  - Z32: second node visible
  - Z37: flag leaf
- during heading
  - Z55: the head is 1/2 emerged.
- during ripening
  - Z92: grains are ripe

Another cereal development scale is the *Feekes scale*.

11. In Mineralogy the **Mohs' scale of mineral hardness** characterizes the scratch resistance of various minerals through the ability of a harder material to scratch a softer material. It was created, in 1812, by the German mineralogist Friedrich Mohs and is one of several definitions of hardness in materials science.

Mohs based the scale on ten minerals that are all readily available except the last one, diamond. The hardness of a material is measured against the scale by finding the hardest material that the given material can scratch, and/or the softest material that can scratch the given material. See also **Hardness**.

12. In Atmospheric sciences: Celsius scale, Fahrenheit Scale, Kelvin scale, Saffir-Simpson Hurricane Scale, Fujita scale (tornadoes), and

Beaufort scale (wind). See also **Celsius**; **Fahrenheit Temperature Scale**; **Fronts and Storms**; **Temperature**; **Tornado**; and **Winds and Air Movement**.

13. In metallurgy, scale is the oxide layer that forms on the surface of metals upon heating in air or other oxidizing gases. The heavy scale that forms on steel ingots or billets upon heating for rolling or forging breaks away as the metal is deformed in the mill or under the hammer; however a lighter, often very adherent scale always remains after hot-working operations and after annealing or other heat treatments unless a nonoxidizing protective atmosphere is provided. Scale is removed from steel by pickling, generally in warm dilute sulfuric or hydrochloric acid. The scale which forms on stainless steel is much more resistant and its removal requires strong acids such as mixtures of hot nitric and hydrofluoric. A tight adherent scale is often left on steel for its protective value; for example, steam-blued steel sheets are used for stovepipe.

14. In animal anatomy, a scale is a flat structure developed as a covering. (A) The scales of fishes are in many cases arranged like shingles to form a complete armor at the surface of the body, and in other forms are small and scattered, merely adding to the resistant qualities of the skin. The elasmobranch fishes have placoid scales, whose form includes a broad base and a projecting enamel-covered point. This form of scale is much like the teeth of these fishes and is supposed to be ancestral to all vertebrate teeth. *Ganoid scales*, found in relatively few fishes, are regarded as a modification of the placoid type by the loss of the point and the addition of a hard outer layer known as ganoin. Some of the more primitive fishes of other groups have rounded scales, with smooth margins, known as cycloid, and others have ctenoid scales, with comb-like edges. The two last forms are found in the higher fishes. They bear neither enamel nor ganoin. (B) The scales found over the entire surface of the body in reptiles, on the legs of birds, and to a much more limited extent in mammals, as on the tails of rodents, are quite different from the scales of fishes. Each is a modified area of the skin, thickened and hardened by the development of the horny substance, keratin. Scales reach their highest development among the mammals in the pangolins and armadillos. In the latter they are underlaid by bony plates. (C) The butterflies and moths, a few beetles, and some other insects have the surface of the body and wings more or less covered by flattened scales. These structures are modified setae. They often contain pigments and in many species are so formed that they produce iridescent, metallic, or glossy physical colors by breaking up the light rays they reflect. (D) Scale insects, often called scales, are highly specialized sucking insects that live on plants. They belong to the order *Hemiptera* and are related to the plant lice and phylloxerans. Most species are minute. The young and the female adults are simplified and remain closely attached to the plant, secreting over themselves a protective covering or scale which gives them their name. This covering is usually characteristic of the species.

Scale insects include many species of economic importance. Among them are the useful cochineal insect, a source of dye, and the lac insect whose scale is the raw material from which shellac is made. China wax is also a scale insect product. Among the harmful species the purple scale of citrus fruits, the San José scale, and the oystershell scale are important. Because of the protective scale these species are not easily destroyed by the usual contact sprays. They are controlled by spraying but the concentration of poison must be high and spraying during the dormant stage of the plant is often necessary as a result. Fumigation of citrus trees with cyanide is practiced extensively. This method requires special equipment since the tree must be enclosed in a tent. See also **Scale Insects**.

SCALE FACTOR (Computer System). In analog computing, a proportionality factor which relates the magnitude of a variable to its representation within a computer. In digital computing, the arbitrary factor that may be associated with numbers in a computer to adjust the position of the radix so that the significant digits occupy specified columns.

SCALE FISH. See **Flatfishes**.

SCALE HEIGHT. The height within which some parameter, such as pressure or density, decreases by a factor $1/e$ in an isothermal atmosphere. The term is most often used in an ionospheric context, but is equally applicable to the neutral atmosphere. It is a measure of the effective "thickness" of an atmospheric layer and is expressed mathematically as

$$H = \frac{kT}{mg} = \frac{R^*T}{Mg}$$

where T, m, and g are, respectively, the absolute temperature, the molecular mass, and the acceleration due to gravity; R^* is the universal gas constant; and k is Boltzmann's constant.

See also **Atmospheric Pressure**.

AMS

SCALE INSECTS *(Insecta, Hemiptera)*. These insects include numerous species of the family *Coccidae*, of which the mealy bugs also are members. However, there is a marked contrast: Whereas the mealy bugs can move about freely, the scale insects, within a few hours after birth or hatching, remain fixed throughout the remainder of their life. The typical scale insect may be described as wingless and grub-like in appearance, but masked by a covering of a cottony, powdery, or waxy secretion. In some species, this coating hardens into a scale-like shell or skin — hence the term *scale insects*. See Fig. 1. Generally, the scale insects tend to become specialists, thriving on a few select trees and fruits as their source of food and habitat. For certain food crops, such as apple, citrus, and other deciduous fruits, the scale insects are regarded as very damaging pests. The insects are found throughout the world wherever these crops are cultivated.

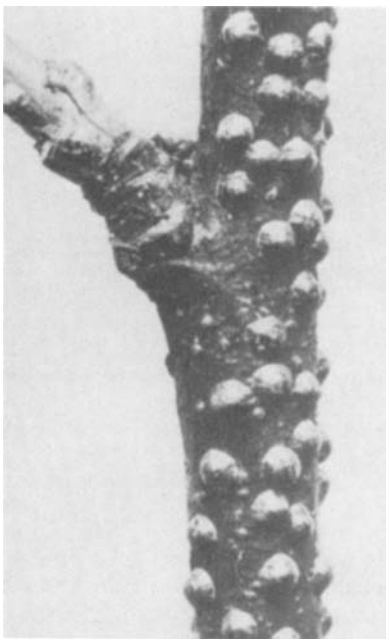

Fig. 1. Terrapin scale attached to twig of peach tree.

The scale-like coverings make it difficult to kill these insects. They are very small and thus easy to transport as stock may be moved from a glasshouse or nursery for transplanting. They multiply very rapidly. For example, researchers have found that a single female of the *San Jose species* can rear from 100 to 600 young at a rate of 4 to 5 generations per year. It has been established that one *Lecanium scale insect* can lay over 2000 eggs. Fortunately, the scale insects have a number of natural enemies which most likely control the highest percentage of these pests, even though chemical intervention is often required to make up for any deficiencies of the natural enemies. A number of years ago, the *cottony cushion scale* (*Icerya purchasi*) was accidentally introduced into California. Originally an Australian insect, this scale multiplied very fast once free of its natural enemies and spread rapidly over the West Coast citrus crop. A very large measure of control was accomplished biologically by the purposeful introduction of lady beetles which have a great preference for this scale insect as a food source. Parasitic wasps and mites also are effective in naturally keeping the scale populations under control.

Because the scale insects have a considerable amount of built-in protection, however, including an ability to tightly attach themselves to the bark of trees, which makes them difficult to remove by washing, for years the most effective means of controlling really bad infestations has been the use of various fumigants, notably cyanogen gas. Gastight buildings for use in treating plants prior to transplanting have been used, as well as large tent-like enclosures over trees, glasshouses, and other buildings. For mild populations of the insects, however, various sprays, such as oil and kerosene emulsions, sometimes lime-sulfur formulations, and even soap solutions (under high pressure), are effective. In some cases, mechanical scraping of bark or twigs can be effective.

The principal damage caused by scale insects is their sucking out plant juices, causing discolored (sometimes red) spots on leaves, stems, and fruit. Wounds make excellent sites for invasion by fungus spores.

Following is an abridged list of various scale insects that are damaging to crops.

Barnacle Scale (*Ceroplastes cirripediformis*). Found on citrus and Eupatorium. Insect is about $\frac{1}{5}$ inch (5 millimeters) in length. Scales are dark brown and surface of scale sculptured to appear like miniature barnacles.

Black Scale (*Saissetia olex; Lecanium oleae*). Found on citrus and deciduous fruits; olive. Insect is oval-shape, about $\frac{1}{4}$ inch (6 millimeters) in diameter. Scale covering is black. On back of female, there is an H marking. Scales secrete honeydew, providing a locale for fungus to grow, thus smutting the fruit.

Black Parlatoria Scale (*Parlatoria zizyphus*). A pest to citrus in many parts of the world. The insect spends most of its life beneath a dull-black scale. It gives off a whitish or brownish secretion that sometimes extends beyond the scale. The female is about $\frac{1}{16}$ inch (1.5 millimeters) long; the male is somewhat smaller. The insects attach themselves to leaves and fruit of citrus. When abundant, they form a black crust. A heavy infestation causes the leaves to turn yellow and drop and prevents full development of the fruit.

Coconut Scale (*Aspidiotus destructor*). Found mainly on coconut. Insect is white to cream in color and has transparent scales. The insects frequently are found in large numbers on underside of leaves and fruit.

Cottony Cushion Scale (*Icerya purchasi*). Found on almond, apricot, citrus, and fig. Insect is red to yellowish in color and covered with comparatively large, white, fluted cottony masses for covering eggs. Insect is from $\frac{1}{4}$ to $\frac{1}{2}$ inch (6 to 12 millimeters) in length. Control is mainly by natural enemies, such as *Vedalia* lady beetle. See Fig. 2.

Fig. 2. Cotton cushion scale insects on orange tree. (*USDA*.)

Date Palm Scale (*Parlatoria blanchardii*). Found mainly on date palm. A small, elongate insect having gray or black scales with white edges. The males are always white.

European Fruit Scale (*Lecanium corni*). Found mainly on plum. A rather large, circular-shaped insect which sometimes can be very destructive.

Euonymous Scale (*Chionaspis evonymi*). Found on small trees and shrubs of genus *Euonymous*. Insect is about $\frac{1}{12}$ inch (2 millimeters) in diameter with dark brown, convex scales on female and pure white scales on males.

Fig Scale (*Lepidosaphes ficus,* Signoret). This insect is a pest in fig orchards and traces of its presence may persist on the fruit after harvest. When infestation on the leaves becomes heavy, crawlers go to the developing fruit, settle, and feed on the green fig. Heavy infestations result in dried figs that are somewhat spotted and deformed.

Florida Red Scale (*Chrysomphalus aonidum*). Found on aspidistra (Asian herb and sometimes houseplant), *Betula* (alder and birch trees), citrus, coconut, and *Hedera* (woody vines; true ivy). Insect is circular with flat brown scales. Size ranges from $\frac{1}{16}$ to $\frac{1}{8}$ inch (1.5 to 3 millimeters) in diameter. Infestations require fumigation. See Fig. 3.

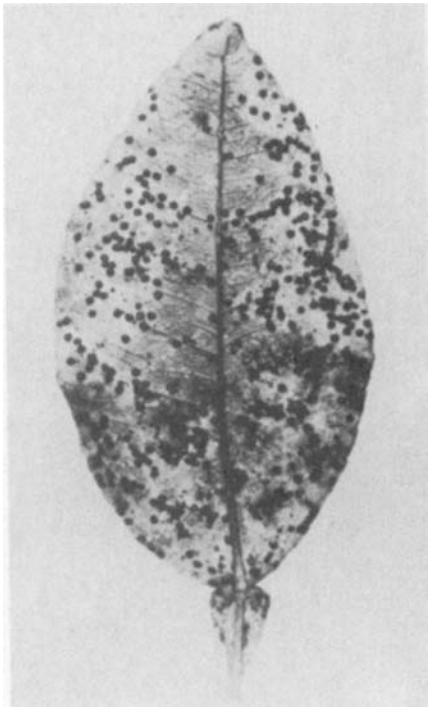

Fig. 3. Infestation of Florida red scale insects on tree leaf. (*USDA*.)

Frosted Scale (*Eulecanium pruinosum*). Found on apricot, *Betula* (particularly birch in California), and *Laurus*. Insect is comparatively large (about $\frac{1}{2}$ inch; 12 millimeters long), is hemispherical in shape, and has a frosty-appearing wax covering.

Hemispherical Scale (*Saissetia hemisphaerica*). Found on *Betula*, citrus, coffee, *Cycas*, ferns, guava, *Hedera*. Insect is covered with a smooth, soft scale without markings. Very commonly found in glasshouses.

Japanese Wax Scale (*Ceroplaste ceriferus*). Found mainly on gardenia, but can spread to other plants. Insect is from $\frac{1}{4}$ to $\frac{1}{3}$ inch (6 to 8 millimeters) in diameter. It is covered with white-to-creamy waxy masses.

Juniper Scale (*Diaspis carueli*). Found mainly on juniper, but can spread to other plants. Insect is snow white with circular scales and with yellow central exuviae.

Oyster Scale (*Lepidosaphes ulmi*). Found on apple, *Betula*, *Ceanothus*, *Crataegus*, currant, and poplar. Sometimes also called the bark louse, this scale is about $\frac{1}{8}$ inch (3 millimeters) long and resembles an oyster shell in shape. The insect hibernates as small white eggs under old scales. The young hatch in late spring and appear as whitish lice crawling on the bark.

Pineapple Scale (*Diaspis bromeliae*). Found on *Billbergia*, olive, and pineapple. The insect is thin and circular, usually with very white scales and yellow exuviae infesting the leaves and fruit.

Pine Leaf Scale (*Chionaspis pinifoliae*). Found mainly on pine trees. The insect is quite small with white scales.

Pit-Making Oak Scale (*Asterolecanium variolosum*). Found mainly on oak. The insect is circular in shape and has glossy greenish-yellow scales. The scale is particularly damaging to the golden oak.

Purple Scale (*Lepidosaphes beckii*). Found on citrus, *Codiaeum*, fig, and olive. The insect ranges from a reddish-brown to a rich purple in color and has oyster-shell shaped scales. The insect is from $\frac{1}{16}$ to $\frac{1}{8}$ inch (1.5 to 3 millimeters) in length.

Rose Scale (*Aulacaspis rose*). Found mainly on rose. The insect is circular, with small whitish scales.

San Jose Scale (*Aspidiotus perniciosus*). One of the better known and more damaging of the scales. Found on almond, apple, cherry, *Cornus*, *Crataegus*, currant, pear, plum, *Sorbus*, etc. The insect is nearly circular and about as large as a pinhead. See Fig. 4. When in large numbers, the insects form a crust on branches, causing small red spots on the fruit. This scale multiplies with amazing rapidity. Three to four broods per year are possible. The young are born alive. Breeding goes on until quite late in the autumn, at which time all stages of the insect are killed, with exception of the small, half-grown black scales which often hibernate through the winter safely. The scale also sometimes attacks rose, gooseberry, elm, chestnut, oak, and walnut.

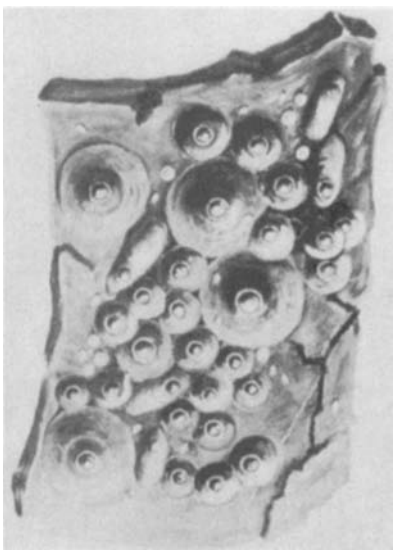

Fig. 4. Magnified view of San Jose scale insects fastened to branch of fruit tree. (*USDA*.)

Scurfy Scale (*Chionaspis furfurus*). Found on apple, *Crataegus*, and *Sorbus*. The insect is pearl-shaped, white to off-white in color, and about $\frac{1}{8}$ inch (3 millimeters) long. The insect frequently becomes intimately encrusted to the bark, with a resulting scurfy appearance of the bark. Hibernation is in the form of purple eggs located under old scales.

Soft Brown Scale (*Coccus hesperidum*). Found on citrus, *Cycas*, fig, *Hedera*, *Ipomoea*, jasmin, and *Laurus*. The insect is oval-shaped, flat, about $\frac{1}{4}$ inch (6 millimeters) long, and with flat, soft scales.

White Peach Scale (*Diaspis pentagonia*). Found on *Cycas*, *Diospyros*, *Laurus*, and peach. The insect is circular in shape, with gray scales and with exuviae at one side of center.

Several closely related scale insects have had economic significance outside the realm of agriculture over the years. Some have been used as the source of dyes, such as cochineal (*Coccus cacti*), a species very common in Mexico, and the scarlet grains (*Coccus poionicus*), which occur in Poland on the roots of the knawel plant and once were used as a source of dye for fabrics. One scale, known as the wax insect of China (*Coccus sinensis*) has been used for centuries as a source of wax used in candles, lacquers, sealers, and varnishes. The shell-lac insects (from which shellac is derived) are closely related.

The iridescent covering secreted by some of the scale insects, known as *ground pearl*, is useful in making ornaments.

More detail on scale insects can be found in *Foods and Food Production Encyclopedia* (D.M. and G.D. Considine, eds.), Van Nostrand Reinhold, New York, 1982.

SCALES (Fish). See **Fishes**.

SCALE (Weighing). See **Weighing**.

SCALING (Boiler). See **Feedwater (Boiler)**.

SCALING CIRCUIT. A circuit that produces an output pulse whenever a prescribed number of input pulses have been received. A binary scaler produces an output pulse whenever two input pulses have been received. By putting binary scalers in sequences, scales of two, four, eight, sixteen, etc., are obtained. A decade scalar produces an output pulse whenever ten input pulses have been received. By putting decade scalers in sequence, scales of ten, one hundred, one thousand, etc., are obtained.

SCALLOP. See **Mollusks**.

SCANDIUM. [CAS: 7440-20-2]. Chemical element, symbol Sc, at. no. 21, at. wt. 44.956, periodic table group 3, is a member of the rare earth group of elements along with yttrium and the lanthanides, mp 1541 °C (2,806 °F), bp 2831 °C (5,128 °F), density 2.989 g/cm^3 (alpha form), 3.73 g/cm^3 (beta form). The alpha form is close-packed hexagonal and beta is the face-centered cubic allotrope. Scandium is a relatively soft metal with a silvery luster. The metal is stable in air. Scandium combines readily with acids and at elevated temperatures with oxygen, halogens, and chalcogenides. ^{45}Sc occurs in nature and is not radioactive. Nine radioactive isotopes have been identified ^{40}Sc through ^{44}Sc and ^{46}Sc through ^{51}Sc, all with relatively short half-lives, ranging from a fraction of a second up to 84 days. Scandium occurs widely throughout nature, but in reasonably concentrated forms only in a few uncommon minerals. Abundance in the Earth's crust is estimated at approximately $5-6 \times 10^{-4}$%, ranking it ahead of such elements as antimony [CAS: 7440-36-0], bismuth [CAS: 7440-69-9], silver [CAS: 7440-22-4], and gold [CAS: 7440-57-5]. It is estimated that a cubic mile of seawater contains about 375 pounds (170 kilograms) of the element. Scandium was predicted by Mendeleev in 1869, at which time he called it *ekaboron* and foretold accurately a number of its properties. A small amount of scandium oxide was extracted from euxenite and gadolinite by the Swedish chemist Lars-Fredrick Nilson (Uppsala, Sweden) in 1879, a material that Nilson called *scandia*. In the same year, Cleve isolated a greater quantity of the oxide, from which several compounds were prepared and favorably compared with Mendeleev's predictions for ekaboron. See also **Chemical Elements: History of the Origin**. Ionic radius Sc^{3+} 0.745. First ionization potential, 6.54 eV; second, 12.80 eV; third, 24.76 eV. Other physical properties are given under **Chemical Elements**.

Scandium occurs in some ores with the Rare Earth Series elements. It is easily separated from the Lanthanides, as well as yttrium, by taking advantage of the greater solubility of its thiocyanate in ether. The three recognized scandium minerals are thortveilite, a silicate; and sterrettite and kolbeckite, both phosphates. Wiikite and bazzite, complex niobates and silicates, are known to contain more than 1% scandium. The recovery of scandium from uranium and tungsten from mining tailings, however is the major source of the element. Scandium has not been found without the other Rare earth elements. The element usually is separated from ore extracts and concentrates by precipitation as the oxalate. Scandium metal with a purity of 99.9% has been produced.

In water solutions, the scandium ion has a triple positive charge. Studies show, however, that the simple Sc^{3+} ion seldom exists. Rather, the form is highly polymerized and hydrolyzed — with hydroxy-bonded structures. In forming compounds, scandium parallels aluminum, yttrium, gallium, indium, and tellurium. Several carbides of scandium have been reported,

the most stable carbide being ScC, including scandium clusters in fullerene cages.

Like the hydroxides of the Rare earth, scandium hydroxide, [CAS: 17674-34-9] $Sc(OH)_3$, is precipitated by addition of alkalies to solutions of scandium salts; however, the latter is precipitated at pH 4.9, while the former require pH 6.3 or more, a property which is utilized in one method of separation. Upon heating the hydroxide (or certain oxyacid salts), scandium oxide, [CAS: 12060-08-1] Sc_2O_3 is produced. Scandium hydroxide is less acidic than aluminum hydroxide [CAS: 21645-51-2] AlH_3O_3, requiring boiling potassium hydroxide [CAS: 1310-58-3] KOH solution to form the complex potassium compound, $K_2[Sc(OH)_5{\cdot}H_2O]{\cdot}3H_2O$.

All four trihalides of scandium are known. The trifluoride is very slightly soluble in H_2O, and is precipitated from scandium nitrate, [CAS: 13465-60-6] $Sc(NO_3)_3$, solutions by hydrofluoric acid [CAS: 7664-39-3] FH. It dissolves in alkali fluorides to yield the complex ion $[ScF_6]^{3-}$. The chloride is formed in solution by treating the hydroxide or oxide with hydrochloric acid [CAS: 7647-01-0] HCl, yielding hydrated crystals on concentration, which give hydroxychlorides on heating. The bromide is also prepared from the oxide or hydroxide and hydrobromic acid, or in anhydrous form from the oxide, carbon, and bromine, on heating. The iodide is also prepared by the latter method.

The thiocyanate is prepared in solution by adding ammonium thiocyanate, NH_4SCN to HCl solutions of the chloride. Both basic and double carbonates are known. The former is precipitated from Sc^{3+} solutions by adding carbonate solutions, and is probably $Sc(OH)CO_3{\cdot}H_2O$. The latter are obtained by the use of an excess of the soluble carbonate. Normal, basic, and double sulfates are known. The first exists in several degrees of hydration; the second is obtained as $Sc(OH)SO_4{\cdot}2H_2O$, by treating the normal sulfate tetrahydrate with the hydroxide. The alkali double sulfates and alums are obtained by treating the sulfate solution with an excess of the alkali (or ammonium) sulfate solution.

The nitrate is readily obtained by action of dilute nitric acid [CAS: 7697-37-2] HNO_3 on the hydroxide. In aqueous solution, the anhydrous nitrate yields a monobasic nitrate on heating.

To date, the applications for scandium and its compounds have been limited, mainly because of its high cost. The main uses of scandium are in sporting goods equipment and in lighting, including automotive headlights. In former application scandium is added to improve the strength of aluminum, while in the latter ScI_3 is used in metal halide arc lamps to increase the intensity and to improve the color rendition to match that of natural sunlight. Minor applications include: scandium substitution for yttrium in yttrium garnets for electronic uses, analytical standards, semiconductor applications, welding wire, and metallurgical research.

SCANNING. In radar meteorology, the motion of the radar antenna during data collection. Scanning usually follows a systematic pattern involving one of the following: 1) In horizontal scanning, used to generate PPI displays, the antenna is continuously rotated in azimuth around the horizon or is rotated back and forth in a sector (sector scanning); at the completion of each 360° or sector scan, the elevation angle of the scan typically is increased; 2) Vertical scanning, used to generate RHI displays, is accomplished by holding the azimuth constant while continuously varying the elevation angle of the antenna; at the completion of each vertical scan, the azimuth typically is incremented and the vertical scan proceeds in the opposite direction.

SCANNING MICROWAVE SPECTROMETER (SCAMS). A five channel scanning radiometer on *Nimbus-6* (launched June 1975) used to measure temperatures over ocean surfaces, water vapor, and liquid water. SCAMS was a precursor to the MSU used operationally on the TIROS-N (NOAA series) satellites since 1978.

See also **Nimbus Satellite Program**.

SCANNING MULTIFREQUENCY MICROWAVE RADIOMETER (SMMR). An instrument designed to measure precipitation rate, column-integrated liquid water and water vapor, sea surface temperature and wind speed, soil moisture, and sea ice concentration.

This radiometer flew on Seasat (launched in June 1978) and *Nimbus-7* (launched in October 1978). See also **Nimbus Satellite Program**; and **Satellites (Scientific and Reconnaissance)**.

SCANNING TUNNELING MICROSCOPE. This microscopic technique (STM), invented by Gerd K. Binnig and Heinrich Rohrer (IBM Research Laboratory, Zurich, Switzerland) in 1981, generates topographic images of surfaces with atomic resolution. With the STM, scientists have obtained previously unseen images of gold, silicon, nickel, oxygen, and carbon atoms. STM views can reveal flaws and contaminants in atomic surface structure. Detailed views of three-dimensional atomic "landscapes" are improving and will continue to improve the knowledge of surface physics and chemistry and thus be of exceptional value in technical fields as varied as metallurgy, magnetism, semiconductor technology, and biology. Before development of the STM technique, scientists had been puzzled about the exact surface structure of silicon, the basic material from which computer chips are made. Many models of the silicon surface have been constructed. The STM has enabled researchers to sort out prior assumptions and hypotheses. In connection with gold, the STM has revealed a surface structure created by the spontaneous formation of ribbon-like facets, features that previously had not been distinguished with such clarity. The renowned physicist, Wolfgang Pauli, many years ago observed, "The surface was invented by the devil," with reference to the fact that the surface of a solid is its boundary or interface with the environment outside and beyond the solid. Whereas atoms within a solid interact with other atoms within the solid, those atoms on the surface can interact only with those atoms directly underneath and those atoms in the environment beyond the surface. Thus, surface atoms behave with different rules.

Instrumental means for investigating the atomic pattern of surfaces have included electron microscopy and later (1950s), the field-ion microscope (invented by Edwin W. Müller). These techniques continue, but are generously abetted by the STM. In 1984, the inventors of the STM received the Hewlett-Packard Europhysics Prize for outstanding achievements in solid state physics and the King Faisal International Prize in Science. In 1986, Binnig and Rohrer shared in the Nobel Prize in Physics.

Expanded Applications of STM

Since its introduction for practical uses in the early 1980s, the scanning tunneling microscope has found scores of applications that were not contemplated at the outset of STM technology. These applications include the manufacture of optical grating masters, the manufacture of recording thin-film magnetic recording heads, the manufacture of compact disk stampers, and the repair of costly masks used for integrated circuit manufacture — just to mention a few examples of practical usage in the electronics field. STM can be operated under water and other fluids, permitting the examination of biological materials in a more natural setting. The versatility of the STM is demonstrated by the appearance of hundreds of technical papers in the literature over a 1-year period. The STM can achieve lateral resolution of 1 to 2 angstroms and, in the vertical dimension, better than 0.05 angstrom. To overcome the

relatively few limitations of STM, the technology has spawned several other microscopic techniques, including the atomic force microscope, the friction force microscope, the magnetic force microscope, the electrostatic force microscope, the attractive mode force microscope, the scanning thermal microscope, the optical absorption microscope, the scanning ion-conductance microscope, the scanning near-field optical microscope, the scanning acoustic microscope, and the molecular dipstick microscope — all resulting from the character of innovative thinking that scientists have come to apply to the application of new forms of energy to microscopy, once wholly dependent upon materials interactions with visible light. STM has played an invaluable role, not only in the development of new materials, but in understanding how surface atoms differ from the permanently embedded atoms of a material.

STM Fundamentals

As put forth in their excellent 1985 paper (reference listed), Binnig and Rohrer credit *electron tunneling* as the phenomenon that underlies the operation of the STM. As indicated by Fig. 1, an electron cloud occupies the space between the surface of the sample and the needle tip used. The cloud is a consequence of the *indeterminacy*[1] of the electron's location (a result of its wavelike properties). Because the electron is "smeared out" so to speak, there is a probability that it can lie beyond the surface boundary of a conductor. The density of the electron cloud decreases exponentially with distance. A voltage-induced flow of electrons through the cloud thus is extremely sensitive to the distance between the surface and the tip. As the STM tip is swept across the surface, a feedback mechanism senses the flow (the *tunneling current*) and holds constant the height of the tip above the surface atoms. In this way, the tip follows the contours of the surface. The motion of the tip is read and processed by computer and displayed on a screen or plotter. By sweeping the tip through a pattern of parallel lines, a high-resolution, three-dimensional image of the surface is obtained.

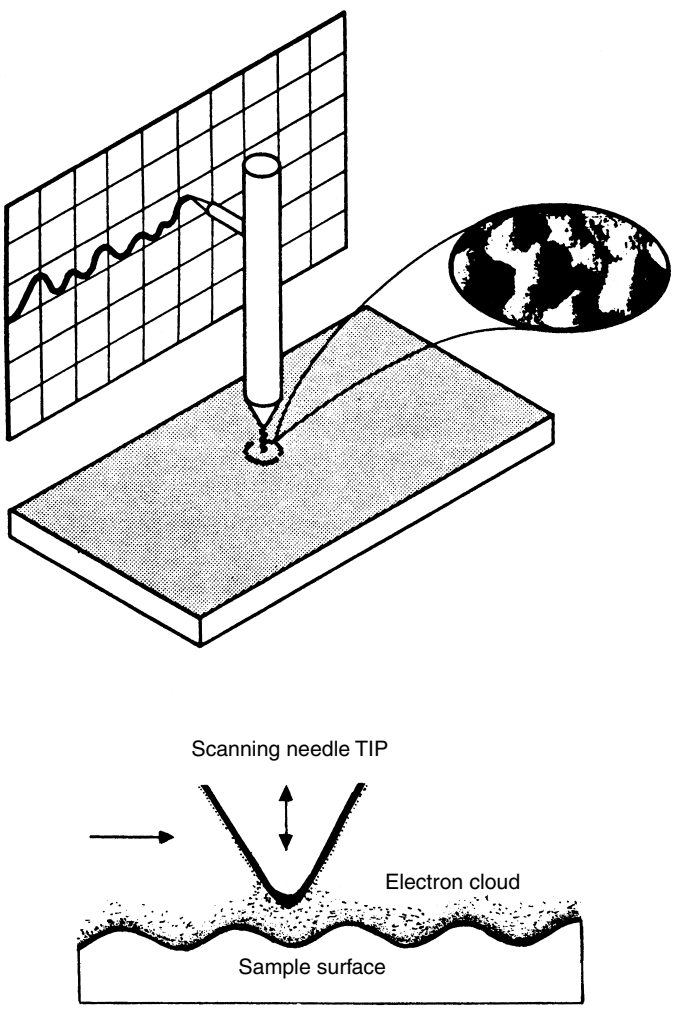

Fig. 1. As the probe tip of the STM is scanned across the microscopic "hills and valleys" of a surface, the vertical position of the probe is precisely adjusted to maintain a constant tip-to-surface distance. This is accomplished by keeping the tunneling current constant. Consequently, the probe follows the surface contour as it moves, yielding a 2-dimensional, enlarged representation of the surface contour for each such scan. A full 3-dimensional image is obtained by assembling an entire sequence of scans. (*IBM Corporation.*)

Views of the STM are shown in Figs. 2 and 3. Binnig and Rohrer describe the STM as having two stages, suspended from springs, that operate within a cylindrical steel frame. The microscope mechanism is contained by the innermost stage. Vibration is a severe problem, requiring special preventive measures. To obtain images with high resolution (Fig. 4) of surface structures, obviously the microscope must be protected from even very small vibrations as may be caused by sound and footsteps and other disturbances within the laboratory. To subdue vibration, copper plates are attached to the bottom of the stainless-steel frame and magnets are attached to the bottom of the inner and outer stages. Any disturbance causes the copper plates to move up and down in the field generated by the magnets. The movement induces eddy currents in the plates. Interaction of the eddy currents with the magnetic field retards the motion of the plates and thus the motion of the microscope stages. Where investigations require vacuum conditions, a steel cover is placed over the outer frame of the microscope.

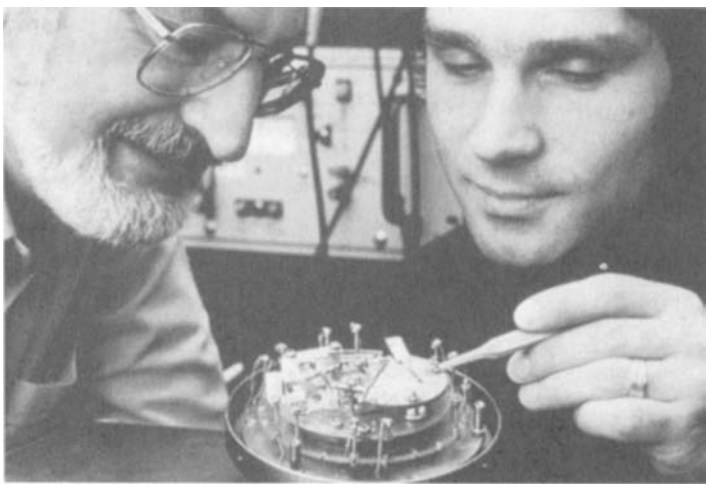

Fig. 2. Inventors Rohrer (left) and Binnig (right) shown adjusting the sample in the chamber of an early (1981) version of the scanning tunneling microscope. Later (1986), these scientists shared in the Nobel Prize in Physics for developing the STM instrument and technique. (*IBM Corporation.*)

The microscopic device incorporates a sample and a scanning needle. Piezoelectric materials (expand or contract with applied voltage) make it possible for the device to resolve features that are about a hundredth the size of an atom. A piezoelectric drive positions the sample on a horizontal metal plate and a piezoelectric tripod then sweeps the scanning needle over the surface of the sample, simultaneously achieving high stability and precision. See also Figs. 5 through 8.

Not only does the STM portray atomic topography, but it also reveals atomic composition. The inventors observe that the tunneling current depends both on the tunnel distance and the electronic structure of the surface and on the fact that each atomic element has an electronic structure unique to itself. The ability of the STM to resolve both topography and electronic structure assures wide use of the technique in numerous fields.

[1] The roots of atomic structure extend back over 50 years, to the development of the concept of quantum mechanics and experiments in 1927 by Davisson and Germer, the researchers who confirmed the wave nature of the electron. The first experimental verification of tunneling was made about three decades ago by Ivar Giaever.

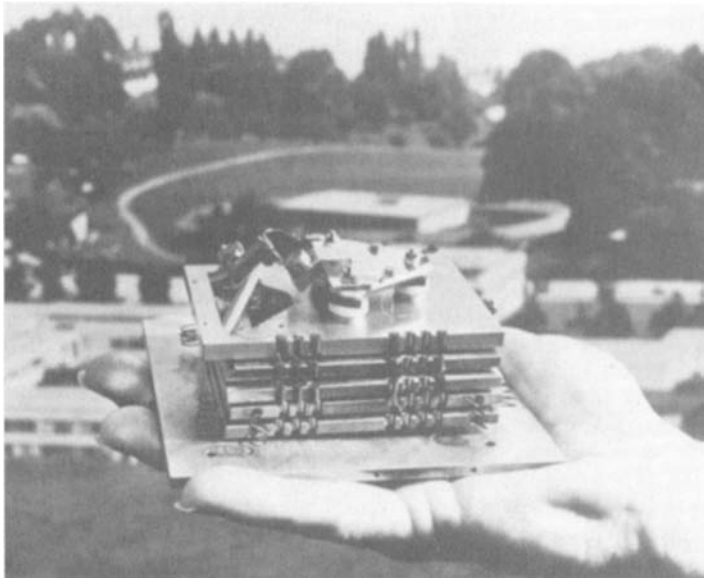

Fig. 3. Miniaturized version of the scanning tunneling microscope. The STM has become a very important tool for materials research and, in particular, to gaining new knowledge of computer chips. STMs are being used or are under construction by some fifty research groups worldwide in a broad range of physical, chemical, biological, and materials studies. (*IBM Corporation*.)

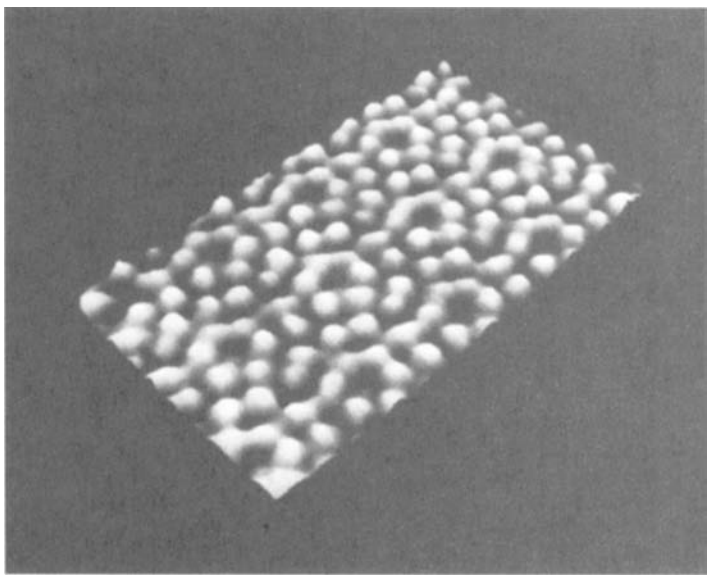

Fig. 4. Magnified millions of times are surface atoms of silicon. The image is computer-generated from data produced by a scanning tunneling microscope. (*IBM Corporation*.)

Unlike other imaging techniques, the STM does not alter or partially destroy the sample. The STM already has demonstrated its utility in biology even though lateral resolutions of only 10 angstroms can be achieved. In this instance, the relatively poor resolving power of the microscope is more than compensated for by its ability to provide a direct and nondestructive method of viewing biological samples. Researchers at the IBM Zurich Research Laboratory and the Swiss Federal Institute of Technology have scanned the surface of DNA and observed a series of zigzags which correspond to its helical structure. Researchers at the Autonomous University of Madrid have made detailed examinations of viruses, notably phi 29 which measures $40 \times 300 \times 200$ angstroms. It is currently visualized that the STM also will be very useful for testing electronic circuits, particularly as further reductions in size are achieved.

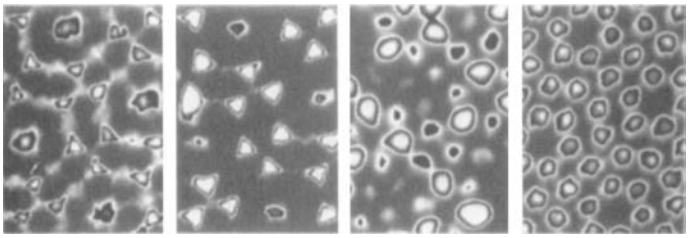

Fig. 5. Looking successively deeper into the atomic structure of silicon. Sequence shows surface magnified some ten million times, to a depth of about nine angstroms (36 billionths of an inch). Shown from left to right are the geometric positions of the atoms and three different classes of electronic bonds. (**a**) shows the position of the top atoms; (**b**) the dangling bonds that reach up from those atoms; (**c**) the dangling bonds that reach up from other atoms in the second layer in the surface; and (**d**) bonds (called "back bonds") that reach out sideways from the atoms in the second layer in the surface. (*IBM Corporation*.)

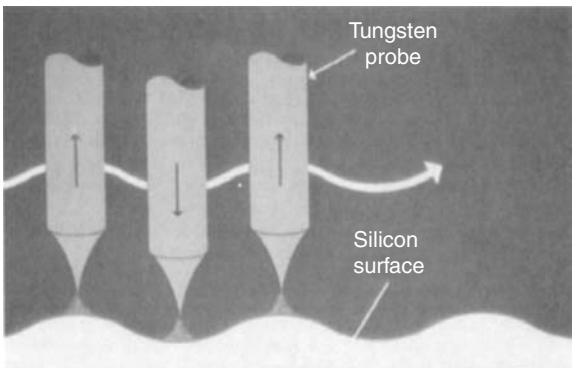

Fig. 6. As probe is scanned across silicon surface, its height above the surface is adjusted to keep the tunneling current constant. The monitoring of those height changes provides the desired topographic information. (*IBM Corporation*.)

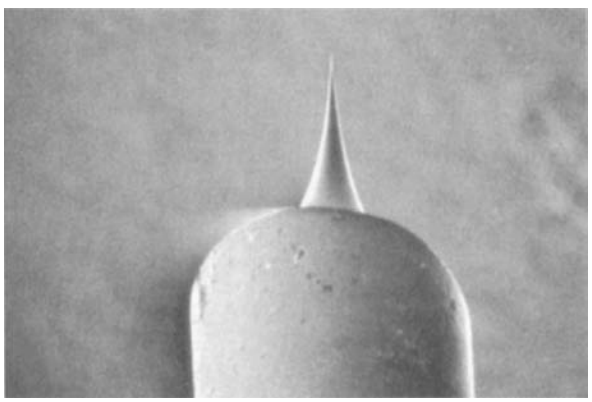

Fig. 7. Tungsten probe tip for scanning tunneling microscope as seen by a scanning electron microscope. Such probes, produced by field-ion microscopy, can be constructed with tips only one atom in width. (*IBM Corporation*.)

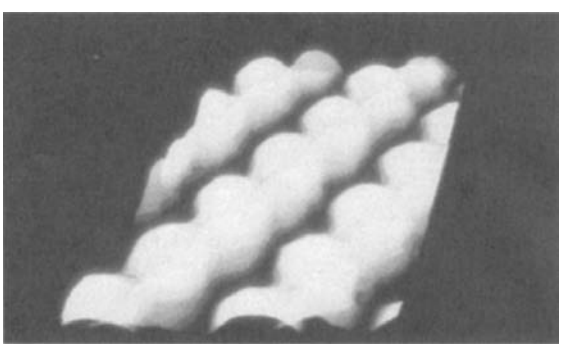

Fig. 8. Scanning tunneling microscope image of gallium arsenide (GaAs). Atoms to the left of each row are gallium; others are arsenic. (*IBM Corporation*.)

SCAPIE. See **Virus**.

SCAPOLITE. The mineral scapolite is a silicate of calcium and aluminum that contains also some potassium, sodium, and chlorine. The name identifies all intermediate members of a series with the following end members: Marialite $3Na(AlSi^3)O8 \cdot NaCl$, Meinoite $3Ca(Al^2Si^2)O^8 \cdot CaCO_3$. Its tetragonal crystals are coarse and thick, often very large. It occurs also in massive forms. It has a distinct prismatic cleavage; subconchoidal fracture; is brittle; hardness, 5.5–6; specific gravity, marialite, 2.5–2.62, meionite, 2.72–2.78; luster, vitreous to rather dull, color, white to gray, red, green, blue, or yellow; translucent to opaque, rarely transparent. The name comes from the Greek "skapos", meaning "shaft" alluding to its common long prismatic form.

Scapolite is found in the metamorphic rocks, particularly those rich in calcium; also in contact metamorphic deposits in limestones. It has been found in basic igneous rocks, probably as a secondary mineral. Notable localities are Lake Baikal, Siberia; Arendal, Norway; and Madagascar. In the United States, it is found in Massachusetts, New York, and New Jersey. Greenville, in the Province of Quebec, Canada is an important locality. Superb transparent yellow gem crystals have recently been found in Brazil and Tanzania. Wernerite (scapolite) was named in honor of A.O. Werner, a famous German mineralogist (1749–1817).

SCARAB *(Insecta, Coleoptera)*. A species of beetle that was regarded as sacred by the ancient Egyptians. The term is applied especially to the sculptured likenesses of the beetle. From this name the family *Scarabeidae* has arisen, containing, among the many North American species, the June bugs or May beetles, the tumble bugs, and the rose chafer.

SCARLET FEVER. Although staphylococci can induce a similar infection (scalded skin syndrome), Group A streptococci (*S. pyrogenes*) are essentially responsible for this disease, which is characteristically one of school children. There is no doubt that scarlet fever is caused by an erythrogenic toxin because its symptoms are reproduced by injection of filtrates of cultures of *S. pyrogenes* (the so-called Dick test). The disease is now regarded as a combination of the direct toxicity of the erythrogenic toxin together with a secondary toxicity due to hypersensitivity to a heat stable component of streptococcal toxin.

In the latter half of the nineteenth century, scarlet fever was the most common cause of death in children over one year old and was often simply referred to as "the fever." Although mild infections still are quite common, most instances escape attention and the disease has now virtually disappeared in the developed countries.

The disease is usually easy to recognize. An abrupt fever (100–103 °F; 37.8–39.5 °C) is accompanied by a disproportionate tachycardia. Coughing is notably absent. As well as an initial tonsillitis, an exanthem develops on the palate and the tongue is covered by a white fur through which red-tipped papillae project (*strawberry tongue*). The fur later peels off, leaving a raw red surface (*raspberry tongue*).

The rash, which is attributed to capillary damage, usually appears on the chest, neck, and arms within 24 hours of onset and lasts from 2 to 20 days before peeling begins with desquamation of fine flakes or large areas of skin.

All group A streptococci are still highly susceptible to benzyl penicillin and this, with closely related antibiotics, is the first choice for therapy. When penicillin allergy is suspected, erythromycin may be prescribed. In untreated patients, the possibility of subsequent development of rheumatic fever cannot be excluded. Otherwise, prognosis is excellent.

R. C. V.

SCARLET TANAGER. See **Tanager**.

SCATTER DIAGRAM. Also called scattergram. A plot representing corresponding observed values of two variables x and y as points in rectangular coordinates. If the two variables are functionally related, the points will be bunched, but if they are not functionally related, the points will be scattered uniformly over the plane.

Scatter diagrams are used to explore the influence of one variable upon another, strong relationships being revealed as a concentration around a definite curve. The Hertzsprung–Russel diagram showing individual stars is an example of a scatter diagram. See also **Coordinate System**.

SCATTERING. In its general sense, this term refers to the redistribution of a group of entities, or bringing about a less orderly arrangement, either in position or direction. Thus when visible light enters a body of matter, however transparent, part of it is diffusely reflected or "scattered" in all directions. This is due to the interposition in the light stream of particles of varying size, from microscopic specks down to electrons, and the deflection of light quanta resulting from their encounters with these small obstacles. Similar effects are produced upon infrared, ultraviolet, x-rays, and other forms of electromagnetic radiation, and upon streams of particles such as

cathode rays or alpha rays. More specifically, the term denotes the change in direction of particles or photons owing to collision with other particles or systems; it may also be regarded as the diffusion of a beam of sound or light (or other electromagnetic radiation) due to the anisotropy of the transmitting medium.

Coherent or elastic scattering, either of particles or photons, is scattering in which there are definite phase relations between incoming and scattered waves. Ordinary or Rayleigh scattering (defined below) is of this nature. In coherent scattering, interference occurs between the waves scattered by two or more centers. This type of scattering is exemplified by the Bragg scattering of x-rays and the scattering of neutrons by crystals, which gives constructive interference only at certain angles, called Bragg angles.

Rayleigh scattering is coherent scattering in which the intensity of the light of wavelength λ, scattered in any direction making an angle θ with the incident direction, is directly proportional to $1 + \cos^2\theta$ and inversely proportional to λ^4. The latter point is noteworthy in that it shows how much greater is the scattering of the short wavelengths. These relations apply when the scattering particles are much smaller than the wavelength of the radiation. Thus the sky is blue, and tobacco smoke appears blue, because blue light is scattered more than red. The unscattered light is of course complementary to blue, i.e., orange or yellow — which explains the "warm" hues of the sunset.

Mie scattering is any scattering produced by spherical particles without special regard to comparative size of radiation wavelength and particle diameter; to be contrasted, therefore, with Rayleigh scattering.

Rutherford scattering is a general term for the process in which moving charged particles are scattered at various angles by interaction with the nuclei of atoms of a solid material. In Rutherford's original work, high-speed α-particles from radon were focused in a narrow beam to strike a thin gold foil. Most of them pass through, but some are scattered.

On the other hand, *incoherent or inelastic scattering* is scattering in which the scattering elements act independently so that there are no definite phase relations between different parts of the scattered beam. The intensity of the scattered radiation at any point is determined by adding the intensities of the scattered radiation reaching the point from the independent scattering elements.

Thomson scattering is the scattering of electromagnetic radiation by free charged particles, computed either classically or according to nonrelativistic quantum theory. Scattering by electrons is interpreted classically as a process in which some of the energy of the primary radiation is reduced because electrons radiate when accelerated in the transverse electric field of the radiation. The scattering cross section is given by

$$\sigma_r = \frac{8}{3}\pi \left(\frac{e^2}{mc^2}\right)^2$$

which is 0.657 barn for an electron, and is called the *Thomson cross section*, or the *classical scattering cross section*.

Compton scattering is inelastic scattering of photons by electrons in the Compton effect. Because the total energy and total momentum are conserved in the collisions, the wavelength of the scattered radiation undergoes a change that depends in amount on the scattering angle. If the scattering electron is assumed to be at rest initially, the Compton shift is given by the equation:

$$\lambda' - \lambda = \lambda_0(1 - \cos\theta) = (h/m_e c)(1 - \cos\theta)$$

where λ' is the wavelength associated with the scattered photons, λ_0 is the wavelength of the incident photons, l0 is the (Compton) wavelength of the electron, and θ is the angle between the paths of incident and scattered photons.

Delbrück scattering is the scattering of light by a Coulomb field, a process which according to quantum electrodynamics occurs as a scattering of the light by the virtual electron-pairs produced by the Coulomb field. The total cross section is approximately 6 millibarns for uranium.

Single scattering is the deflection of a particle from its original path owing to one encounter with a single scattering center in the material traversed. This is to be distinguished from plural scattering and multiple scattering, which involve successive encounters with scattering centers.

Multiple scattering is any scattering of a particle or photon in which the final displacement is the sum of many displacements, usually small. A type of scattering intermediate between single and multiple scattering is called *plural scattering*.

Potential scattering is that portion of scattering by the nucleus of the atom that has its origin in reflection from the nuclear surface, thus leaving the interior of the nucleus undisturbed. The term usually is used in contradistinction to *resonance scattering*, which is the scattering arising from the part of the incident wave that penetrates the surface and interacts with the interior of the nucleus. In general, the scattered wave may have components arising from both kinds of scattering processes. The term potential scattering is also used to denote scattering of an incident wave by reflection at a change or discontinuity in the potential field.

Acoustic scattering is the irregular and diffuse reflection or diffraction of sound in many directions. Scattering frequently occurs when the reflecting surfaces or bodies are small compared with the wavelength of sound; in certain cases the reflecting bodies may be small inhomogeneities in the medium.

SCATTEROMETRY. Scatterometry has its origin in early radar used in World War II. Early radar measurements over the oceans were corrupted by sea clutter (noise) and it was not known at the time the cause of this clutter. It was not until the 1960s that the noise in the radar signal was found to be the radar's response to the winds over the ocean.

The first scatterometer flew as part of the Skylab missions in 1973 and 1974, demonstrating that spaceborne scatterometers were indeed feasible. Then, from June to October 1978, the *Seasat-A Satellite Scatterometer* (SASS) proved that accurate wind velocity measurements could be made from space. In the 1990s, a single-swath (-beam) scatterometer was one of the instruments to fly on the European Space Agency's *ERS-1* (currently in stand-by mode) and *ERS-2* Remote Sensing Satellites, launched in July 1991 and April 1995 respectively.

The *NASA Scatterometer* (NSCAT) which launched aboard Japan's *ADEOS-Midori Satellite* in August 1996, was the first dual-swath, Ku-band scatterometer to fly since *Seasat*. From September 1996, when the instrument was first turned on, until premature termination of the mission due to satellite power loss in June 1997, NSCAT performed flawlessly and returned a continuous stream of global sea surface wind vector measurements. Unprecedented for coverage, resolution, and accuracy in the determination of ocean wind speed and direction, NSCAT data has already been applied to a wide variety of scientific and operational problems. These applications include such diverse areas as weather forecasting and the estimation of tropical rain forest reduction. Because of the success of the short-lived NSCAT mission, future Ku-band scatterometer instruments are now greatly anticipated by the ocean winds user community.

The Science of Scatterometry

Winds over the ocean modulate air–sea changes in heat, moisture, gases and particulates (matter in the form of small liquid or solid particles), regulating the crucial bond between atmosphere and ocean that establishes and maintains global and regional weather and climate. Data derived from ocean scatterometers is vital to researchers in their studies of air–sea interaction, ocean circulation, and their effects on weather patterns and global climate. In the past, weather data could be acquired over land, but our only knowledge of surface winds over oceans came from infrequent, and sometimes inaccurate, reports from ships and buoys. These data are also useful in the study of unusual weather phenomena such as El Niño, the long-term effects of deforestation on rain forests, and changes in the sea ice masses around the Polar Regions. These environmental changes all play a central role in regulating global climate. See also **El Niño**.

Winds over the Ocean. Wind affects the full range of oceanic motion, from individual surface waves to complete current systems. The tropical Pacific Ocean and overlying atmosphere react to and influence each other. Easterly surface winds along the equator control the amount and temperature of the water that upwells (moves or flows upward) to the surface. This upwelling of cold water determines sea surface temperature distribution, which affects rainfall distribution. This in turn determines the strength of the easterly winds; a continuous cycle.

Applications: Observing Oceans from Space

As the human population grows and international commerce expands, more effective use of resources becomes more important than ever before. Efficient utilization of the sea is particularly vital to human survival. Today, satellite technology can be employed to observe Earth's oceans from space without much of the uncertainty encountered by mariners of times gone by. By measuring global sea−surface wind speed and direction, ocean scatterometer data can help meteorologists more accurately predict the marine phenomena that affect human life on a daily basis. Some examples follow:

Weather Forecasting. Data from ocean scatterometers greatly enhance overall weather-forecasting capabilities. Most of the weather over the west coast of the United States, and some over the east coast, is generated over the oceans. The measurements derived from ocean scatterometers are assimilated into numerical models (computer programs that represent natural processes in terms of equations), which can be used to predict global and regional weather patterns. The data are delivered to the National Oceanic and Atmospheric Administration (NOAA) within two hours, where they are used for timely, accurate weather forecasting.

Storm Detection. The ocean scatterometer data can determine the location, direction, structure and strength of storms at sea. Severe marine storms; hurricanes near the Americas, typhoons in Asian waters, and mid-latitude cyclones worldwide are among the most destructive of all natural phenomena. In the United States alone hurricanes have been responsible for at least 17,000 deaths since 1900, and hundreds of millions of dollars in damage annually. If worldwide statistics are considered, the numbers are substantially higher. Although typically not as violent as hurricanes and typhoons, mid-latitude cyclones exact a heavy toll in casualties and material damage.

In recent years, our ability to detect and track severe storms has been dramatically enhanced by the advent of weather satellites. Cloud images from space are now routine on weather reports. Data from ocean scatterometers augment these familiar images by providing direct measurements of surface winds to compare with the observed cloud patterns. These wind data help meteorologists to more accurately identify the extent of gale force winds associated with a storm and provide inputs to numerical models that provide advanced warning of high waves and flooding.

Ship Routing. Wind-observation data from ocean scatterometers are of particular significance in ship routing. Prior knowledge of wind behavior will enable shipmasters to choose routes that avoid heavy seas or high headwinds that may slow ships' progress, increase fuel consumption, or possibly cause damage to vessels and loss of life. In the past, ship captains relied on widely-spaced measurements from buoys and sporadic, sometimes unreliable reports from other ships. Data from satellite-based scatterometers are much more regular, extensive, and dependable.

Oil Production. Earth's oceans are increasingly used as a source of fuel. As continental fossil-fuel supplies are depleted, the more challenging task of extracting oil and gas from the seabed becomes a necessity. Oil and gas production is already ongoing at numerous offshore sites around the world, including the Gulf of Mexico, the North Sea, the Persian Gulf. Thorough knowledge of the historical wind and wave conditions at any specific location is crucial to the design of drilling platforms. Safe, efficient drilling operations depend on an accurate understanding of the current state of the sea as well as warning of impending storms.

In the event of an oil spill, surface-wind information is key to determining how the oil will spread. Ocean scatterometer data could help clean-up and containment crews to minimize the environmental effects of such a disaster.

Food Production. Perhaps the oldest use of the ocean is in the harvesting of food. Today, ocean fishing is a highly systematic activity that makes extensive use of advanced technology to reduce the cost and to increase the value of every catch. Detailed wind data from scatterometers can aid in the management of commercial seafood crops. The annual U.S. shrimp harvest in the Gulf of Mexico, for example, depends on favorable on-shore winds that help transport offshore plankton larvae to estuaries where the larvae can develop into adult shrimp. SeaWinds data can help fishermen monitor wind conditions during this critical phase in life of shrimp.

Missions

Seasat-A. In the 1970s, JPL engineers and scientists realized that the sensors they were developing for interplanetary missions could be turned upon Earth itself to better understand our home planet. In 1978, JPL built an experimental satellite called *Seasat* to test a variety of oceanographic sensors including imaging radar, altimeters, radiometers and scatterometers.

The *Seasat* flight-tested four instruments that used radar to study Earth and its seas. Radars are useful tools because they can penetrate clouds, they operate in all weather conditions, and they provide their own illumination so they can function day and night. The radar instruments on *Seasat* measured the satellite's distance from the sea surface, measured near-surface ocean winds and took pictures using radar rather than light for illumination. *Seasat* also carried a visual and infrared radiometer that provided measurements that were used to judge the results of the radar instruments.

Seasat was launched on June 26, 1978, on an Atlas Agena rocket from Vandenberg Air Force Base, California (Mass: 2,300 kilograms (5,070 pounds) Science instruments: Radar altimeter, scanning multichannel microwave radiometer, microwave scatterometer, imaging radar, visual and infrared radiometer.) Unlike launches of interplanetary spacecraft from Florida on eastward flight paths, launches from Vandenburg place the satellite in a north-south orbit that takes it close to Earth's poles. *Seasat* sent data to Earth for 106 days. See Figs. 1 and 2. Seasat-A was lost when a short circuit drained all power from its batteries

Fig. 1. Painting of *Seasat-A* spacecraft as it studies oceans from Earth orbit. (*NASA/JPL.*)

Many later Earth-orbiting instruments developed at JPL owe their legacy to the *Seasat* mission. These include imaging radars flown on NASA's Space Shuttle as well as such Earth-orbiting satellites and instruments as *Topex/Poseidon*, the *NASA Scatterometer* (NSCAT), *QuikScat* and the planned *Jason 1*.

ERS-1 and ERS-2. The European Remote Sensing Satellites (ERS) were designed to study many processes of the Earth's oceans and land with a suite of instruments, one of which is a SAR on the AMI. *ERS-1* was launched in 1991 and *ERS-2* in 1995.

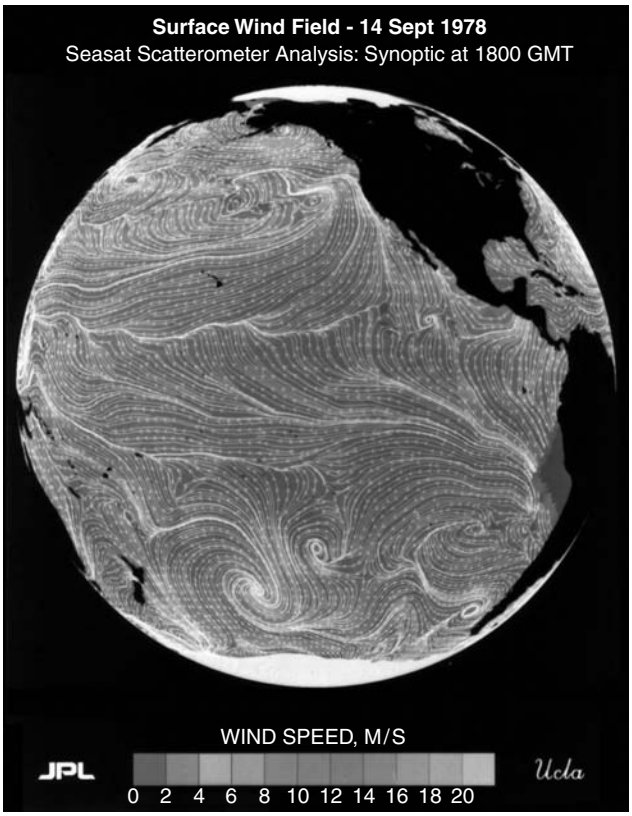

Fig. 2. Global wind speed and direction are shown in this image using recently processed data acquired in 1978 by *Seasat-A* spacecraft.

The Active Microwave Instrument (AMI) operates in three modes: (1) SAR Image Mode, for the acquisition of wide swath images over the oceans, polar ice caps and land areas. (2) SAR Wave Mode, yielding 5 km $\times$ 5 km images at regular intervals along track for the derivation of length and direction of ocean waves, and (3) Wind Scatterometer Mode, using three separate antennae for measurements of sea-surface, wind speed, and direction.

***NASA Scatterometer* (NSCAT).** NSCAT, a microwave radar scatterometer, measured near-surface wind vectors (both speed and direction) over the global oceans. This information is critical in determining regional weather patterns and global climate. NSCAT had two major systems - the spaceborne instrument system and the ground data processing system.

NSCAT was launched at 6:54 p.m. U.S. PDT, Friday, August 16, 1996, aboard the Advanced Earth Observing Satellite (ADEOS), a mission of the National Space Development Agency of Japan. ADEOS was launched into a near-polar Sun-synchronous orbit, by an H-II launch vehicle from Japan's Tanegashima Space Center. The largest satellite ever developed by Japan, ADEOS had a mass of approximately 3,500 kilograms (7,720 pounds) and a power-generation capability of approximately 4500 watts; its overall dimensions at launch were $4 \times 4 \times 5$ meters ($13 \times 13 \times 16$ feet). When the NSCAT antenna and the solar array paddle were deployed, the satellite was an impressive 11 meters (36 feet) in height and the solar array extends outward 29 meters (95 feet).

Science Objectives:

- Acquire all-weather high-resolution measurements of near-surface winds over the global oceans.
- Determine atmospheric influences, ocean response and air-sea interactions on various spatial and temporal scales.
- Develop improved methods of assimilating wind data into numerical weather and wave prediction models.

Fig. 3. NASA's *Quick Scatterometer* (*QuikScat*) lofted into space on June 19, 1999 from California's Vandenberg Air Force Base. *QuikScat* provides climatologists, meteorologists, and oceanographers with daily, detailed snapshots of ocean winds. The mission will greatly improve weather forecasting.

The satellite was launched on a U.S. Air Force Titan II launch vehicle soaring over the Pacific Ocean at sunset. Approximately two and a half minutes after launch, the Titan II first-stage engine shut down and the second stage ignited. A minute later, the nose cone separated in two halves and was jettisoned as planned. An hour into flight, *QuikScat* deployed its solar arrays.

- Combine wind data with measurements from various scientific disciplines to understand processes of global climatic change and weather.

Measurements:

- The instrument was operated continuously at a frequency of 13.995 GHz.
- Six dual-polarized, 3-meter long, stick-like antennas collected backscatter data with a resolution of 50 km for nine months before loss.
- Backscatter data was combined and processed to yield 268,000 globally distributed wind vectors per day.

Every two days, under all weather and cloud conditions, NSCAT measured wind speeds and directions over at least 90% of the Earth's ice-free oceans. Since oceans cover approximately 70% of Earth's surface, NSCAT played a key role in scientists' efforts to understand and predict complex global weather patterns and climate systems. NSCAT used eight antenna beams to scan two wide bands of ocean, one on each side of the instrument's orbital path. NSCAT transmitted short pulses of microwave energy to probe ocean surfaces and then measured the reflected or backscattered power. Variations in the magnitude of this backscattered power are caused by changes in small (centimeter-sized), wind-driven waves. Using a method called Doppler processing (a change in the observed frequency of the radio waves due to relative motion of source and observer), the measured backscattered power was separated into cells at specific locations on Earth's surface; these were then transmitted to the ground for processing. During ground processing, wind direction and speed was determined from these variations. Within two weeks of receiving the raw data, the ground system processed wind measurements.

Nine months after launch, the Midori satellite lost power, ending its and NSCAT's mission. NASA approved a rapid replacement mission called the *Quick Scatterometer* to take the place of NSCAT.

Quick Scatterometer. NASA's *Quick Scatterometer* (QuikSCAT) was lofted into space at 7:15 p.m. Pacific Daylight Time on Saturday, June 19, 1999 atop a U.S. Air Force Titan II launch vehicle from Space Launch Complex 4 West at California's Vandenberg Air Force Base. The satellite was launched in a south-southwesterly direction, soaring over the Pacific Ocean at sunset as it ascended into space to achieve an initial elliptical orbit with a maximum altitude of about 800 kilometers (500 miles) above Earth's surface. See Figs. 3 and 4.

Built in a record time of just 12 months, *QuikScat* will provide climatologists, meteorologists and oceanographers with daily, detailed snapshots of the winds swirling above the world's oceans. Labeled as NASA's next "El Niño watcher," *QuikSCAT* will be used to better understand global weather abnormalities and to generally improve weather forecasting.

QuikSCAT's predecessor, NSCAT (NASA Scatterometer), a microwave radar scatterometer, measured near-surface wind vectors (both speed and

Fig. 4. This is an artist rendering of NASA's *Quick Scatterometer* (*QuikScat*). The large, dishlike feature at the bottom of the satellite is the scatterometer instrument that will measure winds over the ocean surface. (*NASA/JPL.*)

direction) over the global oceans starting in August 1996. The *QuikSCAT* mission is a "quick recovery" mission to fill the gap created by the loss of data from NSCAT, after the satellite it was flying on lost power in June 1997.

Winds play a major role in every aspect of weather on Earth. They directly affect the turbulent exchanges of heat, moisture and greenhouse gases between Earth's atmosphere and the ocean. To better understand their impact on oceans and improve weather forecasting, *QuikSCAT* carries a state-of-the-art radar instrument called a scatterometer for a two-year science mission. Known as "SeaWinds," this scatterometer operates by transmitting high-frequency microwave pulses to the ocean surface and measuring the "backscattered" or echoed radar pulses bounced back to the satellite. The instrument senses ripples caused by winds near the ocean's surface, from which scientists can compute the winds' speed and direction. The instruments can acquire hundreds of times more observations of surface wind velocity each day than can ships and buoys, and are the only remote-sensing systems able to provide continuous, accurate and high-resolution measurements of both wind speeds and direction regardless of weather conditions.

SeaWinds uses a rotating dish antenna with two spot beams that sweep in a circular pattern. The antenna radiates microwave pulses at a frequency of 13.4 gigahertz across broad regions on Earth's surface. The instrument is currently collecting data over ocean, land, and ice in a continuous, 1,800-kilometer-wide band (1,120 miles), making approximately 400,000 measurements and covering 90% of Earth's surface each day.

Science Objectives:

- Acquire all-weather, high-resolution measurements of near-surface winds over global oceans.
- Determine atmospheric forcing, ocean response, and air-sea interaction mechanisms on various spatial and temporal scales.
- Combine wind data with measurements from scientific instruments in other disciplines to help us better understand the mechanisms of global climate change and weather patterns.
- Study both annual and semi-annual rain forest vegetation changes.
- Study daily/seasonal sea ice edge movement and Arctic/Antarctic ice pack changes.

Operational Objectives:

- Improve weather forecasts near coastlines by using wind data in numerical weather- and wave-prediction models.
- Improve storm warning and monitoring.

Ground Systems:

- Tracking by Earth Polar Ground stations Svalbard, Norway; Poker Flats, Alaska; Wallops Island, Virginia; and McMurdo, Antarctica; Hatoyama, Japan (contingency station).
- High-quality research data products produced at JPL and distributed to science community within two weeks of receipt.
- Scatterometer science data products are distributed through the JPL Physical Oceanography Distributed Active Archive Center (PO.DAAC), a scientific data distribution site: http://podaac.jpl.nasa.gov.
- Operational data products produced at National Oceanic & Atmospheric Administration (NOAA) for international meteorological community within 3 hours of data collection. http://www.noaa.gov/

SCAVENGING. 1. The use of an unspecific precipitate to remove from solution by adsorption or coprecipitation a large fraction of one or more undesirable radionuclides. Voluminous gelatinous precipitates are usually used as scavengers, e.g., $Fe(OH)_3$. 2. The removal of impurities from molten metal by addition of substances to form slags, or other compounds that can readily be removed. 3. The removal of unwanted gases from systems, e.g., of products of combustion from an internal combustion engine, or residual gases from an evacuated tube.

SCHALLY, ANDREW VICTOR (1926–). Andrew Schally was a Polish-born (now Latvia) American biochemist, oncologist and Nobel Prize winner who discovered peptide-releasing hormones.

Schally was born at Wilna, Poland (now Vilnius, Latvia) on 30 November 1926. He grew up during the Nazi occupation, but as a Jew he survived the Holocaust by escaping to Romania, and eventually to Scotland. He only began the study of chemistry at the University of London in 1946 and became a biochemistry research student at the Medical Research Council's Laboratories, Mill Hill, London. In 1952 he joined the Endocrine Unit of the Psychiatry Institute at McGill University, Montreal, where he finally took his BSc in 1955 and a PhD in 1957. In 1960 he became Professor of Physiology at the Baylor College of Medicine in Houston. In 1962 he became an American citizen and Director of Research of the Endocrine and Polypeptide Laboratory of the Veterans Administration Hospital in New Orleans, and a professor at Tulane University School of Medicine in New Orleans. He has been twice married and has two children. He was identified by *Current Contents* (1978) as the world's most frequently cited endocrinologist during the period 1961–1976.

While working at McGill, Schally was stimulated by the work of G.W. Harris on the nervous control of the anterior pituitary gland. In 1955, using pig pituitaries, and in intense rivalry with Roger Guillemin, he succeeded in identifying a corticotrophin-releasing factor (CRF). In 1962 he isolated, characterized and subsequently synthesized thyrotrophin-releasing hormone (TRH). He also made pioneering studies of the luteinizing hormone releasing hormone (LH-RH). He shared the Nobel Prize in Physiology or Medicine in 1977 with Guillemin and Rosalind Yalow for his discovery of peptide-releasing hormone. Since 1977 he has spent much time working on oral contraception. See also **Guillemin, Roger Charles Louis (1924–Present)**; and **Yalow, Rosalyn Sussman (1921–Present)**.

SCHARRER, BERTA VOGEL (1906–1995). Berta Scharrer was a German-born American physiologist who was one of the founders of neuroendocrinology.

Scharrer was born in Munich, Germany, to Johanna Weiss Vogel and Karl Phillip Vogel, a judge who served as vice-president of the federal court of Bavaria. While a student at the gymnasium she became interested in biology and decided on a career as a research scientist. At the University of Munich, she became intrigued by the work of Karl von Frisch and joined his laboratory to conduct her doctoral work. She earned her PhD in 1930. While a graduate student, Berta met Ernst Scharrer, another of von Frisch's students, and the two young scientists began a personal and professional relationship that lasted until Ernst's sudden death in 1965.

Berta Vogel and Ernst Scharrer moved to Walter Spielmeyer's Research Institute of Psychiatry in Munich, where Ernst Scharrer completed an additional degree in medicine. Berta Vogel studied spirochaetes and brain infections in birds and amphibians. Aware that prevailing prejudices against women might preclude an academic appointment, Berta Vogel also prepared herself to earn a certificate to teach at a gymnasium. In 1934, when Ernst Scharrer was appointed Director of the Edinger Institute for Brain Research, Berta and Ernst married and moved to Frankfurt. The Institute had been established by Ludwig Edinger (1855–1918), a pioneer of comparative neuroanatomy. Because of nepotism rules, Berta was unable to secure an academic title or salary. However, she was able to obtain laboratory space to conduct research. For many years during her long research career Berta Scharrer worked without pay or recognition because of prejudice against women.

In 1928, while conducting his doctoral work in von Frisch's laboratory, Ernst Scharrer had discovered secretory droplets in hypothalamic neurons of the European minnow *Phoxinus*. Scharrer called these neurons *nerve-gland cells* and he suggested that they secreted certain substances in a manner analogous to the way in which endocrine cells secreted hormones. At the time, this proposal was very controversial because the basis of nerve function was thought to be purely electrical. When Berta and Ernst Scharrer began their research on neurosecretions, chemical transmission at the nerve synapse was still unknown and the idea that neurons could send out signals by secreting substances into the blood was regarded as highly implausible. To provide further evidence for the neurosecretion hypothesis, the Scharrers decided to search for nerve-gland cells in other species. While Ernst studied various vertebrates, Berta investigated invertebrates. The comparative approach provided important evidence supporting the concept of neurosecretion and led to the formulation of Berta Scharrer's ideas about the evolution of the neuroendocrine system. In 1935 and 1936, Berta Scharrer published landmark papers on the neurosecretory cells in the Opisthobranch snail *Aplysia* and in the polychaete worm *Nereis*. See also **Endocrine System**.

As a privately endowed research facility, the Edinger Institute seemed to offer some shelter from Nazi laws and influence. However, the Scharrers found the pressure to join Nazi organizations and support Nazi beliefs increasingly intolerable. Assuring the authorities that they would return to Germany in one year, Ernst Scharrer accepted a Rockefeller fellowship at the University of Chicago. In 1937 the Scharrers left behind virtually all their possessions and research materials and arrived in the United States. Once again Berta Scharrer was able to continue her research on neurosecretory cells, but she was unable to obtain a title or salary. Lacking funds to purchase experimental animals, she began to trap and study the cockroaches that lived in the basement of her building in Chicago. When Ernst Scharrer accepted a position as visiting investigator in Herbert Gasser's laboratory at the Rockefeller Institute for Medical Research (now Rockefeller University) in New York City, Berta Scharrer continued her research as an unpaid research associate. See also **Gasser, Herbert Spencer (1888-1963)**.

Shortly before leaving Rockefeller, Berta Scharrer began her research on the woodroach. Surprisingly, the cockroaches that had been so plentiful in Chicago were not available in New York City. In 1940 she discovered that woodroaches (*Leucophaea maderae*), found in a shipment of monkeys from South America, were better suited to her work. The brains and nervous systems of these large roaches allowed her to perform the painstaking microsurgery that demonstrated the importance of neurosecretory bodies. When Ernst Scharrer obtained a position as assistant professor at Western Reserve University (now Case Western Reserve University) in Cleveland, Ohio, Berta brought along her woodroaches. Members of the faculty later blamed every encounter with cockroaches on Berta Scharrer's research, even though the local roaches were quite different from those in her breeding colony. Although she was not paid, Berta Scharrer served as an instructor for the histology laboratory and as a research fellow. Until she agreed to prepare tea for the faculty, Berta Scharrer was not even allowed to attend departmental seminars. The Scharrers became American citizens in 1945.

Using microsurgical techniques, Berta Scharrer investigated the function of several neuroglandular bodies found in the head of the woodroach. She demonstrated that removal of the corpus allatum affected egg development, but removal of the corpus cardiacum had no apparent effect. Her work indicated that the corpus cardiacum served as a storage depot and transfer station for certain hormones. Neurosecretory cells sent their hormones to this body, but they continued to produce hormones in the absence of the normal storage depot. Therefore, egg development occurred even when the corpus cardiacum was removed. Scharrer also noted that tumors were induced when the corpus allatum and corpus cardiacum were removed, apparently because nerves were severed during microsurgery. These studies, along with Ernst Scharrer's work on the hypothalamic-hypophyseal system of vertebrates, provided rigorous support for the theory of neurohormonal secretions.

After Ernst Scharrer became an associate professor at the University of Colorado Medical School in 1946, Berta finally received financial support through a Guggenheim fellowship (1947–1948) and a special fellowship from the US Public Health Service. When Berta was asked to organize an international meeting in 1950, the dean of the Medical School allowed her to be listed as an (unsalaried) assistant research professor.

The field of neurosecretion became increasingly accepted as other scientists began to study the neurosecretory cells of various mammals. Other researchers established the concept of the chemical transmission of nerve impulses at the synapse. By the 1950s these developments led to the establishment of neuroendocrinology as a distinctive and fruitful discipline. The First International Symposium on Neurosecretion was held in 1953 at the Zoological Station in Naples. In 1955, Ernst Scharrer was appointed chairman of the Department of Anatomy at the newly founded Albert Einstein College of Medicine of Yeshiva University in New York and Berta Scharrer was offered a full professorship. She developed a course in histology and served as adviser to the medical students. A series of lectures the Scharrers gave in 1960 at Columbia became the basis of their classic text *Neuroendocrinology* (1963). Tragedy struck the Scharrers in April 1965 during an anatomy meeting held in Miami, Florida, when Ernst was swept away by a strong rip current. For two years after Ernst's death, Berta served as chair of the Anatomy Department. This marked the first time in her career that she received appropriate financial compensation for her work. In 1976 she again served as acting chair while guiding the recruitment of the next permanent chairperson. She became Distinguished University Professor Emeriti in 1978.

In addition to her administrative duties, Scharrer continued her research and, by adopting the new technique of electron microscopy, established the ultrastructure of the insect nervous system. Her research demonstrated the fine structure of the classic neurosecretory cell and established the various targets of its secretory granules. In some cases the granules were released into blood vessels and reached their targets through the bloodstream. However, Scharrer discovered that secretory granules were sometimes released from terminals that were very close to their target cells, including other neurons, rather like chemical transmission at the synapse. From 1975 to 1981 she published about a dozen reviews of neurosecretion and neuroendocrinology, and new theories of the evolution of the nervous and endocrine systems. In the 1980s, Scharrer studied the nature, action, evolutionary conservation of neuropeptides, and comparative neuroimmunology. She continued this research until her death in 1995. In 1967 Berta Scharrer was elected to the National Academy of Sciences and the American Academy of Arts and Sciences. Scharrer served as president of the American Association of Anatomists (1978–1979) and as associate editor of the journals *Cell and Tissue Research* and *Advances in Neuroimmunology*. She became a member of the Deutsche Akademie der Naturforscher Leopoldina in 1972. She was awarded many honorary degrees and awards, including the Kraepelin Gold Medal (1978), the Fred C. Koch Award of the Endocrine Society (1980), the Henry Gray Award of the American Association of Anatomists (1982), the Schleiden Medal of the Leopoldina (1983), the US National Medal of Science (1983), and the Bavarian Order of Merit (1994). A species of cockroach was named *scharrerae* in her honor.

SCHEELE, C.W. (1742–1786). One of the outstanding early chemical thinkers and experimenters, Scheele was a Swedish scientist who discovered a number of previously unknown substances, among which are tartaric acid, chlorine, manganese salts, arsine, and copper arsenite (Scheele's green). He also noted the oxidation states of various metals, observed the nature of oxygen two years before Priestley's discovery, and discovered the chemical action of light on silver compounds, thus laying the foundation of photochemistry and photography. Scheelite, or natural calcium tungstate, is named after him.

See also **Scheelite**.

SCHEELITE. The mineral scheelite is calcium tungstate, [CAS: 7790-75-2], $CaWO_4$, with molybdenum [CAS: 7439-98-7] substituting for tungsten [CAS: 7440-33-7] up to 25% in the molybdian scheelite variety. It is a tetragonal with an octahedral habit although also at times tabular, and may occur massive. It displays an octahedral cleavage; is brittle; hardness, 4.5–5; specific gravity, 5.9–6.1 (very heavy for translucent minerals); luster, vitreous; color, white to yellowish, reddish, greenish and brownish; white streak; transparent to translucent. Scheelite is a popular mineral for collectors. It forms perfect tetragonal dipyramidal crystals that look very much like octahedrons. These pseudo-octahedral crystals are sometimes truncated with minor pyramids, but only on the top and/or bottom points of the crystal; giving evidence of their true symmetry. Other minerals that form pseudo-octahedral crystals similar to scheelite include wardite, anatase and powellite. Scheelite is found in pegmatite and ore veins associated with granites, also as a contact metamorphic mineral. It is known from the Czech Republic and Slovakia, Saxony, Italy, Alsace, Finland; Cumberland and Cornwall in England; and Mexico. Crystals of exceptional length (6–10 inches; 15–25 centimeters) are found at various localities in Korea and Japan; and in the United States, in Connecticut, Colorado, South Dakota, Arizona, Nevada, and California. The Swedish chemist, Karl Wilhelm Scheele, discovered tungsten in this mineral, which later was named for him.

The mineral fluoresces vivid bluish white to white; or yellowish white with increasing molybdenum content under exposure to short-wave ultraviolet light.

SCHERING BRIDGE. See **Bridge Circuits (Electrical/Electronic)**.

SCHILBEIDS. See **Catfishes**.

SCHINUS TREE. A shrubby tree capable of reaching a height of about 30 feet (9.1 meters) for some years has posed a wildlife and vegetation threat in the ecosystem of Everglades National Park, Florida. The schinus tree (*Schinus terebinthifolius*) is one of several exotic and tropical specimens introduced into Florida in the early 1890s as an ornamental shrub. It became known as Brazilian holly, Florida holly, or Brazilian pepper. In the early 1900s, the plant was studied in some detail at the U.S. Department of Agriculture's plant-introduction station in Miami and its remarkable growth rate was noted. It was found that seedlings would reach a height of 15 feet (4.6 meters) within a period of three years, producing fruit in the second year. Dwellers in south Florida, notably in the Homestead area, were pleased with the manner in which great numbers of birds were attracted to the red berries of the schinus. It was soon noted, however, that the tree was taking root in locations where it was not planted or wanted. The schinus was extremely difficult to control, and it spread rapidly and profusely. It was also found that the schinus irritated the skin much as poison ivy does (not surprising in retrospect, because the schinus is closely related to the poison ivy and poison sumac family). It was inevitable that the schinus would spread into parts of Everglades National Park, crowding out native species. The schinus also has spread into stands of native slash pine. It tolerates flooding and drought and sprouts prolifically after fires. Other imported trees (all with a positive intent on the part of the original introducers) which have caused somewhat similar problems include the *casuarina* and *melaleuca* trees/shrubs. The latter two plants are described in separate entries in this volume.

SCHIST. The schists form a great group of metamorphic rocks chiefly notable for the preponderance of the lamellar minerals such as the micas, chlorite, talc, hornblende, graphite, etc. Quartz often occurs in drawn out grains to such an extent that a quartz schist is produced. By definition, schist contains more than 50% platy and elongated minerals, often finely interleaved with quartz and feldspar.

The individual mineral grains in schist, drawn out into flaky scales by heat and pressure, can be seen by the naked eye. Schist is characteristically *foliated*, meaning the individual mineral grains split off easily into flakes or slabs. The characteristic flaky texture of schist gives rise to the adjective "schistose".

Most schists have in all probability been derived from clays and muds which have passed through a series of metamorphic processes involving the production of shales, slates and phyllites as intermediate steps. Certain schists have been derived from fine-grained igneous rocks such as lavas and tuffs. Most schists are mica schists, but graphite and chlorite schists are common. Schists are named for the prominent or perhaps unusual mineral constituent, as garnet schist, tourmaline schist, glaucophane schist, etc. The word schist is derived from the Greek meaning to split, with reference to the easy separation of these rocks in a direction parallel to that in which the platy minerals lie.

It is the most abundant rock in the state of New Hampshire.

SCHISTOSOMIASIS. Once known as bilharziasis, this is an invasion of the body by a genus of trematode parasites or flukes, the *chistosomae*. The disease reaches far back into history and ancient Egyptians even had a hieroglyphic symbol for it — a penis dripping blood. The disease was indeed so common that blood in the urine was considered a puberty symbol for males. Approximately 5% of the world's population is affected, with most cases appearing in Africa, the Middle East, Central and South America, China, the Philippines, and Malaysia. Many cases are also found in the Caribbean countries.

Infected persons excrete the microscopic schistosome eggs in their feces and urine. If these reach fresh water, tiny embryos hatch and invade an intermediary host, usually a snail. Therein, they develop and multiply and 6 to 8 weeks later the snail releases cercariae, or schistosome larvae, in numbers amounting to some tens of thousands per day.

Humans are infected when swimming in the water, the infective larvae penetrating the skin very rapidly to the blood stream where they travel to various organs. Species of schistosomes select different target sites in which to reside. *S. mansoni* targets the mesenteric veins of the upper intestine; *S. japonicum*, the mesenteric veins of the lower intestine; *S. hematobium*, the bladder veins. Once settled, the schistosomes produce a steady output of eggs (1000 or more per day) and live for years in their selected sites.

About half the eggs produced migrate through the wall of the intestine or bladder and the remainder are swept to the liver by the blood stream where they cause a severe inflammatory reaction. The eggs that do exit to the intestine or bladder are excreted and able to enter a new host.

Schistosomiasis patients frequently suffer vomiting and diarrhea. An infection by *S. mansoni* or *S. japonicum* develops a hard, cirrhosis-like hepatomegaly; *S. hematobium* patients have intense bladder damage and heavy bleeding into the urine.

Diagnosis depends upon finding schistosome eggs in urine or feces or by serological tests, such as complement-fixation or ELISA (enzyme-linked immunosorbent assay).

Some progress has been made toward development of an anti-schistosome vaccine but, despite optimism, the body's immune system is continuously evaded by the organism's ability to camouflage itself with major histocompatibility antigens so that it resembles the host's own body. Meanwhile, praziquantel is the most effective drug against the parasite although metrifonate and niridazole are also of value.

R.C. VICKERY, M.D., D.Sc., Ph.D., Blanton/Dade City, FL

SCHIZOPHRENIA. A major medical illness. It has been estimated that a child living at the age of 15 years statistically has a 2 to 3% risk of being diagnosed as a schizophrenic sometime during its lifetime. Persons with the disease in the United States exceed the population of New York City. No real medical breakthroughs in diagnosing and curing the disease have occurred. Inasmuch as the disease is not fatal, lifetime costs of care are astonishing.

If one were to condense all that is known concerning the disease, three elements would predominate: (1) the disease appears to run in families; (2) neuroleptics (drugs that act in some manner with the brain's dopamine system) help to improve the symptoms of the disease; and (3) there may be something structurally awry in the schizophrenic brain.

Fundamentals still are argued among the experts: — Does schizophrenia represent a discrete mental disorder, or is it just one component of a spectrum of mental illness? Ming Tsuang (Harvard Medical School) has expressed the opinion that present data seem to favor the traditional view that schizophrenia is made up of two discrete, major psychoses: (1) schizophrenia that starts during adolescence and usually worsens; and (2) affective (mood) disorders that occur later in episodes and are less likely to incapacitate the patient. Researchers are now looking to molecular genetics for evidence to prove the two stages. Still other researchers, for example Timothy Crow (Northwick Park Hospital, Harrow, England), views affective illnesses and schizophrenia at opposite ends of a continuum of psychotic disorders. Depression is at one end of the spectrum, followed by manic depression, mixed schizophrenia and affective disorder, and schizophrenia sans affective disorder. Crow observes that there are more patients in the middle of the spectrum than at the extremes.

Numerous studies of identical twins have been made to get a handle on the familial or hereditary characteristics of the disease. The evidence of a concentration is strong. If one identical twin has the disease, the chances of the other identical twin having the disease is greater than 50%. Another research finding reveals the less obvious, i.e., the children of schizophrenics who are adopted by nonschizophrenic parents surprisingly show a higher incidence of schizophrenia than a control population. These and other similar studies have not convinced all specialists, however, that there is a strong hereditary factor. Researcher Kendler has observed that it is not fair to call schizophrenia a genetic disease; it is not a classic Mendelian trait inherited like the gene for Huntington's chorea. But, one cannot deny evidence that like coronary heart disease and early-onset hearing loss, schizophrenia tends to run in families. Presently, there are two principal hypotheses regarding the inheritance of schizophrenia: (1) a model based on a single major gene locus (supported by Philip Holzman, Harvard University); and (2) a model that suggests multiple genetic causes, of which Tsuang is an advocate. Some researchers consider that poor eye tracking may be a biological marker for schizophrenia. Others claim that poor eye tracking stems from other causes as well, including drug-induced effects, Parkinson's disease, multiple sclerosis, and some brain lesions.

Crow has suggested that a retrovirus may be involved. Perhaps the virus may incorporate into the human genome and thus be capable of passage from one generation to the next. There have been other viral postulates, supported by a survey which indicates over half of the schizophrenic population were born in winter or spring (virus season). Other researchers have associated the disease with the immune system. Although very generalized, Sedvall (Karolinska Institute, Stockholm) observes that schizophrenia probably represents a complex interplay of genetic and environmental factors.

More recent research targets include direct studies of the brain — to observe blood flow, brain metabolism, and receptor mapping to monitor brain structure. The effects of various drugs can be observed with key instrumental tools in connection with human and experimental animals. These tools include computerized tomography (CT) scans, magnetic resonance imaging, and photon imaging.

Symptoms and Treatment

Several decades ago, schizophrenia was called *dementia praecox*. This terms means "a precocious demented state." In 1911, Blueler advocated the substitution of *schizophrenia — schizo* standing for splitting and *phrenia* for the mind, thus indicating a "breaking away" of the patient's mind from a normal evaluation of reality. There are several forms in which the illness manifests itself. However, denial of reality and inappropriate emotional responses are the most common symptoms. The distorted psyche is revealed by the patient's behavior. During some spans of time, the patient may be wild in behavior, as illustrated by the breaking up of furniture and the throwing of portable objects. During some periods, a patient may rip off clothing and go naked; or, during other periods, dress in a fantastic manner. The patient may laugh or cry without apparent cause. The patient may use a language consisting of jumbled fractions of words and phrases that are incomprehensible.

The patient may be confused as to identity and make fantastic claims as being someone of high repute. In all, the actions and mannerisms of the schizophrenic appear bizarre and unintelligible when viewed in the light of the real world. The actions are more easily understood when one realizes that this behavior is the product of a dream world, erected because the patient does not have the ability to perceive reality in a normal way.

When a schizophrenic becomes unable to find any solution that will enable the acceptance of a painful situation, the patient's normal defenses break down entirely and "reality" is imagined in terms of desires. Daydreams offset the poverty of true relationships and thus become more gratifying than reality.

Traditionally, patients who present the symptoms of acute schizophrenia are referred to a psychiatrist. A wide variety of antipsychotic drugs is available. Generally, these drugs can be used safely with most patients because of the wide difference between therapeutic and lethal doses. Further, most of these drugs are not addictive and, in most situations, the patient does not develop a tolerance (thus decreasing the effectiveness) to the antipsychotic effects of these drugs. Among the antipsychotic agents commonly used are the phenothiazines, thioxanthenes, dibenzoxazepines, butyrophenones, and indolones. Certain generalizations can be made concerning these drugs — rapid absorption $\frac{1}{2}$ to 1 hour with oral doses; 10 minutes with intramuscular administration); oxidative metabolism, usually in the liver, with byproducts excreted in the urinary tract. There are side effects of these drugs, particularly in elderly patients.

Often a considerable period of time will be required to find the most satisfactory antipsychotic agent for a given patient. With some of these drugs, however, a minimum period of three months is required to determine the full clinical response. Proper dosage of a given drug also varies considerably from one patient to the next. Acute schizophrenia may not require indefinite maintenance. In chronic schizophrenia, the drug maintenance program is long-term.

SCHLEIDEN, MATTHIAS JACOB (1804–1881). Matthias Schleiden was a German botanist who elucidated the role of the nucleus in plant cell development.

The son of a wealthy physician in Hamburg, Schleiden first studied law in Heidelberg between 1824 and 1826, and practiced this profession for four unhappy years. He would be "the most unfortunate person on earth," he wrote at the time, would he have to pursue this vocation for the rest of his life. A deep crisis followed, culminating in a suicide attempt; he shot himself in the head but survived. He then decided to study medicine and moved first to Göttingen and later (1835) to Berlin. Already in Göttingen, especially under the influence of the botanist F.G. Bartling, he became attracted to botany. In Berlin, close to his uncle, the medical professor J. H. Horkel, he became associated with several of Germany's leading life scientists, including the physiologist Johannes Müller and the microscopist Christian Gottfried Ehrenberg. There he also met the British botanist Robert Brown who stimulated his interest in the plant cell. See also **Brown, Robert (1773–1858)**.

Brown was the first to report the consistent presence of a *nucleus* in plant cells. Schleiden, influenced by the German biological tradition of Naturphilosophie, was especially interested in investigating the "developmental histories" (i.e. life cycles) of plants. Schleiden's innovative step was to consider the cell as an "individual" unit, in lower as well as in higher plants, specifically to consider it as having its own developmental scheme, and to hypothesize Brown's nucleus as the origin of cell development. Schleiden was less attentive to the numerous observations available at the time of cell division, and instead envisaged the cell as developing directly out of the nucleus, by way of the gradual inflation of the cell wall. The nucleus itself (which he termed *cytoblast*) was envisaged to crystallize out of a granular mass inside existing cells. In October 1837, over lunch, Schleiden discussed his observations with a Berlin colleague, Theodor Schwann, thus stimulating the latter to formulate the general cell theory. Schleiden's work on plant cells, *Contributions to Phytogenesis*, was published almost simultaneously with Schwann's work. See also **Schwann, Theodor Ambrose Hubert (1810-1882)**.

At that time Schleiden prepared another extraordinary paper (published in 1839), in which he claimed to have observed the (plant) embryo forming in the grain of pollen and penetrating the ovule with the pollenical tube. He consequently concluded that the vegetable ovule was the male organ of plants, and the grain of pollen the producer of the embryo, as a female organ. Although this theory was soon to be discarded it did stimulate the ongoing debate about the sexual nature of plant reproduction. See also **Plant Reproduction**.

Shortly thereafter another mental crisis followed. Schleiden fell in love with a young woman working at a confectioner's and wanted to marry her, but had to put an end to the affair under pressure from his family. Schleiden fled from Berlin to the small city of Wernigerode where he again attempted to put an end to his life. Once more he survived, recovered, and in autumn 1839 moved to Jena where he attained the doctoral degree. There followed a few most productive years, culminating with a comprehensive methodological textbook, the *Grundzüge der wissenschaftliche Botanik* (1842), which in later editions he renamed *Botany as an Inductive Science*. This work was a landmark in establishing botany as part of the new life sciences, based on rigorous physiological experimentation and microscopical observations. Schleiden made Jena a centre of plant physiology, and played a key role in the establishment of a small research laboratory. He also fostered microscopical technology through the employment of the young Carl Zeiss, the later founder of the Jena optical industry. See also **Plant Sciences (The History)**.

Within the scientific community Schleiden remained a controversial figure. His actual scientific contributions were soon to be rejected, and even Robert Brown was quoted in 1842 as considering Schleiden's work as too "poetic and transcendental." Still one should not underestimate the impact of Schleiden's methodological stance, especially his rigorous formulation of the idea of the developmental scheme as a major conceptual tool in the investigation of plants and plant's organs, and his emphasis on the study of cryptogams (the "lower" plants, e.g. algae and mosses) as the key for understanding phanerogams (the "higher," flowering plants). It was largely through Schleiden's influence that the emphasis on the life cycle as a reliable category of identification became a central premise of microbiology.

Schleiden retired from Jena in 1863, allegedly because of poor health (deteriorating eyesight, asthma), but mainly because of a series of conflicts with the university authorities. First he settled in Dresden, but shortly thereafter accepted a post as a professor of anthropology at the University of Dorpat. He left Dorpat in 1864, went back to Dresden, and from 1872 moved his place of residence between the cities of Darmstadt, Wiesbaden and Frankfurt where he died in 1881.

SCHLIEREN. Refraction anomalies produced in transmitted light by differences in density or other anisotropy in parcels or strata of air (or other fluids). All the natural scintillation phenomena in the atmosphere result from density schlieren developed by turbulent processes. Schlieren optical systems are frequently used for observing and photographing colloidal refractive index gradients which arise in the study of electrophoresis, diffusion, sedimentation velocity, chromatography, and airflow in wind tunnels. Figure 1 shows a diagram of schlieren measurements in a wind tunnel, in which an interferometer is used to determine the interference effects produced by turbulence. Steady flow of air at constant density does not show on the interference pattern, but turbulent flow, shock waves and similar density variations do appear in the interference pattern. The word *schlieren* is used to describe the whole phenomenon. The interferometer plates are called *schlieren plates*, the interference pattern is called a *schlieren picture*, and the whole instrument is called a *schlieren interferometer* or simply *schlieren apparatus*.

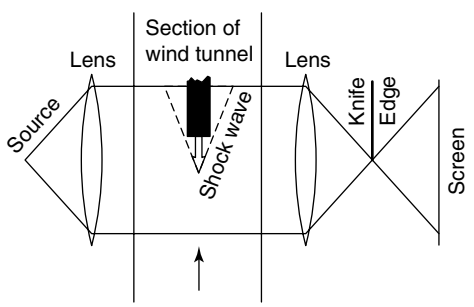

Fig. 1. Idealized Schlieren apparatus for observing shock wave in supersonic tunnel.

SCHMIDLIN KETENE SYNTHESIS. Formation of ketene by thermal decomposition of acetone over electrically heated wire at 500°–750 °C (932°–1,382 °F) degrees by a reaction involving radical formation with generation of methane [CAS: 74-82-8] and carbon monoxide [CAS: 630-08-0].

SCHMIDT, MAARTEN (1929–). Schmidt was born in Groningen, the Netherlands. He received a Ph.D. in astronomy from the University of Leiden and worked at the Leiden Observatory. In 1959, he moved to American and joined the astronomy department at the California Institute of Technology where at first he continued working on the mass distribution and dynamics of the Galaxy. When Rudolph Minkowski retired, Schmidt

took over his project of taking spectra of objects, which had been found to be radio emitters. In 1963 he discovered the first quasar, showing that these starlike objects exhibit ordinary hydrogen lines, but at redshifts far greater than those observed in stars. Since then he has investigated the evolution and distribution of quasars, discovering that they were more abundant when the universe was younger, one of the major reasons for the decline in favor of steady-state models of the universe. He is currently seeking to find the redshift above which there are no quasars. He also studies X-ray and gamma ray sources.

He won the Warner Prize of the American Astronomical Society in 1964 and in 1968, he was awarded the Rumford Award of the American Academy of Arts and Sciences. In 1992 he was awarded the Bruce Medal.

See also **Quasars**.

J. M. I.

SCHMIDT NUMBER. A dimensionless number relating the ratio of inertial to molecular diffusive forces. Explicitly,

$$\mathrm{Sc} = UL/\mathrm{k}_D$$

in which U and L are characteristic velocity and length scales, respectively, and k_D is the diffusion constant of a solute in solution, such as salt in water.

SCHMIDT OBJECTIVE. An objective for reflecting telescopes, designed to correct the aberration of the spherical mirror without introducing the coma (blurring) to which even a parabolic reflector is subject for wide fields. The results are obtained in somewhat the same way that spectacles correct for defects in vision. A slight chromatic aberration is introduced.

The Schmidt objective as originally designed consists of a concave spherical mirror, functioning in the same way as the objective of any reflecting telescope, but with a plate of glass interposed in front of it perpendicular to its axis at its center of curvature. This glass plate is not plane, but has one surface "figured" in such a way that, as the rays pass through it on their way to the mirror, it so modifies their course as to effect almost perfect correction for the spherical aberration and coma that the mirror would otherwise produce. In a later design, the objective consists of two coaxial cylinders of glass, in contact along a plane perpendicular to the axis. The rear surface of the rear piece is spherically convex and is silvered on the outside, thus presenting a concave spherical mirror to the interior of the glass cylinder. The front surface of the front piece, passing through the center of curvature of the mirror, is the correction surface, serving the same purpose as the glass plate in the older design. The reason for using two pieces is that the final real image F is of course produced between the mirror and the correction surface; and it is here that the plane of separation is located, so that the small photographic film used may be introduced. The general nature of these arrangements will be clear from Fig. 1. There are numerous other variations of this idea, all referred to as Schmidt telescopes.

See also **Telescope (Astronomical-Optical)**.

SCHMIDT PROCESS. A method for converting a given set of vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n$ into an orthonormal set $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$. If the length of $\mathbf{v}_i$ is l_i and $\mathbf{e}_i = \mathbf{v}_i/l_i$ is a unit vector, the calculation may be performed with the recursion formula

$$\mathbf{v}_{i+1} = \mathbf{u}_{i+1} - \sum_{k=1}^{n} (\tilde{\mathbf{e}}_k \mathbf{u}_{i+1}) \mathbf{e}_k$$

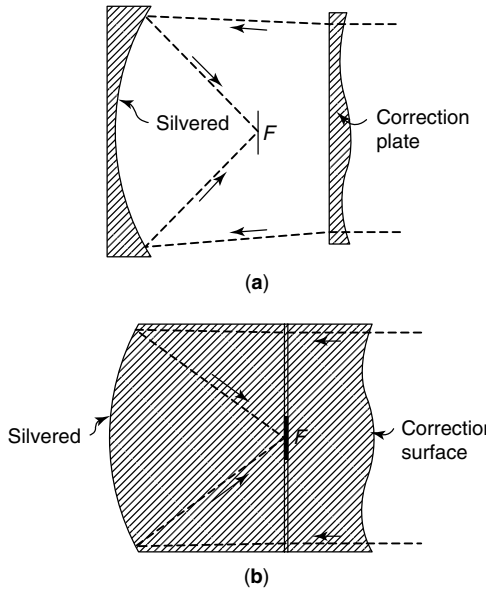

Fig. 1. Schmidt objective: (**a**) Original design; (**b**) the "solid" Schmidt (diagrammatic).

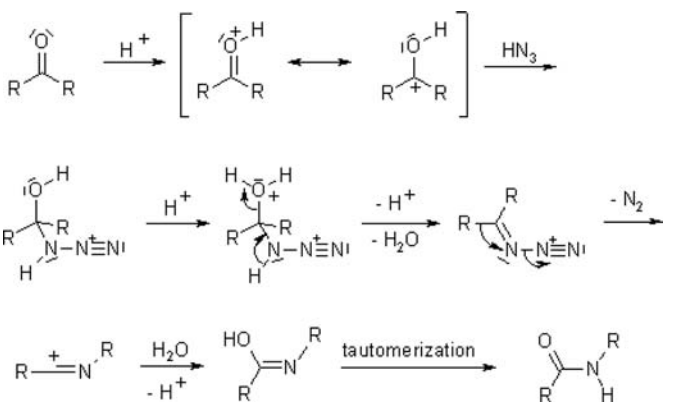
where $\tilde{\mathbf{e}}_k$ is the transpose of $\mathbf{e}_k$. The procedure may also be used for functions with the appropriate integrations in place of summations. If, for example, the original functions are $1, x, x^2, \ldots$, defined over the range $x = \pm 1$, the orthonormal set obtained from them by the Schmidt process is a set of Legendre polynomials.

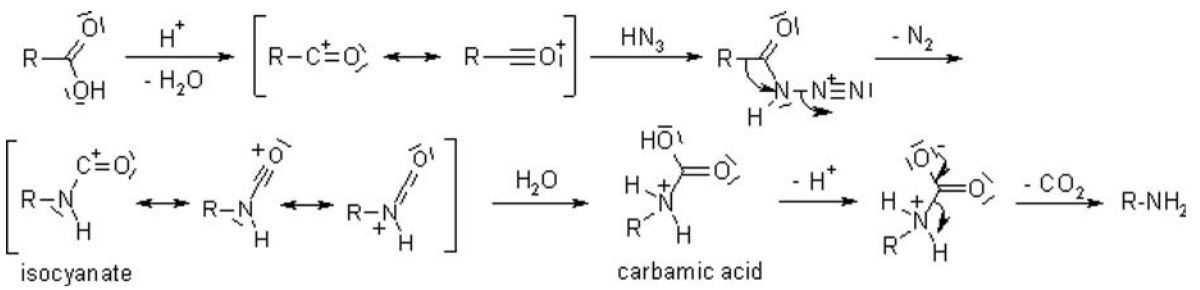
See also **Legendre Differential Equation**.

SCHMIDT REACTION. Acid catalyzed addition of hydrazonic acid to carboxylic acids, aldehydes, and ketones to give amines, nitriles, and amides, respectively.

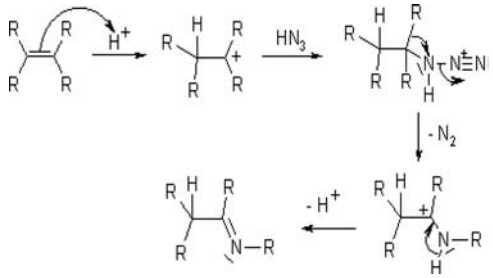
Reaction of carboxylic acids gives acyl azides, which rearrange to isocyanates, and these may be hydrolyzed to carbamic acid or solvolysed to carbamates. Decarboxylation leads to amines.

The reaction with a ketone gives an azidohydrin intermediate, which rearranges to form an amide:





Alkenes are able to undergo addition of HN_3 as with any HX reagent, and the resulting alkyl azide can rearrange to form an imine:



Tertiary alcohols give substitution by azide via a carbenium ion, and the resulting alkyl azide can rearrange to form an imine.

Schmidt Reaction: http://www.organic-chemistry.org/namedreactions/schmidt-reaction.shtm

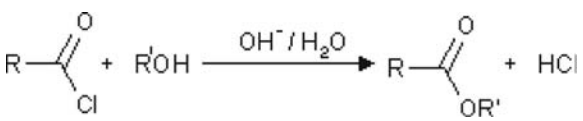
SCHMITT TRIGGER. A form of bistable multivibrator which furnishes a fast-acting on-off switch action, is capable of generating rectangular pulses from sinusoidal or other nonrectangular waveforms, and can determine when a signal reaches a specified D.C. level.

SCHORIGIN (OR SHORYGIN) REACTION. Organometallic reactions of the Grignard type, employing sodium in place of magnesium; the reaction of alkyl sodium compounds with carbon dioxide to give monobasic acids is sometimes known as the Wanklyn reaction.

$$Hg(C_2H_5)_2 + 2Na \longrightarrow Hg + 2C_2H_5Na$$

$$C_2H_5Na + 2CO_2 \longrightarrow 2C_2H_5COONa$$

SCHOTTEN-BAUMANN REACTION. Transformation of carboxylic acid chlorides with alcohols. The corresponding ester is formed.



The carboxylic chloride is insoluble in H_2O and thus the reaction takes place only at the phase boundary. The reaction is fastened when pyridine or DMAP is added (->;Einhorn Variation). See also **Einhorn Variation**.

SCHOTTKY DEFECT. A lattice vacancy created by removing an ion from its site and placing it on the surface of the crystal. For electric neutrality, the number of cation Schottky defects must equal the number of anion Schottky defects. The number, n, of Schottky defects is given by

$$\frac{n}{N-n} = C_s e^{-W/kT}$$

where there are N lattice points, and W is the energy required to remove an ion from a lattice point, and then add it to the surface. C_s is a numerical factor of the order of 10^3–10^4. This relation may be derived from thermodynamic arguments. It can be shown that the factor C_s includes a vibrational entropy term.

SCHRÖDINGER EQUATION. The basic equation of wave mechanics. It is developed by using the de Broglie wavelength in the description of a particle and then associating with the measurement of the energy E or of the x-component of momentum p_x of the particle a differential operator

$$E = i\hbar\frac{\partial}{\partial t} \text{ or } p_x = -i\hbar\frac{\partial}{\partial x}$$

where is the Dirac **h**. The Hamiltonian function can be expressed either in terms of total energy or in terms of potential energy and momentum. Expressing it in both ways, one obtains:

$$-\frac{\hbar^2}{2m}\nabla^2\psi + V(\mathbf{r})\psi = i\hbar\frac{\partial\psi}{\partial t} = E\psi$$

where ∇^2 is the Laplacian, m the mass of the particle, E, its total energy, and $V(\mathbf{r})$ its potential energy (usually a function of position). This is the time dependent Schrödinger equation for ψ.

In many instances, we are interested in the allowed values of E in stationary states of the system. Using the Planck law we may set $E = hv = 2pi\hbar v$ and write

$$\psi = \phi(\mathbf{r})e^{2\pi ivt} = \phi(\mathbf{r})e^{iEt/h}$$

where $\phi(\mathbf{r})$ is a function of position only.-We then obtain the time independent equation:

$$\left[\nabla^2 + \frac{2m}{\hbar}\{E - V(\mathbf{r})\}\right]\phi = 0$$

It is often found that solutions of the equation exist only for specific eigenvalues of E. To each eigenvalue E_n there corresponds an eigenfunction of the coordinates ϕ_n. The probability of finding the particle in a region of volume dV is

$$\int |\phi| dV = \int \phi\phi^* dV$$

assuming that ϕ has been normalized so that the integral over all space is unity.

See also **Quantum Mechanics**.

SCHRODINGER, ERWIN (1887–1961). Schrodinger was born in Vienna, Austria. He earned a Ph.D. in physics from the University of Vienna. He worked with Weyl and Debye researching a number of problems in theoretical physics. He wrote papers on problems of thermodynamics, he studied the theory of color vision and writing on color blindness, and more importantly, he studied the atom trying to find a wave equation for the motions executed by the electrons and their interactions. Today, Schrodinger is known for his discovery, Schrodinger's wave equation. He won the Nobel Prize in Physics in 1933, jointly with Paul Dirac for his wave theory of atomic phenomena.

Beginning in 1927, Schrodinger was professor of theoretical physics at the University of Berlin. When the Nazi regime came to power, he left for England. He later accepted a position at the University of Graz, Austria but when Germany annexed Austria, Schrodinger left and took a position in Ireland at the Institute for Advanced Studies. His work in physics continued here. He also became interested in philosophy and biology and published a book, *What Is Life?*, which was influential in the scientific world.

See also **Schrödinger Equation**.

J. M. I.

SCHUCHERT, CHARLES (1858–1942). Schuchert was an American paleontologist. He was a pioneer paleogeographer teaching historical geology at Yale from 1904–1923. He made significant contributions towards the geologic time scale. He is especially remembered for his book, *Historical Geology of North America*.

See also **Geologic Time Scale**.

J. M. I.

SCHUMAN-LUDLAM LIMIT. Critical liquid water content for growth by accretion of a hailstone or other object in a supercooled cloud such that for a given temperature and air speed all the accreted water is frozen and the surface temperature is above 0 °C (32 °F). Above this limit more water is accreted than can be frozen and either is shed as liquid or is retained as spongy ice.

SCHUMANN RESONANCE. Electromagnetic waves in the ELF range trapped in the spherical cavity formed by the conductive earth and the conductive ionosphere. The fundamental resonance mode represents one wavelength around the earth with a corresponding frequency of approximately 8 Hz. The resonances are maintained continuously by global lightning activity. Five to seven higher-order modes are frequently discernible.

SCHWANN, THEODOR AMBROSE HUBERT (1810–1882). Theodor Schwann was a German physiologist who established the cell as the elementary unit of living tissues and introduced new experimental methods into physiology.

Schwann was born in the lower Rhine city of Neuss. His father was a goldsmith and printer whom Schwann occasionally assisted. Theodor Schwann was himself a gifted craftsman, already in his youth constructing and experimenting with electrical devices and microscopes. He was an introverted person, preoccupied with metaphysical and religious thoughts. Growing up in a religious Catholic environment he entered a Jesuit College in Cologne in 1826, intending to serve the church. He later changed his mind and in 1829 began premedical studies at the University of Bonn. One of his teachers there was the physiologist Johannes, whose influence would become crucial for Schwann's later career. After 2 years in Bonn, Schwann moved in 1831 to the University of Würzburg, where he spent 2 years and heard the lectures of the influential pathologist Johann Lukas Schoenlein. In 1833 Schwann went to Berlin to complete his medical studies. Johannes Müller had meanwhile been appointed Professor of Anatomy and Physiology at the University of Berlin and in 1834 Schwann submitted to him his doctoral dissertation, dealing with the necessity of atmospheric air for embryonic development. Müller convinced Schwann to devote himself to research and offered him a position as his assistant at the "anatomical museum" of the university. It was there, in the very short period of 1835–1838, that Schwann arrived at most of his scientific discoveries.

From the start, Schwann aimed at introducing new experimental methods into physiology. Schwann's major accomplishment was his successful explanation of life processes in terms of causal agents, without having recourse to vital forces. At the time, practically all life scientists were still considering physiological and pathological processes as being in one way or another, the manifestations of an underlying life force. Schwann believed that if one could construct the right experimental setting, it should be possible to discern specific agents for specific physiological phenomena, and to show strict causal relations between the agent and its effect. One of his first investigations, in 1835, was an attempt to discover the "laws of muscle activity." For this he constructed an experimental apparatus which enabled him to measure the extent to which a frog's muscle contracted under a given electrical stimulus. Next he managed to define (in 1836) the agent of stomach digestion — he termed it pepsin — without actually being able to observe it or identify it chemically. Similarly he was able to show, in 1837, that fermentation is a microbiological process brought about by yeast and that putrefaction, too, is brought about by living microscopic organisms (then termed "infusoria"). This he did by demonstrating that when vessels containing organic infusions were first heated and then provided only with preheated air, no putrefaction took place and no microorganisms appeared in the infusion. From this he concluded that the agents of putrefaction were germs (*Keime*) of microscopic organisms. This last discovery was of utmost importance, as putrefaction was assumed at the time to be a spontaneous process, i.e. the decomposition of organic bodies in the absence of the life force. By redefining this process, Schwann practically banished the life force from physiology. Furthermore, Schwann's experiment was a major blow to the then still widely held belief in spontaneous generation.

Although the cellular structure of plant tissues was quite an established fact at the time, no clear view prevailed as to the microscopical structure of animal tissues. In October 1837, over lunch, Schwann was informed by the botanist Matthias Schleiden about his latest investigations into the development of plant cells. Inspired by these ideas, Schwann attempted a similar endeavor for animal tissues. In the treatise *Microscopical Researches into the Accordance in the Structure and Growth of Animals and Plants* (1839), Schwann was able to show how the cellular scheme fitted a whole series of animal tissues, including the connective tissue, nerves, muscles, the feather of the raven and the ovum. For Schwann, cells were not only structural units, but first and foremost the manifestation of force-exerting agents. Thus Schwann believed that cells are generated out of an amorphous generative substance — he termed it Cytoblastem. Within this substance the nuclei were assumed to form, and around the nuclei the cells, in turn, were supposed to build up. Thus in Schwann's theory cell formation is a process akin to crystallization; the recognition of division as the sole way of cell proliferation had to await the work of Rudolf Virchow and Robert Remak, some two decades later. It is important to note that Schwann assumed cells to be the units not only of tissue formation, but also of tissue nutrition. Schwann introduced the concept (and terminology) of "metabolic processes" and attributed a "metabolic force" to the cell, thus making cells into the chief agents of physiological processes. See also History **Schleiden, Matthias Jacob (1804–1881)**; **Virchow, Rudolf Carl (1821–1902)**.

Schwann's work had an immediate impact on the development of microscopical anatomy, and his physiological methodology had a direct influence on the younger generation of Johannes Müller's disciples — notably on Herman Helmholtz and Emil Du Bois-Reymond. See also **Du Bois-Reymond, Emil Heinrich (1818–1896)**.

Immediately after publishing his work on cells, Schwann moved to Belgium, where he was offered a position at the Catholic University of Louvain. This was, in fact, also the end of his scientific career. In 1849 Schwann was appointed Professor of Anatomy at the University of Liege, where he stayed until his retirement in 1879. An active teacher in both Belgian universities, Schwann hardly pursued further research in that period. In his later years he became more and more obsessed with religion, and wrote several metaphysical works which were never published. He also remained a passionate craftsman and devoted much time and effort to the design and construction of a portable respiratory apparatus. Schwann remained a bachelor throughout his life.

OHAD S. PARNES, Max Planck Institute for the History of Science, Berlin, Germany

SCHWARZSCHILD, KARL (1873–1916). Schwarzschild was a Germany theoretical astrophysicist who computed solutions of Einstein's field equations in relativity. Knowledge of events is limited at the Schwarzschild radius and this has led to research on black holes. Shortly after this work, Schwarzschild died of a rare metabolic disorder.

J. M. I.

SCHWARZSCHILD TELESCOPE. A reflecting telescope using two mirrors designed to be free of spherical aberration and coma. It requires a large secondary mirror, which causes a loss of light, and a long foretube to act as a light baffle. See also **Telescope (Astronomical-Optical)**.

SCHWEITZER'S REAGENT. A solution of copper hydroxide in strong ammonia used in analytical chemistry as a test for wool. It dissolves cotton, silk, and linen.

SCIENTIFIC BALLOONS. Large unmanned helium balloons provide NASA with an inexpensive means to place payloads into a space environment. The unique capabilities of this program are crucial for the development of new technologies and payloads for NASA's space flight missions. Many important scientific observations in fields such as hard x-ray/gamma-ray and infra-red astronomy, cosmic rays and atmospheric studies have been made from balloons. The newly developed capability for long duration ballooning has greatly expanded the opportunities for scientific studies from balloons.

Balloons have been used for decades to conduct scientific studies. While the basics of ballooning have not changed, balloon capabilities have increased and their dependability has improved greatly.

Scientific Balloons: can be launched from locations worldwide to support scientific needs; can be readied for flight in as little as six months; offer a low-cost method of conducting science investigations; and provide a stable platform for longer flight durations.

Scientists use scientific data collected during balloon flights to help answer important questions about the universe, atmosphere, the Sun and the space environment. Questions such as "How did the universe, galaxies, stars, and planets form and evolve?" and "Are there Earth-like planets beyond our solar system?" are being answered by NASA with the help of experiments flown on scientific balloons.

Standard NASA scientific balloons are constructed of polyethylene film; the same type material used for plastic bags. This material is only 0.002 centimeters (0.0008 inches) thick, about the same as an ordinary sandwich wrap. The film is cut into banana-peel shaped sections called gores and heat sealed together to form the balloon. Up to 180 gores are used to make NASA's largest balloons. See Fig. 1. These standard, zero-pressure balloons are open to the atmosphere at the bottom to equalize the internal pressure with the surroundings. The balloon system includes the balloon, the parachute and a payload that holds instruments to conduct scientific measurements.

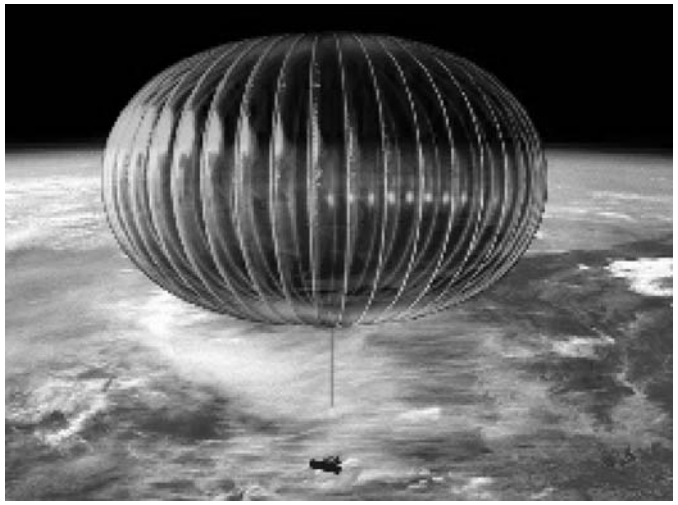

Fig. 1. Artist rendition of an ultra long duration balloon. (*NASA*.)

Helium, the same gas used to fill party balloons, is used in NASA balloons. These very large balloons can carry a payload weighing as much as 3,600 kilograms (8,000 pounds), about the weight of three small cars. They can fly up to 42 kilometers (26 miles) high and stay there for up to two weeks.

The Balloon Program's capabilities are being expanded with the development of an Ultra Long Duration Balloon (ULDB). The ULDB is made of advanced materials and uses a new pumpkin-shaped balloon design to achieve flights of up to 100 days. The ULDB is completely sealed and pressurized in order to maintain constant altitude night and day. The ULDB payload consists of a solar power system, radio receivers and transmitters, computers, batteries and other systems required for science experiments.

The balloon is launched by partially filling it with helium and launched with the payload section suspended beneath it. As the balloon rises, the helium expands, filling the balloon until it reaches float altitude in two to three hours. After the science measurements are complete, flight controllers send a radio command that separates the payload from the balloon. The payload floats back to the ground on a parachute where it can be retrieved and flown again. Payload separation creates a large tear in the balloon material, which releases any remaining helium. The balloon also falls to the ground, where it s retrieved and discarded. The balloon and payload land approximately 45 minutes after separation.

On August 25, 2002 a NASA Scientific Balloon set a new altitude world record. Slowly rising from the Northwest region of Manitoba, Canada, near a small gold mining town called Lynn Lake, a massive NASA balloon began a journey that took it to the fringes of space. Silently drifting in the rarefied upper edges of our atmosphere, the scientific balloon reached a peak altitude of 161,000 feet (49 kilometers), and with a volume of 60 million cubic feet (1.7 million cubic meters), was the largest balloon ever launched successfully.

The balloon carried a solar and heliosphere experiment called Low Energy Electrons (LEE), weighing 1,500 pounds (690 kg), which was provided by Dr. Paul Evenson of the University of Delaware.

"Aside from our excitement and the fact that this balloon established a new record for balloon volume (50 percent greater than NASA's standard balloon designs), this flight should help establish a new platform for science such as ultra-violet and x-ray astronomy", said Steve Smith, chief of NASA's Balloon Program Office at Goddard Space Flight Center's Wallops Flight Facility, Wallops Island, VA.

The Wallops Flight Facility manages NASA's Scientific Balloon Program for the Office of Space Science, Washington. Launch operations are conducted by the National Scientific Balloon Facility, which is managed for NASA by the Physical Sciences Laboratory of New Mexico State University, Las Cruces. Raven Industries, Inc., Sioux Falls, SD, designs and manufactures NASA's scientific balloons. The balloon for this launch was built in their plant in Sulphur Springs, Texas.

On January 27, 2005 flying near the edge of space, a NASA scientific balloon broke the flight record for duration and distance. It soared for nearly 42 days, making three orbits around the South Pole. See Fig. 2.

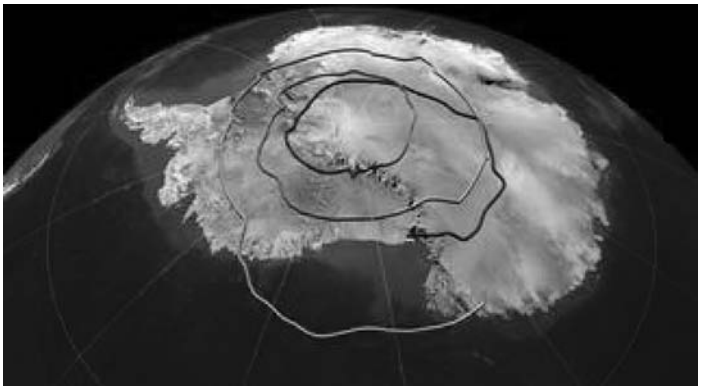

Fig. 2. This still shows the path of the CREAM balloon during its record-breaking flight. (*NASA*)

The record-breaking balloon, almost as large as one and one half football fields, (Fig. 3) carried the Cosmic Ray Energetics And Mass (CREAM) experiment. CREAM is designed to explore the supernova acceleration limit of cosmic rays, the relativistic gas of protons, electrons and heavy nuclei arriving at Earth from outside the solar system.

Fig. 3. The CREAM Experiment is carried on this record breaking balloon. (*NASA*)

In addition to gathering scientific data, the flight was a demonstration of the capabilities of the NASA Ultra-Long Duration Balloon (ULDB) support system.

The pilot-less, helium-filled scientific balloon was launched from the National Science Foundation's McMurdo Station, Antarctica on Dec. 16, 2004. See Fig. 4. The balloon traveled 41 days and 22 hours. It landed on January 27, 660 kilometers (410 miles) from McMurdo Station. Payload recovery operations are in progress.

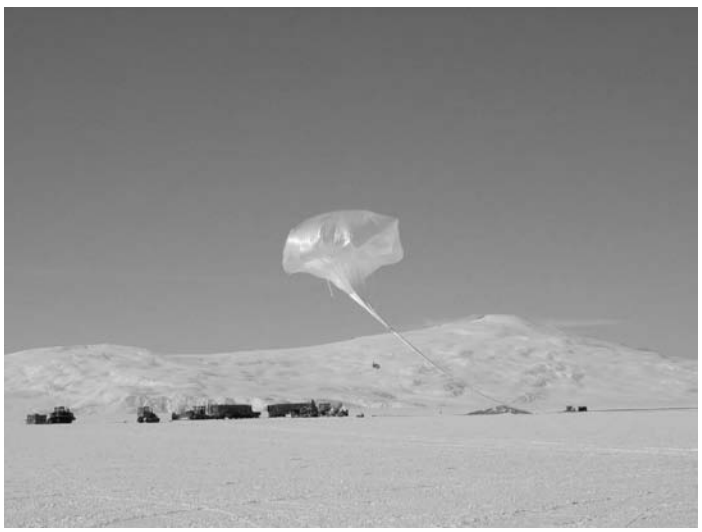

Fig. 4. The CREAM Experiment lifts off. (*NASA*)

The previous endurance record for a balloon flight was in December 2001 from McMurdo. The flight orbited the South Pole twice over 31 days, 20 hours. The CREAM mission extended the continuous science observation time over previous balloon missions.

The pilot-less, helium-filled scientific balloon was launched from the National Science Foundation's McMurdo Station, Antarctica on Dec. 16, 2004. The balloon traveled 41 days, 22 hours, landing on January 27, 660 kilometers (410 miles) from McMurdo Station. Payload recovery operations are in progress.

The previous endurance record for a long duration balloon flight was in December 2001 from McMurdo. The flight was for two orbits of the South Pole that lasted 31 days, 20 hours. The CREAM mission was able to extend the amount of continuous science observational time over any previous balloon mission.

Personnel from the National Scientific Balloon Facility, Palestine, Texas, who support approximately 25 NASA balloon flights annually from sites worldwide, conducted the launch, flight, and recovery operations of the CREAM balloon mission. "We are really proud of our crew in Antarctica," said Danny Ball, Site Manager of the Texas facility. "Everyone at NSBF has contributed to this success, but the crew that spent Thanksgiving, Christmas, and New Years on the "ice" deserves the most of the credit for a great mission and yet another record flight."

Conventional Ballooning. Conventional missions typically use direct line-of-sight electronics for command and data with flight durations ranging from a few hours to days. The balloons fly as high as 140,000 feet.

Long Duration Ballooning. A Long Duration Balloon (LDB) mission normally traverses between continents or around the world for one circumnavigation. LDB flights may last up to three weeks and satellite-based electronic systems are utilized for command and data. The data are typically recorded to tape or disk on board. When the mission is complete, the payload is released from the balloon and parachutes to the ground where it can be retrieved.

Ultra Long Duration Ballooning (ULDB). The superpressure pumpkin balloon (Fig. 1) has been designed to increase flight durations up to one hundred days. This new balloon will significantly increase the amount of data that can be collected in one balloon mission. The payloads that are designed to be handled by these flights are more elaborate than typical balloon payloads and more similar to satellite payloads.

The National Scientific Balloon Facility (NSBF) has launched six ELBBO (Extended Life Balloon Borne Observatories Program) super pressure balloons including the longest balloon flight in history, (lasting over 4 months) which was flown for Professor Bob Holzworth of the University of Washington.

Scientific Use of Balloons in the Second Half of the Twentieth Century

During the second part of the twentieth century and into the current century, balloons have gathered data used by researchers in many discipline areas. Instruments on high-altitude balloons have carried out magnetosphere research and studied the magnetic field around the Earth and how it interacts with cosmic winds, as well as studies on micrometeorites and cosmic dust. Simultaneous flights of balloons launched from widely separated locations have mapped plasma flow and the interaction of plasma wave particles. Instruments carried by balloons have performed planetary observations, visible light particle sampling, and pressure-temperature sensing.

Balloon instruments have answered questions about the concentration of ozone, carbon dioxide, carbon-14, nitrous oxide, and ratios of oxygen and nitrogen in the atmosphere above 100,000 feet (30,480 meters). They have measured trace constituents in the stratosphere that reveal ozone depletion from manmade propellants in aerosol sprays and the emission of nitrogen oxides from jet aircraft. Geophysicists and earth scientists have used balloons to monitor earth resources, take pictures from the air, and study light from the aurora and constellations. Biologists and aerospace medical specialists have sent plants and animals into the upper atmosphere via balloons.

During the Cold War, balloons were used to collect data on atmospheric radiation levels. The Atomic Energy Commission's Project Ash Can, with some co-sponsorship by the Advanced Research Projects Agency (ARPA), monitored radioactivity in the environment. Launched in 1956, Ash Can used polyethylene balloons designed by Otto Winzen to collect particle samples in the stratosphere. These samples were tested for the presence of radioactive dust raised by nuclear blasts and nuclear bomb tests.

As part of the Stratoscope program, a series of three 10-million-cubic-foot (283,169-cubic-meter) Winzen balloons were launched from the deck of the *Valley Forge* aircraft carrier in the Caribbean starting on January 26, 1960. These huge thin-film polyethylene plastic balloons lifted cosmic ray research equipment weighing two tons (1,814 kilograms) for the National Science Foundation (NSF) above 100,000 feet (30,480 meters).

On March 10, 1960, the Office of Naval Research (ONR) and National Center for Atmospheric Research (NCAR) sent Coronascope I, another solar instrument package, to 80,000 feet (24,384 meters) and a second coronascope aloft on May 3, 1964, under a 32-million-cubic-foot (906,139-cubic-meter) balloon.

Stratoscope II was an even more ambitious project. The balloon carried a 3.5-ton (3,175-kilogram) astronomical observatory that took high-resolution celestial photos. Launched on January 13, 1963, the balloon's 36-inch (91-centimeter) telescope transmitted infrared spectral data on the Moon, Mars, Venus, six giant red stars, and other space phenomena. The information gleaned from the Stratoscope and other balloon explorations changed existing astronomical theories on the evolution and structure of the stars and the characteristics of the planets.

In January 1959, Project Stargazer began to study high-altitude astronomical phenomena from above 95 percent of the Earth's atmosphere, which allowed undistorted visual and photographic observations of the stars and planets. On December 13-14, 1962, Captain Joseph Kittinger and astronomer William White rose to an altitude of 82,200 feet (25,055 meters) over New Mexico in the Stargazer gondola. In addition to obtaining valuable telescopic observations, the flight provided useful information relating to the development of pressure and associated life support systems during an extended period on the edge of space.

During the second part of the twentieth century, giant plastic balloons built of better materials were able to carry heavier cargoes higher and higher. These giant balloons were so tough that they carried instruments through 155 mile per hour (249 kilometers per hour) jet stream winds and temperatures as low as $-86\,^{\circ}\mathrm{C}$ ($-123\,^{\circ}\mathrm{F}$). They were exposed to the

full force of cosmic and solar radiation and proved remarkably reliable. By 1972, the largest balloons had a 53-million-cubic-foot (1.5-million-cubic-meter) capacity, measured 750 feet (229 meters) tall, had 24.8 miles (40 kilometers) of heat-welded seams, and could carry seven tons (6,350 kilograms) of instruments to low altitudes or lighter packages to 31 miles (50 kilometers).

In 1970, the United States launched more than 500 high- and constant-altitude balloons. In addition to x-ray, gamma ray, infrared, and ultraviolet instruments, balloons have also carried instruments performing neutron spectroscopy and those that have counted micrometeorites. On October 16, 1970, an x-ray telescope from the Massachusetts Institute of Technology (MIT) lofted by a 34-million-cubic-foot (962,663-cubic-meter) balloon remained above 148,000 feet (45,110 meters) for more than 10 hours.

One of the most unusual flights of the 1970s, combined science and art. Vera Simons and Rudolf J. Englemann, a National Oceanic and Atmospheric Administration scientist, planned a series of four *Da Vinci* flights to study atmospheric structure, turbulence, and pollution; the suspension of fine particles in clean air; gather landscape and cloud images for art; and demonstrate the balloon as kinetic visual art. Their second flight, *Da Vinci II*, launched on June 8, 1976, and traveled the length of the St. Louis plume, an air pollution band, for 24 hours.

In 1960, two years after the National Aeronautics and Space Administration (NASA) was established, the National Center for Atmospheric Research (NCAR) was organized in Boulder, Colorado, under the sponsorship of the National Science Foundation, to coordinate the activities of more than 40 universities engaged in atmospheric and cosmic research. Among its activities, the organization has coordinated work in balloon construction, instrumentation, telemetry, and tracking and has launched some of the largest plastic balloons to date.

NASA uses large unmanned helium balloons to explore the atmosphere on the edge of space and to place scientific instruments and equipment into space. Balloons make an inexpensive platform for developing new technologies and payloads and are quick to construct. They also have more flight opportunities than rockets, satellites, or human missions and provide more accurate vertical flight profiles, although satellites provide broader area coverage. Balloons have been important for the development of spacecraft and spaceflight instrumentation. For example, the coronagraph used on Skylab (launched on May 4, 1973) was the final improved design stemming from earlier balloon-borne models.

In 2000, two balloon experiments sponsored by NASA, MAXIMA and BOOMERANG, determined that the Universe is geometrically flat; will expand forever; and comprises about five percent ordinary visible matter, thirty percent dark matter of an unknown nature, and 65 percent dark energy, a mysterious force that is accelerating the expansion rate of the Universe.

Cutting-edge cosmic radiation balloon research continues to the present day. On January 4, 2001, NASA launched TopHat successfully from McMurdo Station, Antarctica. See also http://topweb.gsfc.nasa.gov/tophat_overview.html. TopHat is a hat-shaped experiment that sits on top of a main balloon and carries the Advanced Thin Ionization Calorimeter for Louisiana State University. The balloon circled above Antarctica at 120,000 feet (36,576 meters) for two weeks collecting light from the cosmic microwave background radiation. Observing the microwave background, which was formed 300,000 years after the big bang, enables scientists to understand the nature of the Universe when it was an infant. TopHat is just one of many balloon cosmic radiation experiments. The Advanced Thin Ionization Calorimeter, another balloon experiment that Louisiana State University has flown over Antarctica, gathered data on galactic cosmic rays.

Other research includes NASA's Ultra-Long Duration Balloon (ULDB) program, which has had two test launches from Alice Springs, Australia, in early 2001. ULDB is the largest single-cell, super-pressure (sealed) balloon ever flown. Made of a newer lightweight polyethylene, the balloon is partially inflated with helium at launch and expands as it rises. It uses enhanced computer technologies, high-tech materials, and advanced design for long-range (around the world), long-duration (100 days) flight. The ULDB floats at 115,000 feet (35 kilometers), three to four times higher than passenger planes and above 99 percent of the Earth's atmosphere. The project has been testing the balloon material on these launches and has determined that modifications to its composition may be needed. When the project becomes operational, ULDB experiments will study the source of cosmic rays generated from supernovae shock waves and survey X-ray-emitting objects in the universe.

SCINTILLATION (Astronomical). Any scintillation phenomena, such as irregular oscillatory motion, variation of intensity, and color fluctuation observed in the light emanating from an extraterrestrial source. To be distinguished from terrestrial scintillation primarily in that the light source for the latter lies somewhere within the Earth's atmosphere. Also called *stellar scintillation*. See also **Seeing (Astronomy)**.

SCINTILLATION (Atmospheric). Generic term for rapid variations in apparent position, brightness, or color of a distant luminous object viewed through the atmosphere. If the object lies outside the Earth's atmosphere, as in the case of stars and planets, the phenomenon is termed *astronomical scintillation*; if the luminous source lies within the earth's atmosphere, the phenomenon is termed *terrestrial scintillation*. As one of three principal factors governing astronomical "seeing" (i.e., the disturbing effects produced by the atmosphere upon the image quality of an observed astronomical body), scintillation is defined as variations in luminance, only.

It is clearly established that almost all scintillation effects are caused by anomalous refraction occurring in rather small parcels or strata of air (schlieren), whose temperatures and, hence, densities differ slightly from those of their surroundings. Normal wind motions transporting such schlieren across the observer's line of sight produce the irregular fluctuations characteristic of scintillation. Scintillation effects are always much more pronounced near the horizon than near the zenith. Parcels of the order of only centimeters to decimeters are believed to produce most of the scintillatory irregularities in the atmosphere.

See also **Schlieren**.

SCINTILLATION COUNTER. Radiation detectors that respond by emitting a flash of visible light are classified as scintillators or fluors. Typical scintillators used for counting gamma radiation are thallium doped crystals of sodium iodide, Nal(TI). Plastic (organic) scintillators are commonly used for counting beta radiation, and for counting alpha particles; zinc sulfide, ZnS, is a good detecting crystalline substance.

SCINTILLOMETER. A type of photoelectric photometer used in a method of determining high-altitude winds on the assumption that stellar scintillation is caused by atmospheric inhomogeneities (schlieren) being carried along by the wind near tropopause level. Also called *scintillation meter*.

In one design a star is observed with a single telescope that looks through a four-inch long rotatable slit. Two scintillation frequencies are monitored, one high and one low. The slit is rotated until the ratio of high-frequency to low-frequency scintillation is a minimum. At this point, the slit is oriented parallel to the wind. The magnitude of the frequency ratio is a function of the wind speed. In another design, two telescopes mounted four inches apart are focused on a star. Only one frequency need be monitored. By direct observation of phase relationships as the telescopes are rotated about a mutual axis, both direction and speed can be determined with less ambiguity and uncertainty than with the single telescope type.

SCLERAL BUCKLE. A scleral buckle is the traditional surgical procedure used in repairing a detached retina. A detached retina occurs when a portion of the retina inside the back of the eye comes loose from the underlying epithelium. Because the retina is responsible for receiving

and sending visual images to the brain, a detachment can seriously affect vision and should be repaired by a retina surgeon immediately.

There are two types of surgery available for retinal detachments: scleral buckling and pneumatic retinopexy. The scleral buckle is the more common treatment. During this surgery, the sclera (the outside covering or white of the eye) is indented or "buckled" inward, usually by attaching a piece of preserved sclera or silicone rubber to its surface.

The surgery is usually performed in an operating room under general anesthesia, although local anesthesia may be used in some cases. Because most retinal detachments are caused by a retinal tear, the first step is to repair the tear with either a laser or a freezing instrument known as a *cryoprobe*. This treatment creates a scar around the tear preventing further tears or detachment. Next, a piece of solid silicone or a silicone sponge is sewn onto the outside wall of the eye over the retinal tear site. The silicone pushes in on the sclera until scarring from the cryotherapy (or laser treatment) seals the tear. The surgery is called *scleral buckling* because the sclera is buckled (pushed) in by the silicone. This buckle is left on the eye permanently and is not usually visible following surgery. On occasion, a vitrectomy may also be performed in conjunction with the scleral buckling surgery. During a vitrectomy, the vitreous fluid, which fills the eye, is removed and replaced with air or gas to push the retina back into place. These gases are gradually replaced by new vitreous fluid produced by the eye. The success of retina surgery depends on a number of factors including the length of time from when the retina detached until it was repaired, the size and location of the damage, and whether a fibrous growth has formed on the retina. If the macula (portion of the retina responsible for central or reading vision) was detached, vision rarely returns to normal.

In most cases, the retina can be successfully reattached, but reattachment does not necessarily mean restored vision. It may take many months after surgery for the best vision to occur and, if the first retinal detachment operation is not successful, a second operation may be performed. Treatment almost always prevents further loss of sight from this type of retinal problem.

Following scleral buckle surgery, the eye may be red and sore for a time and vision may be blurry. A scratchy sensation may also be felt as the stitches used to close the lining around the eye heal. The eye may be patched and eye drops given to prevent infection. Physical activity is usually restricted to ensure that the retina remains attached. Regular follow-up visits are necessary to ensure the retina is healing properly.

Serious complications from scleral buckling surgery are infrequent but can happen. The most common is redetachment of the retina. Occasionally, double vision can result from damage to the muscles that control eye movement. Other rare complications include cataract formation, bleeding beneath the retina, glaucoma, infection, and drooping of the eyelid.

Vision Rx, Inc., Elmsford, NY

SCLERENCHYMA. Sclerenchyma is a specialized tissue, adapted to withstand both compressive and tensile stresses in plants.

Functions and Cell Types

Sclerenchyma is a type of plant tissue that is not easy to define. The name means "hardened tissue." Sclerenchyma is best defined by its mechanical function, but providing hardness is only one of its possible mechanical roles, demonstrated for example in the tips of thorns. More widely important is the provision of rigidity and both tensile and shear strength in plant stems [Niklas, 1991].

The chief semantic problems are in distinguishing sclerenchyma from xylem and collenchyma tissues. The primary function of the xylem is water conduction, which requires xylem vessels to sustain radial crushing stresses from surrounding tissues at higher pressure, but the secondary xylem is also well adapted to withstand the longitudinal components of bending stress on plant stems. In wood these two functions of the xylem are shared unequally among vessels, tracheids, fibers and xylem parenchyma cells. The fibers and some parenchyma cells are nonconducting, are specialized for longitudinal mechanical properties and generally fit the functional definition of sclerenchyma. This makes the distinction between sclerenchyma and xylem difficult, and the term sclerenchyma can include at least the fibre cells of the secondary xylem. See also **Parenchyma**.

Sclerenchyma and collenchyma are both tissues that provide mechanical strength. Collenchyma, however, is flexible, can grow in step with adjacent cells and is strong only in tension. Sclerenchyma is adapted to withstand the compressive as well as the tensile component of bending stresses in stems. It needs rigidity, and shear strength between cells, to avoid buckling in compression. Differences in cell wall structure reflect these functional differences and are explored below. See also **Collenchyma**.

Sclerenchyma tissue can include a variety of cell types. The two principal classes are fibers and sclereids, fibers being longer than sclereids and unbranched. Fibers are further classified according to their association with vascular elements and sclereids according to their shape.

Fibers. Fibers are long, narrow, thick-walled cells. At up to 0.5 m, the fiber cells of Ramie (*Boehmeria nivea*) are probably the longest cells in any terrestrial plant. Fiber cells (Figure 1) usually occur in bundles which may be associated with the phloem, the xylem, or neither. The *fibers* of commerce are bundles of fiber cells, with a few exceptions such as cotton hairs.

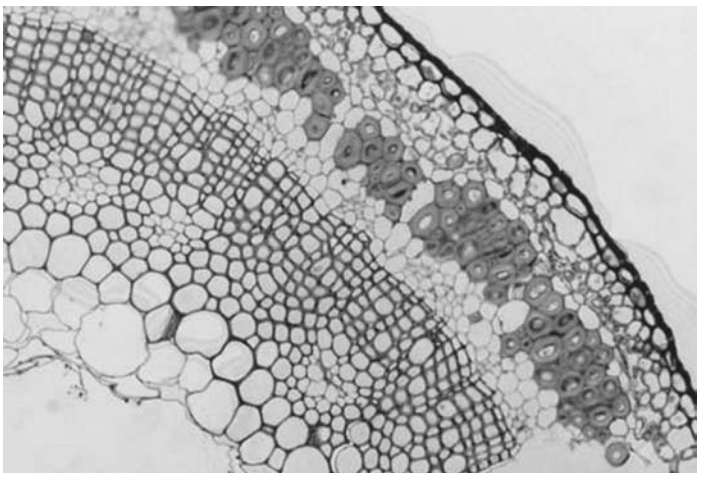

Fig. 1. Phloem fibers of flax (*Linum usitatissimum*) in transverse section. The thick-walled fiber cells (red) are attached together in bundles. Some are of small diameter: the plane of the section passes through these close to their intrusively growing tips, where they are tapering towards a point.

Phloem fibers ("bast" fibers) are associated with the primary phloem in stems of a variety of economic plants such as ramie and flax (*Linum usitatissimum*). In other dicotyledons such as *Vitis vinifera*, fiber bundles are distributed between the primary and secondary phloem, while secondary phloem fibers are found in some gymnosperms. Xylem fibers are a substantial component of wood. The libriform xylem fibres resemble phloem fibres in dimensions. They are generally longer, and thicker walled relative to their diameter, than other cells in wood but they vary in form and merge into tracheids. Many monocotyledons contain leaf fibers that are not specifically associated with either xylem or phloem. These can form either a cylinder just under the epidermis, or a sheath around each vascular bundle.

Sclereids. Sclereids, like fibers, are cells with thick secondary walls but they are not as elongated: they vary greatly in dimensions and are sometimes distinctive enough in form to be useful in plant taxonomy. Unlike fiber cells they are often isolated amidst tissues of other types. Sclereids are classified according to their shape:

- Brachysclereids or stone cells are thick-walled but approximately isodiametric. They give a gritty texture to fruit such as pears (*Pyrus communis*). There, hardness is presumably the important mechanical characteristic, related to selective consumption by animals and hence to seed dispersal.
- Marcosclereids (rod cells) and osteosclereids (bone cells) are columnular in shape. Bone cells are enlarged at the ends. These, unlike most other sclereids, are packed together to form tough, relatively impermeable structures such as the seed coats of legumes.

- Filiform sclereids are thread-like and sometimes branched. They occur, for example, in a strengthening mat dispersed through the mesophyll of olive (*Olea europaea*) leaves.
- Astrosclereids are star-shaped and are often located at the ends of leaf veins, where they may help to distribute local stresses imposed by the rigidity of the vein as the leaf flutters in the wind. Trichosclereids are similar in shape but project into the large intercellular spaces of aquatic plants such as water lilies (*Nymphaea* spp.).

Development

Ontogeny. There is nothing unique about the initials that give rise to sclerenchyma cells. Xylem and secondary phloem fiber initials originate in the vascular cambium like other cells in these tissues, and primary xylem fibers originate in the procambium. Fibers formed outside the vascular region, as in many monocots, are derived partly from the cortex and partly from the phloem. Sclereids originate most commonly as parenchyma cells. The formation of both fibers and sclereids is a process of differentiation that probably depends more on positional cues than on the developmental origin of the cells. The process of differentiation includes the deposition of a thick secondary cell wall.

Intrusive Growth. A common feature of sclerenchyma cells is that they elongate by intrusive growth, penetrating between the walls of pre-existing cells or through intercellular spaces. This does not mean that any significant part of the intrusively growing cell moves relative to the cells on either side. New cell wall material is inserted only at the tip (tip growth) and the rest of the sclerenchyma cell remains fixed to the walls of the cells between which it is elongating. In the bast fibers such as ramie and flax, intrusive growth at both ends of each fiber cell may increase the length of the cell by a factor of 1000 or more. In xylem fibers, intrusive growth on a much smaller scale is common. Filiform sclereids and trichosclereids grow intrusively through intercellular spaces and may branch if their growth is obstructed. In cells elongating by tip growth the tip tapers to a point, and it follows from this geometry that tip growth cannot be driven by turgor pressure in the normal way. It has been suggested the driving force resides in the cytoskeleton [Pickett-Heaps and Klein,1998].

Cell Wall Formation. The definitive stage in the differentiation of sclerenchyma cells is the formation of a continuously thickened, often lignified, secondary cell wall. The secondary cell wall provides strength in all directions, but in particular it gives fibre cells the rigidity to withstand compressive stresses without buckling. In contrast, the thickened primary cell walls of collenchyma are nonlignified, pectin-rich and flexible when hydrated: they provide strength only in tension, while the helical thickenings of primary xylem vessels are adapted to withstand only radial compressive stresses. In sclerenchyma an equally important function of lignification is to attach the cells to one another and so stabilize the mechanical architecture of the plant. For example the sclerenchymatous ring in cereal straw [Travis, et al. 1996] and other plant stems [Niklas, 1991] is well adapted for stiffness under the bending stress of wind, while in vines a central location for the sclerenchyma combines strength in tension with flexibility in bending. Parallel isolated strands of sclerenchyma in grass leaves combine some flexibility with shear strength, influencing grazing by herbivores [Vincent,1991].

The secondary walls of sclerenchyma cells are constructed from an ordered scaffolding of cellulose microfibrils, bonded into a matrix of hemicelluloses and lignin. The hemicelluloses are principally glucuronoarabinoxylans except in conifer wood, which also contains glucomannans. In *Arabidopsis* mutants that have defects in either cellulose or lignin biosynthesis in secondary xylem cells (as well as in primary xylem vessels where the collapsed xylem phenotype results), the secondary cell walls visibly lose cohesion and the tensile strength and bending stiffness of the stems is reduced [Turner and Somerville, 1997]. In intrusively growing fibers, the growing tips have only a primary wall. Secondary wall formation then follows some way behind the growing apex. In wood, the primary cell wall is degraded as the secondary wall is deposited inside it. This is not always the case in sclerenchymatous cells of herbaceous plants, where polymers typical of primary walls may remain abundant at maturity [Engels and Jung, 1998]. Cell death may follow secondary wall formation, but this too is not universal and is more common in mature cells with a conductive function.

The relationship between structure and mechanical properties has been extensively studied in wood, and similar principles apply to sclerenchyma. The amount and orientation of cellulose in the secondary cell wall is the most important factor influencing both rigidity and hardness [Chaffey, 2000]. Approximately longitudinal cellulose microfibrils, as in fibers, maximize longitudinal stiffness. Mean microfibril angles are widely used as a quality characteristic in timber. In contrast the sclereids comprising the stony endocarp of *Prunus* spp. have beautifully complex, writhing microfibril patterns that leave little averaged orientation in any direction [Reis et al., 1992: an adaptation for hardness. Secondary wall structure is where form and function meet in sclerenchyma cells.

ISABELLE HIS,
Glasgow University, Glasgow, Scotland

SCLERODERMA. This may be a localized disease (*scleroderma*) or a diffuse disease (*progressive systemic sclerosis*) which is caused by the deposition of fibrous connective tissue in the skin. Scleroderma is classified as one of the rheumatic diseases. The skin becomes thick and there is moderate swelling of affected tissue, followed by a deadening and wasting away of skin with accompanying loss of hair follicles, sebaceous and sweat glands. The skin tightens, loses pliability, and may be described as hide-like. In the course of the disease, there may be involvement of the lungs, heart, kidneys and other organs. Infrequently, systemic complications can be fatal. Where only the skin is affected, the disease may not be the primary determinant of life span. Sclerodermatous skin is seen most frequently in the hands and fingers and somewhat less frequently in the facial area, this latter involvement frequently reducing the size of the mouth. However, in some patients, the disease may be diffusive and involve all of the skin of the body.

The systemic aspects (sclerosis) of scleroderma are usually more serious than simple scleroderma. When the *musculoskeletal system* is involved, there may be a mild form of arthritis similar to rheumatoid arthritis. Sometimes *acral osteolysis* (shortening of fingers and toes) may develop. Also, there may be weakening of skeletal muscles. Scleroderma may involve the *gastrointestinal tract*, leading to diverticula. Where smooth

muscle of the esophageal mucosa is replaced by fibrous tissue, *dysphagia* (difficulty in swallowing) may result — as well as gastric reflux and peptic esophagitis. *Lung involvement*, in which fibrosis occurs in the walls of the pulmonary arteries, may cause pulmonary hypertension, a condition that can lead to progressive respiratory failure. In *heart involvement*, fibrous tissue replaces extensive areas of cardiac muscle, precipitating arrhythmias, conduction disturbances, and congestive heart failure. In *kidney involvement*, scleroderma may cause chronic mild proteinuria and mild hypertension. The syndrome known as *malignant hypertension* may precipitate oliguric renal failure.

The etiology of scleroderma is unknown. The abnormal amount of collagen present in this disease appears to be normal rather than altered collagen.

SCLEROMETER. An apparatus used to test the hardness of various materials. It measures the pressure on a standard point that is required to scratch the material. A scleroscope is a similar apparatus, which measures hardness by determining the rebound of a standard ball dropped on the subject material from a fixed height.

Methods of Hardness Testing

Typical methods for testing the hardness of metals are the sclerometer method introduced by Turner in 1896; the scleroscope method recently invented by Shore; the indentation test adopted by Brinell about 1900; and the drill test introduced by Keep a few years earlier. See also **Hardness**. The principles underlying each of the four methods are briefly described in the following:

Turner's Sclerometer. In this form of test a weighted diamond point is drawn, once forward and once backward, over the smooth surface of the material to be tested. The hardness number is the weight in grams required to produce a standard scratch. The scratch selected is one which is just visible to the naked eye as a dark line on a bright reflecting surface. It is also the scratch which can just be felt with the edge of a quill when the latter is drawn over the smooth surface at right angles to a series of such scratches produced by regularly increasing weights. See Table 1.

TABLE 1. HARDNESS SCALES COMPARED

Metal	Sclerometer	Scleroscope	Brinell Method[a]	Mohs's Scale for Minerals
Lead	1.0	1.0	1.0	
Tin	2.5	3.0	2.5	
Zinc	6.0	7.0	7.5	Talc–1
Copper, soft	8.0	8.0	...	Gypsum–2
Copper, hard	...	12.0	12.0	Calcite–3
Softest Iron	15.0	...	14.5	Fluor Spar–4
Mild steel	21.0	22.0	16–24	Apatite–5
Soft cast iron	21–24	24.0	24.0	Orthoclase–6
Rail steel	24.0	27.0	26–35	Quartz–7
Hard cast iron	36.0	40.0	35.0	Topaz–8
Hard white iron	72.0	70.0	75.0	Sapphire or Corundum–9
Hardened steel	...	95.0	93.0	Diamond–10

[a]Actual numerals have been divided by 6 for purposes of comparison.

Shore's Scleroscope. In this instrument, a small cylinder of steel, with a hardened point, is allowed to fall upon the smooth surface of the metal to be tested, and the height of the rebound of the hammer is taken as the measure of hardness. The hammer weighs about 40 grains, the height of the rebound of hardened steel is in the neighborhood of 100 on the scale, or about 6-1/4 inches, while the total fall is about 10 inches or 254 millimeters.

Brinell's Test. In this method, a hardened steel ball is pressed into the smooth surface of the metal so as to make an indentation of a size such as can be conveniently measured under the microscope. The spherical area of the indentation being calculated and the pressure being known, the stress per unit of area when the ball comes to rest is calculated, and the hardness number obtained. Within certain limits, the value obtained is independent of the size of the ball and of the amount of pressure.

Keep's Test. In this form of apparatus a standard steel drill is caused to make a definite number of revolutions while it is pressed with standard force against the specimen to be tested. The hardness is automatically recorded on a diagram on which a dead soft material gives a horizontal line, while a material as hard as the drill itself gives a vertical line, intermediate hardness being represented by the corresponding angle between 0 and 90 degrees.

SCOLECITE. This mineral is a zeolite, a hydrous calcium-aluminum silicate, $CaAl_2Si^3O_{10} \cdot 3H_2O$. It occurs in slender monoclinic prisms and in fibrous and nodular masses. Hardness is 5; specific gravity, 2.27 (very light); luster vitreous to silky; transparent to translucent. When heated, some specimens of scolecite curl up like worms; hence its name, derived from the Greek meaning a worm.

Though somewhat rare, scolecite is a popular mineral among collectors. It forms in volcanic bubbles called vesicles along with other zeolites. Scolecite's sprays of radiating crystals are, well ..., exotic, inspiring, awesome, magnificant, etc. They are truly hard to describe, but are something that everyone who loves minerals will enjoy.

Scolecite's structure has a typical zeolite openness about it that allows large ions and molecules to reside and actually move around inside the overall framework. The structure contains open channels that allow water and large ions to travel into and out of the crystal structure. The size of these channels controls the size of the molecules or ions and therefore a zeolite like scolecite can act as a chemical sieve. Scolecite's structure contains aligned chains of silicate tetrahedrons. This produces the needle-like crystals and the cleavage results from the weaker bonds between the chains.

This mineral occurs with other zeolites, at Baden, Switzerland; Iceland; Greenland; the Deccan region of India; and in the United States at Golden, Colorado, and Paterson, New Jersey. Single crystals up to 12 inches (30 centimeters) in length have recently been found in a single large cavity in the basaltic trap rocks near Nasik, India.

SCOLIOSIS. A deformity, usually of the spine, in which there is abnormal lateral displacement of the spine (with at least one other compensatory curve in the opposite direction), which in extreme conditions causes what is commonly termed "hunchback." In *Friedreich's ataxia*, a hereditary spinocerebellar degradative disease, scoliosis is present. In some cases (uncommon), scoliosis can cause pulmonary or cardiac insufficiency, or both. Thoracic scoliosis is the result of a developmental anomaly and is precipitated by weakness in the paravertebral muscles.

SCOMBROID POISONING. See **Foodborne Diseases**.

SCORER PARAMETER. The quantity $l(z)$ arising from the wave equation for atmospheric gravity waves describing flow over a mountain barrier:

$$l^2(z) = N^2/U^2 - (\partial^2 U/\partial z^2)/U$$

where $N = N(z)$ is the Brunt–Väisälä frequency and $U = U(z)$ is the vertical profile of the horizontal wind, both quantities determined from an atmospheric sounding upstream of the barrier.

The first term on the right-hand side usually dominates, but occasionally the second term, the velocity-profile curvature term, can be of similar magnitude. When l^2 is nearly constant with height, conditions are favorable for vertically propagating mountain waves. This parameter is most often used, however, as an indicator of when trapped lee waves (See **Mountain Wave**) can be expected; they occur when $l^2(z)$ decreases strongly with height. This is especially true if this decrease occurs suddenly in mid troposphere, dividing the troposphere into two regions, a lower layer of large $l^2(z)$ (high stability) and an upper layer of small $l^2(z)$ (low stability). l, the square root of the parameter, has units of wavenumber (inverse length), and the wavenumber of the resonant lee wave lies between l of the upper layer and l of the lower layer — the equivalent wavelength generally lying

between 5 and 25 km (3 and 15.5 miles) in the atmosphere. Mountain ranges wide enough to force wavelengths long relative to l_{upper} (the l in the upper layer) produce vertically propagating waves with wavenumbers less than l_{upper}. Small objects (that force wavenumbers greater than l_{lower}) produce waves that are evanescent, or vanishing with height.

AMS

SCORIA. The term applied to lava which is highly vesicular and slaggy in appearance, due to the escape of the volcanic gases while the lava is still viscous. Scoria may be considered as a very coarse variety of pumice, the vesicles occupying approximately the same amount of space as the solid material, and extremely variable in size and shape.

SCORODITE. This hydrated arsenate of ferric iron and aluminum $(Fe_3+, Mg_3+)AsO_4 \cdot 2H_2O$, crystallizing in the orthorhombic system, is the iron-rich isomorphous end member of a complete series extending to the aluminum-rich mineral Mansfieldite. Crystals usually occur as drusy crusts. Also occurs as massive, compact, and earthy material. Hardness is 3.5–4 with specific gravity of 3.278 (average for translucent minerals). Color is colorless, white, green, blue, yellow and brown. Vitreous to subadamantine luster, of pale green to liver-brown color.

Crystals of scorodite can form dipyramids that look like octahedrons. These pseudo-octahedral crystals will also resemble the much harder gem mineral zircon. The color of scorodite is variable but it is most known and revered for its bright green or blue colors that really establish scorodite as a wonderful display mineral.

Scorodite occurs as a secondary alteration mineral in the oxidized zone of metallic arsenic-containing veins. The mineral also may be a product of deposition from certain hot springs. Notable Occurrences include the famous mines at Mapimi, Mexico; also Lavrion, Greece; Ouro Preto, Minas Gerias, Brazil; Cornwall, England; Tsumeb, Namibia; Ontario; California, USA and Zacatecas, Mexico. Scorodite has also been found as a crust precipitated on the outer rims of hot springs at Yellowstone National Park in Wyoming.

SCORPION FLY *(Insecta, Mecoptera).* Moderately large insects with four membranous wings. They are named from the peculiar modification of the terminal segments of the abdomen, which fairly resembles that of the scorpions. The apparent sting is, however, made up of the external genital organs. See also **Mecoptera**.

SCORPION *(Scorpionida).* A terrestrial arthropod with a conspicuous pair of pincers and a slender terminal region of the body bearing a claw-like sting, and the order made up of these animals. See Fig. 1. They are grouped with the spiders, ticks and other forms in the class *Arachnida*.

The order is characterized by the conspicuous pincers and by the sting. The body is divided into cephalothorax and abdomen, and the latter consists of a broad anterior portion and a slender post-abdomen. The sting, a modified telson, bears the opening of the duct of a poison gland. The genital ducts open on the ventral surface of the first abdominal segment, just in front of a pair of comb-like pectines of the second segment which are regarded as accessory reproductive organs.

Scorpions are common in warm dry regions. In the United States, they occur as far north as Kentucky. Their poison is not virulent as a rule.

SCORPIUS (the scorpion). Scorpius is the eighth sign of the zodiac. The constellation is rather far south for observation in Europe and North America, but is a beautifully grouped constellation presenting more resemblance to the figure for which it is named than is the case with most of the others.

The brightest star in the group Antares (α Scorpii) is one of the most beautiful stars in the sky. It is distinctly reddish in color and gets its name from the fact that it opposes or rivals Mars, the red planet, in color. It is the largest star whose diameter has thus far been measured, having a diameter approximately 450 times that of the sun. The star is so large that if Antares were in the position of the sun it would extend out beyond the planet Mars. (See map accompanying entry on **Constellations**.)

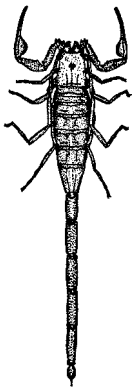

Fig. 1. Scorpion.

SCOTOPIC VISION. See **Parafoveal Vision**

SCREAMER *(Aves, Ciconiiformes).* Peculiar South American birds with moderately long legs and large feet. The beak is like that of the domestic fowl and the wings are provided with two stout spurs on the front margin. The birds are as large as geese and swim readily, although the toes are not webbed. See also **Anseriformes**.

SCREW-WORM *(Insecta, Diptera).* The term *screw-worm* is usually reserved for those maggots of flies that attack a wounded or diseased animal, as contrasted with the egg-laying and larval activities of those flies (such as bot fly) that attack a healthy animal for the purpose of laying eggs within its body just below the skin. Screw-worms are of the family *Calliphoridae*, order *Diptera*. One species is *Callitroga* or *Cochliomyia hominivorax* (Coquerel), or *C. americana*. The adult screw-worm fly appears much like a house fly, but is about double its size. There are 3 prominent black stripes on the back behind the head. This fly lays its eggs on the edges of wounds of injured animals. The resulting maggots first feed on wound tissue and then proceed to sound tissue, a process aided by hooks in their mouth parts. Thus, old wounds do not heal, but spread and the affected animal becomes sullen and withdrawn. A chain reaction is activated because the odor from the spreading wound attracts more and more of the screw-worm flies to further the process. An untreated animal can die in relatively short order because, in this condition, the animal usually will not feed.

The species *Callitroga macellaria* (Fabricius), known as the *secondary screw-worm*, lays its eggs on the bodies of dead animals, but also attacks wounded animals. The species is responsible for a very high percentage of the animal screw-worm attacks in the southern states. Reactions from an infestation can include meningitis and peritonitis. Serious epidemics, involving tens of thousands of animals, have occurred in the Gulf States. Losses in some years run into the several millions of dollars.

Control is aided by continuing inspections of animals for any breaks in their skin that will attract the flies. Operations, such as dehorning, castrating, earmarking, docking of lamb tails, branding, etc., should be performed only during late fall and winter when flies are not active. Dogs should not be trained to bite or nip at livestock. Unavoidable injuries should be treated immediately. Infested wounds can be treated by applying smears of various formulations directly to the wound, using a small paint brush. The material should be thoroughly worked into any pockets where maggots may be hiding.

SCROPHULARIACEAE. This family contains some 2,500 species, most of which are herbs or shrubs. Its members are numerous in temperate regions, where many of them are common plants, as for example mullein, "butter-and-eggs," speedwell, and lousewort. Annuals, biennials and perennials are found in the family.

The flowers are zygomorphic, or bilaterally symmetrical, with the calyx and corolla both tubular and each composed of four or five lobes. In many plants of this family the corolla is distinctly 2-lipped, as in the Snapdragon. Usually there are four stamens, which are inserted on the corolla tube. The

ovary, composed of two united carpels, becomes a dry capsule containing many small seeds. The flowers of this family are mostly pollinated by insects, such as bees, wasps, and flies, which seek the nectar secreted in a disk at the base of the ovary.

In this family are found many plants grown by man as ornamentals. Some, such as Foxglove (*Digitalis*) and *Veronica*, are hardy biennials, or perennials; others, like Snapdragon (*Antirrhinum*), are not hardy; while *Calceolaria*, a native of South America and Mexico, is a hothouse plant grown for its bizarre sac-like flowers of brilliant color. Drugs of medicinal value are also found in several plants of this family, the most important being digitalis, from species of foxglove. In early days many species were used as a source for homemade brews. Others are poisonous herbs.

SCUD. See **Clouds and Cloud Formation**.

SCULPINS *(Osteichthyes).* Of the order *Scleroparei*, family *Cottidae*, sculpins are peculiar fishes, usually small, with a broad depressed head and large pectoral fins. They are of no importance as food fishes. Many of the included species bear other names, including the little miller's thumbs of freshwaters and the sea raven, which ranges from Cape Cod to the Arctic. One species of the northern Atlantic coast is called the big sculpin, or daddy sculpin. The *Hemilepidotus hemilepidotus* (spotted irishlord) occurs in the American Pacific and reaches a length of about 20 inches (51 centimeters). *Enophrys bison* (buffalo sculpin) also occurs in the American Pacific. One of the larger sculpins is *Scorpaenichthys marmoratus* (crab-eating cabezon) which attains a length of about 30 inches (76 centimeters) and weighs up to 25 pounds (11 kilograms). It is found in Pacific waters from Lower California northward to British Columbia. Although the roe is poisonous, the flesh is considered good (even if a green color). The *Leptocottus armatus* (Pacific staghorn sculpin) is common and found in shallow waters of the Pacific coast, usually quite abundant in bays ranging from Lower California northward to Alaska. Their size usually does not exceed 6 inches (15 centimeters). *Hemitripterus americanus* (Atlantic sea raven) has qualities like a puffer in that it can inflate itself by swallowing air when taken from the water. Although rumored to be edible, its major use is for baiting lobster traps.

The grunt sculpin (*Rhamphocottus*) is of the family *Rhamphocottidae* and is named for the grunting noise it makes when taken from the water. Measuring only about 3 inches (7.5 centimeters), the grunt sculpin ranges in Pacific waters from northern California to Alaska. It is well known for its vertical temperature distribution. This sculpin does well in aquariums.

SCUP. See **Porgies**.

SCURVY. See **Ascorbic Acid (Vitamin C)**; and **Nutritional Science (The History)**.

SCYPHOZOA. The jellyfishes. A class of the phylum *Coelenterata* made up entirely of marine animals which are, with very few exceptions, floating forms. The jellyfishes represent the highest development of the medusa form of coelenterates, and have lost the polyp stage with the exception of the reduced hydratuba larva.

Jellyfishes owe their name to the great development of the middle layer of the body (mesogloea), which is a bulky and jelly-like mass. They contain a high percentage of water, sometimes as great as 96%, and are consequently soft-bodied and without rigid support. In the water, however, they are delicate and beautiful. Many are filmy transparent creatures while others are beautifully colored. They are found at various depths and in various seas, and in size they range from species less than 1 inch in diameter to the large *Cyanea* with a body 6–7 feet (1.8–2.1 meters) in diameter and tentacles 120 feet (36 meters) long. They are of no economic importance.

SEA ANEMONE. A complex polyp of the class Anthozoa (*Actinozoa*). Although closely related to the alcyonarians and corals the sea anemones are usually solitary and in some species are large and beautifully colored. They are without hard supporting structures such as the related forms possess.

SEA ARROW *(Mollusca, Cephalopoda).* Small slender squids, *Omnastrephes*, which swim very rapidly. Also called flying squids.

SEA BASS. See **Bass**.

SEA BEAR. See **Sea Lions and Seals**.

SEABOARD PROCESS. Method of removing hydrogen sulfide from a gas by adsorption in sodium carbonate solution. Sodium bicarbonate and sodium hydrosulfide are formed. Blowing air through the solution, hydrogen sulfide is released and carried off, and the sodium carbonate is regenerated.

SEABORG, GLENN T. (1912–1999). An American atomic scientist, and one of the first scientists to produce a transuranium element. He received is A. B. degree at the University of California, Los Angeles in 1934, and his doctorate at the University of California, Berkeley in 1937. As a graduate student in the 1930s doing wet chemistry research for his advisor Gilbert Newton Lewis, Seaborg devoured the text *Applied Radiochemistry* by Otto Hahn, of the Kaiser Wilhelm Institute for Chemistry in Berlin. For several years, Seaborg conducted important research in artificial radioactivity using the Lawrence cyclotron at Cal Berkeley. He was excited to learn from others that nuclear fission was possible, but also chagrined, as his own research might have led him to the same discovery. In 1939 he became an instructor in chemistry at UC Berkeley.

In the same year in which he produced plutonium, 1941, he also discovered that the isotope U^{235} undergoes fission under appropriate conditions. He therefore was responsible for two different approaches to the development of nuclear weapons. At this time he was transferred to the Manhattan Project and was part of Enrico Fermi's team, which achieved the first nuclear chain reaction in 1942.

In 1951 along with Edwin McMillan he received the Nobel Prize in chemistry for the creation of the first transuranium elements. He created plutonium, americium, curium, berkelium, and californium at Berkeley.

The element seaborgium was named for him in honor of his accomplishments. It was so named while he was still alive, which proved extremely controversial. For the remainder of his life, Seaborg was the only person in the world who could write his address in chemical elements: Seaborgium, Lawrencium, Berkelium, Californium, Americium (Glenn Seaborg, Lawrence Berkeley National Laboratory, Berkeley, California, United States of America).

See also **Chemical Elements**.

SEABORGIUM. See **Chemical Elements**.

SEA BUTTERFLY *(Mollusca, Gasteropoda).* Mollusks with the foot formed into two wing-like lobes, which propel the animal through the sea by slow flapping movements. They make up the order *Pteropoda*.

SEA COWS *(Mammalia, Sirenia).* The manatee and dugong, collectively sea cows, constitute an order of mammals, *Sirenia*. The manatee is a fully aquatic animal with a horizontally flattened oval tail. There are no hind limbs, and the forelimbs are developed as flippers. See Fig. 1. They have a superficial similarity to whales but differ in many details of structure. They live only in shallow coastal waters and estuaries and eat aquatic plants. The several species of the genus *Manatus* are distributed on both shores of the Atlantic and in the Oriental and Australian regions. *M. latirostris* is found off Florida. The dugong is related to the American manatee and is found along the shores of the Oriental region. This animal (*Halicore*) has a blunt muzzle, a broad horizontal tail, and pectoral flippers. Principal diet is seaweed. The dugong is hunted for its flesh and oil.

SEA ELEPHANT. See **Sea Lions and Seals**.

SEA FAN *(Coelenterata, Anthozoa).* Marine polyps of the order *Alcyonaria* whose colonies are in the form of thin lacy fans.

Fig. 1. Florida manatee.

SEA FEATHER *(Coelenterata, Anthozoa)*. Marine polyps of the order *Alcyonaria*. The colony has a central stalk bearing lateral branches, the whole resembling a feather.

SEAFOOD POISONING. See **Foodborne Diseases**.

SEA GULL. See **Petrels and Albatrosses**; and **Waders, Shorebirds, and Gulls**.

SEA HARE *(Mollusca, Gasteropoda)*. A marine mollusk of oval form with two ear-like tentacles near the anterior end which give it this name. The mantle almost conceals the shell and the foot forms two lobes by which the animal swims. Sea hares live on seaweed.

SEAHORSES *(Osteichthyes)*. Of the order *Solenichthys* (tube-mouthed fishes), family *Syngnathidae*, seahorses are of the same family as the pipefishes. See also **Pipefishes (Osteichthyes)**. Because of what might be termed their "cute" figures and their resemblance to equine mermaids, seahorses have been a favorite of commercial and scientific aquarium operators. They would also be favorites of fish hobbyists, were it not for the difficulties encountered in maintaining seahorses in tanks. See Fig. 1. There are about 25 species of seahorses, distributed well, but the majority occurring in the Indo-Australian area. Seahorses are exclusively marine in habitat and are quite small, ranging from a length of about $1\frac{1}{2}$ inches (3.8 centimeters) to a maximum of 8 inches (20 centimeters). There are numerous similarities between seahorses and pipefishes. For example, as with pipefishes, there is independent movement of the eyes. Seahorses are incapable of rapid movement and hence utilize an accurate suction mechanism which is operable within a range of about $1\frac{1}{2}$ inches (3.8 centimeters). It has been observed that juvenile seahorses may feed for a period of up to 10 hours and, during that time, consume from 3,000 to 4,000 brine shrimp. The large species (*Hippocampus hudsonius* or Atlantic seahorse) survives well in tanks but does not reproduce in captivity. In contrast, the *Hippocampus zosterae* (Gulf of Mexico) pigmy seahorse may survive through a number of generations. Seahorses are well known for the display of unusual courting habits. These include odd shaking movements, and in some species, the holding of tails, and, in the female, simply turning of the head stimulates the male. In the forward direction, the tail of the seahorse is used in a prehensile manner.

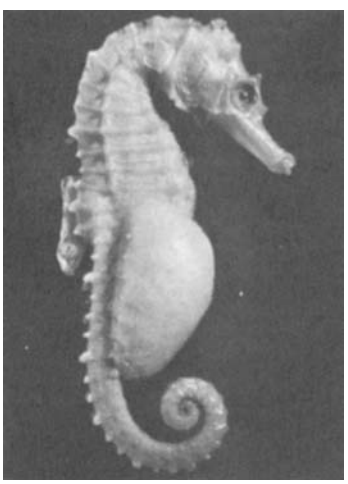

Fig. 1. Seahorse.

SEA ICE. 1. Specifically, ice formed by the freezing of seawater; as opposed, principally, to land ice. In brief, it forms first as lolly ice (frazil crystals), thickens into sludge, and coagulates into sheet ice, pancake ice, or into floes of various shapes and sizes. Thereafter, sea ice may develop into pack ice and/or become a form of pressure ice.

2. Generally, any ice floating in the sea.

SEAL. See **Sea Lions and Seals**.

SEALANTS. A sealant is a material that is installed into a gap or joint to prevent water, wind, dirt, or other contaminants from passing through the joint or gap. This joint or gap may be a fixed joint, but is often an expansion joint which may also be called a working joint. Sealants, which can also be defined by how they are tested, are rated by their ability to stretch, twist, bend, and be compressed while maintaining their bulk properties so that they do not tear apart under stress. A most important rating of a sealant in many applications is the movement ability of the sealant. The adhesion required of a sealant is simply the strength to hold the sealant in position as it is stressed and strained.

Adhesives are used to transfer loads and are typically designed with much higher tensile and shear strengths than sealants. The most important rating of an adhesive in many applications is the determination of how much load it can handle. Some sealants are used as adhesives and some adhesives as sealants and thus arises the occasional blurring of their roles. If the material's primary function is the exclusion of wind, water, dirt, etc, it is a sealant.

Performance Characteristics

Movement Capabilities. The movement capability of a sealant is the amount of displacement the sealant can endure in extension or compression without failing. In general, sealants with lower modulus of elasticity can handle higher movements.

Sealants can be broadly divided into classes according to the amount of movement they can successfully handle. High performance sealants such as silicones, urethanes, and polysulfides can typically handle movements of 25% or higher. Medium performance sealants such as some acrylics can handle movements of 10–25%. Low performance sealants such as butyls, putties, and caulks accommodate movements under $<10\%$. Movement ratings are commonly reported by sealant manufacturers, but these ratings are dependent on the substrate, cure time, rate of movement, etc.

Modulus. The measure of the stress of a sealant at a specific strain is referred to as the modulus of elasticity, sometimes called the *secant modulus*. This important sealant property describes the force exerted by a sealant as it is stressed. Because a primary function of sealants is to adhere to the substrates it is in contact with, the forces generated by a joint opening or closing are transmitted by the sealant to the substrate–sealant bond line. For this reason, it is important to know the modulus of the sealant and also the strength of the substrate. The use of a high modulus sealant on a weak substrate, such as asphalt, concrete, or sandstone, can result in stresses higher than those that the substrate can tolerate, and has a higher potential for failure, often through cohesive failure of the substrate. Normally, concrete is thought of as a high strength substrate, which it is in compression. However, by comparison it is quite weak in tension. Sometimes, upon closer inspection, perceived adhesive failures are actually cohesive failure of the substrate near the substrate–sealant interface caused by such a modulus mismatch.

Although sealant manufacturer's literature commonly reports modulus values, these values must be interpreted carefully. Specimen sizes, test rate, cure conditions, and the time a sealant has been allowed to cure when

tested can all have a significant effect on modulus. Therefore, for a true comparison, sealants should be evaluated by a standard test that examines all sealants by the same procedure. In general, the longer a sealant has been allowed to cure, the more realistic the modulus data.

Durability. A primary factor in sealant durability is its ability to resist decay from environmental elements. For most typical applications this includes extremes of high and low temperature, water, oxidation, and sunlight.

Sealants are used in all kinds of industries and in many of those applications temperature stability is a major concern. Some appliance applications can see 200 °C (400 °F) for prolonged periods of time and even mondane applications like building sealants can see 80 °C (176 °F)–90 °C (194 °F) on dark colored Southern faces in warmer climates. Thus sealants used in high temperature applications require data that they are suitable for such use.

Low temperature flexibility is also an issue for many sealants. At low temperatures, the sealant can stiffen resulting in large forces at the bondline due to movement of the joint. Typically, the sealant does not fail, but the joint does, which is just as severe of a problem. When looking for low temperature data, it is important to get actual modulus of elasticity at low temperatures and compare that to the modulus at room temperature. Simple claims, such as low temperature flexibility, should be supported by these data. Even cold temperature adhesion testing will not always avoid problems, since bond fatigue is also a factor.

One of the more destructive elements is exposure to sunlight; specifically, ultraviolet (uv) light. All sealants are affected by weathering, but there is much difference in the effect of weathering on different sealants. Most silicones are stable with respect to uv exposure. Urethanes and polysulfides show effects of uv exposure, but can be formulated with uv absorbers to provide reasonable lifetimes in most applications. However, there are exceptions in all classes of sealants and specifiers must be careful to look for test data that has proven a specific sealant's durability. The source of the test data is also important; data from an independent testing laboratory is generally apt to be more reliable.

A second key factor in determining the durability of a sealant is the ability of the sealant to adhere to the substrate through its lifetime. A sealant may have excellent resistance to uv effects, but if it has poor adhesion performance and fails adhesively, it is of little use. The same can be said of a sealant with superior adhesion characteristics but poor resistance to uv. Either situation results in a short performance life.

Sealant Types and Formulations

Silicones. Commercially available silicone sealants are typically one of three curing types: moisture-reactive (curing) sealants, moisture-releasing (latex) sealants, and addition-curing sealants. Of these three types, moisture-curing silicones make up the vast majority of silicone sealants sold.

The formulation of moisture-curing silicones includes a silicone polymer, filler, a moisture-reactive cross-linker, and sometimes a catalyst. A newer class of silicone sealants are known as the silicone latex sealants. These sealants are silicone-in-water emulsions that cure by evaporation of the emulsifying water. They should not be confused with siliconized acrylic sealants, which contain <2% silicone and have all the characteristics of acrylic sealants. Addition-curing silicones in general are two-part systems that cure by the platinum-catalyzed reaction of a silicone hydride with typically a vinyl group attached to silicon. Because no by-products are generated by the cure, there are few volatiles and no shrink in thick sections. The cure can take place at room temperature or be accelerated by heat. Addition-curing silicones have little inherent adhesion and proprietary adhesion promoters or primers are often used to give adequate adhesion to substrates.

Urethanes. Urethane sealants are particularly noted for toughness and find some of its more prominent uses in areas where toughness and abrasion resistance are a concern. The basis for urethane chemistry is the reaction of an isocyanate group with a component containing an active hydrogen.

Most urethanes use blends of polymers to achieve desired properties. Urethane sealants have good inherent adhesion to most substrates, but silane adhesion promoters are often used to improve this adhesion.

Urethanes have many uses and most urethanes are readily paintable. Note well the sealants in moving joints will be stretching more than the paint film and thus even if painted the paint can become cracked and checked and occasionally loose adhesion. Typically, but not always, the most stable urethane colors are black and white. However the white can become a tan since the degradation products are highly colored and even small amounts of degradation will effect the sealant's color. See also **Urethane**; and **Urethane Polymers**.

Si-Hybrid Sealants. In order to combine good adhesion on various substrates and properties typical of organic-based sealants, eg, paintability and nonstaining character, organic polymers functionalized with Si-alkoxy groups have been developed. Sealants based on these polymers have similar cure chemistry to standard silicone based sealants; beside the polymer, the formulation contains fillers (preferably calcium carbonate or silica), plasticizers, rheology modifier, silane adhesion promoters, organotin or organotitanium catalysts, silane adhesion promoters, water scavengers, antioxidants, UV, and light stabilizers.

Polysulfides. Polysulfide sealants were the first high performance synthetic elastomeric sealants produced in the United States. The basic polymers are mercaptan-terminated (HS−R−SH), with molecular weights ranging from 1000 to ∼8000. Curing occurs through the mercaptan groups by oxidation and results in an S−S linkage. In addition to the terminal SH groups, pendent SH groups are located along the polymer chain and contribute to cross-linking.

Polysulfide polymers provide inherent resistance to fuel and quite good resistance to alkali. In contrast to the silicone polymers, they have low gas permeability. Although low gas permeability is an asset in certain applications, it also causes slow cure for one-part moisture-activated sealants where the moisture must diffuse through the sealant to initiate cure. Because of the slow cure of the one-part sealant, the most common form of polysulfides is the two-part mix-on-site sealants. Different curing agents have different effects on the properties of the polysulfide sealant. Therefore, the choice of curing agent depends on the sealant application. Adhesion promoting silanes are often added to improve adhesion to various substrates. As is the case with urethane sealants, silanes with a dual-reactive nature are typically used.

Acrylics. There are two principal classes of acrylic sealants: latex acrylics and solvent-release acrylics.

High molecular weight latex acrylic polymers are prepared by emulsion polymerization of alkyl esters of acrylic acid. The emulsion polymers are compounded into sealants by adding fillers, plasticizers, freeze–thaw stabilizers, thickeners, and adhesion promoters. As is true of the silicone latex sealants, the acrylic latex sealants are easy to apply and clean with water. One common characteristic of many, if not all, latex acrylics is they harden with time in the weather.

Another class of acrylic sealants are the solvent-releasing acrylics. Acrylic monomers are polymerized in a solvent. The natural adhesion of most of the solvent-releasing acrylics produces some of the best unprimed adhesion in the sealant industry. However, slow, continual cure generally produces large compression sets and limits their use to low movement applications. Also, the relatively high amounts of solvent and traces of acrylic monomer in these formulations limits their use to outdoor applications, usually in construction.

Butyls. Butyl-based materials are sold in the form of preformed tapes, thermoplastic hot melts, and one-part solvent-releasing sealants. Butyl polymers are made by the copolymerization of 97–98 mol% isobutylene with 2–3% isoprene. Another butyl-based polymer, polyisobutylene, is produced by the polymerization of isobutylene. Both polymers are available in a wide range of viscosities. These polymers are low cost and have the lowest moisture vapor transmission rates of the common sealant types. Formulations of butyl-based sealants also include plasticizer, filler, and tackifier resins. Polybutenes are common plasticizers for butyl sealants. They are made from the polymerization of a mainly isobutylene feedstock and are available in several different viscosities. Butyl sealants are often filled with carbon black, but other fillers such as talc and calcium carbonate are also used, especially for lighter colored sealants. Tackifier resins, eg, the pentaerythritol ester of rosin, are added to provide tack or adhesion to various substrates. Solvents, such as mineral spirits, are used for the one-part solvent-releasing formulations. As the solvent leaves the typical

TABLE 1. SUMMARY OF SEALANTS

Sealants	Key Attribute	Principal Market	Limitation
Silicone	Excellent UV stability, fast cure on account of high moisture vapor transmission, good high temperature stability, good low temperature flexibility	Structural glazing, weatherproofing, insulating glass (secondary seal), pavement, consumer, premium housing	Some not abrasion-resistant, some not recommended for below-grade or continuous water immersion, generally not paintable, some pick up dirt
Urethane	Tough, abrasion-resistant, good adhesion to many substrates, good chemical resistance	Weatherproofing, automotive, parking structures, insulating glass	80 °C (175 °F) temperature limit, limited UV stability, most not used for typical glazing, some have limited stability in water, not suitable for structural glazing
Polysulfide	excellent chemical resistance, low gas permeability	insulating glass, aircraft sealants, fuel-resistant applications, below-grade applications	slow cure for one-part sealants, limited UV stability, not suitable for structural glazing
Acrylic	good UV stability, easy to apply and clean (latex), low cost, good adhesion	residential housing, consumer	low movement capability, limited low temperature flexibility
butyl	Low gas permeability, low cost, paintable	Insulating glass (primary seal), automotive, low cost housing	Low movement capability, limited durability
Si-hybrids	good adhesion, good resistance to weathering, paintable	Weatherproofing	Not used for structural glazing

one-part butyl, the sealant hardens and loses its elastomeric ability. This limits the use of solvents to low movement applications where durability is not of high concern.

Manufacture and Processing. Almost all sealants contain a mixture of a powdered filler incorporated into a viscous liquid, which results in a viscous liquid sealant having a paste-like consistency. Processing conditions can have a dramatic effect on sealant rheology, cure time, and physical properties. Typical processing variables are mixer speed (rpm), time, temperature, and vacuum. Order of ingredient addition is also important.

Health and Safety Factors. Most sealants use mineral-based fillers, which may contain small amounts of crystalline silica. If crystalline silica is present, dust control is important to prevent inhalation of these particles during the manufacturing. Crystalline silica is a known cause of silicosis, a debilitating disease of the lung. Some but not all sealants use flammable ingredients, but for those that do, proper inerting and grounding are needed to prevent potential explosions. In general, sealants should be used in areas that have good ventilation. A careful review of the material safety data sheet is fundamental before use of any sealant.

Uses. Each class of sealants has certain attributes inherent to the polymer on which it is based. These attributes often define the sealant's applications and limitations. Table 1 summarizes each type of sealant's key attributes, principal markets, and limitations.

SEA LEMON *(Mollusca, Gasteropoda; Nudibranchiata).* A flattened oval marine mollusk without shell, which feeds on sponges and other sessile animals. The roughened skin and the oval form suggest the fruit for which the animal is named.

SEA LEOPARD. See **Sea Lions and Seals**.

SEA LEVEL. See **Hydrology**; and **Ocean**.

SEA LEVEL PRESSURE. The atmospheric pressure at mean sea level, either directly measured or, most commonly, empirically determined from the observed station pressure. In regions where the earth's surface is above sea level, it is standard observational practice to reduce the observed surface pressure to the value that would exist at a point at sea level directly below if air of a temperature corresponding to that actually present at the surface were present all the way down to sea level. In actual practice, the mean temperature for the preceding 12 hours is employed, rather than the current temperature. This "reduction of pressure to sea level" is responsible for many anomalies in the pressure field in mountainous areas on the surface synoptic chart.

AMS

SEA LIONS AND SEALS *(Mammalia, Pinnipedia).* This order of mammals contains large swimming animals, including sea lions, seals, walruses, and sea elephants, among others. At one time, some authorities placed these animals under the *Carnivora*.

Sea lions are animals closely related to the seals. They belong to the same family as the fur seals and, with them, differ from the other seals in having external ears. The common sea lion, *Zalophus caliifornianus*, is found on the Pacific coast of Mexico and California, and Steller's sea lion, *Eumetopias stellari*, ranges from the Bering Strait to southern California. See Fig. 1.

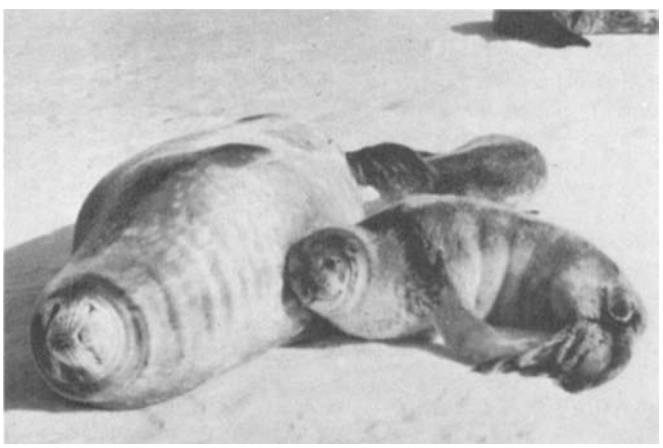

Fig. 1. Weddel seal. (*A.M. Winchester.*)

Seals are animals whose bodies are highly specialized for life in the ocean, although they are able to move about on land rather clumsily. The fore limbs are paddle-like flippers. The hind limbs are shifted so that they lie close together on opposite sides of the rudimentary tail and serve as a powerful propeller, increasing the effectiveness of the vertical undulating movements by which the animal swims. The body proper is formed to offer little resistance to the water in swimming. The fur seal represented on the Pacific coast by *Callorhinus alascanus* (*ursinus*) was once abundant in both hemispheres but was threatened with extermination by relentless hunting practices many years ago. The Pribilof Islands are an important center for these well-known seals. Fur seals are sometimes called sea bears. Seals are relatively long-lived, the average bull seal living up to 20 years of age. The bulls do not mate until they are 10 years old. An adult bull may mate many females within a few days. The cows live even longer, up to 30 years. Some species of seals are found throughout the North Atlantic and in waters around the British Isles. Reports indicate that seals were hunted for their meat as early as 500 B.C.

Although mature seals live to a good age, studies in which pups have been tagged and traced indicate that about 60% of the pups die before they reach one year of age. The pups are quite small and have only a relatively thin skin for protection. The adult seals develop thick layers (up to 2 inches); 5 centimeters of blubber immediately under the outer skin. The females identify their young by sense of smell. The pups are nursed, seal milk being among the richest of all mammal milks. Large bulls may attain a length of some 18 feet (5 meters) and a weight of about 3 tons (2.7 metric tons). The elephant seal may have a trunk some 2 feet (0.6 meter) in length. Also known as the sea elephant, the name refers to the proboscis of the male. They are found principally along the California coast. In arctic regions, polar bears are among the seals' worst enemies. The bears may pounce upon a seal sleeping on the ice, attack it in the water while swimming, or await a seal to come out of its breathing hole. Alaskan fur seals have been studied extensively. At the start of a mating season, a bull will stake out a specific area, to which females gradually arrive. Competing bulls herd as many females as possible into an area that can be protected effectively. The bulls are ferocious fighters and jealously guard their territories. See illustration that accompanies entry on **Sexual Selection**.

The sea leopard is a large seal, *Stenorhynchus leptonyx*, of the Southern Hemisphere. It is yellowish or tawny with gray spots.

The walrus is a giant marine animal related to the seals, but constituting a distinct family. Adults reach a length of more than 12 feet and a weight in excess of a ton. The feet of the walrus are adapted for swimming, but they are used mainly for clumsy locomotion on land, as in the case of seals. In early life, the body is covered with thick light brown fur that tends to disappear after middle age. The muzzle bears a number of very thick bristles. Walruses have the canine teeth of the upper jaw prolonged as tusks. The ivory of these tusks is valued by Eskimos. These animals are confined to the arctic seas and are commonly regarded as constituting an Atlantic, *Odobanus rosmarus*, and a Pacific, *O. obesus*, species, the latter with longer tusks. See Fig. 2.

Fig. 2. Walruses.

SEA MOTHS *(Osteichthyes)*. Of order the *Hypostomides*, family *Pegasidae*, sea moths are well named because, except upon close examination, they appear possibly more like an insect than a fish. In fact, biologists and zoologists have not fully agreed upon the exact fit for this creature. Doubtless, they belong in the great domain of fishes, but the exact place remains to be scientifically determined. Sea moths have been a curiosity for centuries as they were brought by travelers into Europe from the Orient and South Pacific. Because of similarities of the body armor, there is some resemblance to pipefishes, seahorses, and sea poachers. Some relationship with the flying gurnards is indicated by the expanded pectoral fins. Some five species of sea moths are known, all occurring in tropical waters from Hawaii to Africa. No specimens have been encountered in the Atlantic. The largest specimens measure about 5 inches (12.5 centimeters) in length.

SEAMOUNTS. Seamounts are undersea peaks in the ocean floor—"mountains" generally rising 3,000 or more feet (915 meters) from the bottom of the sea that do not break the water's surface. They are important and interesting for several reasons:

- They are excellent case studies for understanding marine biodiversity patterns: seamounts vary greatly in their biodiversity, can have a high degree of endemism, may be centers of speciation, and may act as "stepping stones" for the dispersal of coastal species.
- They are areas of high production that support commercially important fisheries and coral mining.
- They are fragile ecosystems that must be managed carefully and with good scientific information in order to prevent habitat damage.

Seamounts are often found in groupings or submerged archipelagos. A classic example is the Emperor Seamounts, which are an extension of the Hawaiian Islands. Formed millions of years ago by volcanism, they have since subsided to below sea level. The long chain of islands and seamounts stretching thousands of kilometers northwest from the Big Island demonstrates the movement of a plate over a volcanic hotspot. Isolated seamounts and those without clear volcanic origins appear to be less common. In recent years, geologists have confirmed that a number of seamounts are active undersea volcanoes: Lo'ihi in the Hawaiian Islands and Vailu'ulu'u in the Manu'a Group (Samoa) are examples.

Seamounts often project upwards into shallower zones more hospitable to sea life, providing habitats for marine species that are not found on or around the surrounding deeper ocean bottom. In addition to simply providing physical presence in this zone, the seamount itself may deflect deep currents and create upwelling. This process can bring nutrients into the photosynthetic zone, producing an area of productivity in an otherwise desert-like open ocean. Seamounts may thus be vital stopping points for some migratory animals such as whales. Some recent research indicates whales may use such features as navigational aids.

Emperor Seamounts. The Emperor Seamounts are a chain of seamounts (submerged volcanic mountains) extending from the northwestern Hawaiian Islands in a northwesterly direction until approximately 170° east longitude where they trend abruptly northward towards the tip of the Aleutian Islands and the Kamchatka Peninsula. The chain's name reflects the naming of many of the individual volcanoes for

legendary and historic emperors of Japan (Yuryaku, Kimmei, Nintoku and Suiko are examples). They were named by Robert S. Dietz[1] in 1954.

The Emperors are the submerged remnants of volcanic islands of what we now call the Hawaiian Islands and are part of the Hawaiian-Emperor seamount chain Fig. 1. The age and depth of the ancient volcanoes increases toward the northern tip of the chain. Most of the older Emperors are flat topped seamounts (or *guyots*) showing evidence of once having been reef encircled, high islands and then coral atolls. See also **Guyot**.

Alaska Seamounts. A glance at a map of the seafloor of the Gulf of Alaska Fig. 2 reveals underwater mountains, or seamounts. The largest of these are more than 3,000 meters (9,900 feet) tall, and act as islands of abundant marine life in the sparsely inhabited abyssal depths. Many of the seamounts occur in long chains that extend southeast from the Gulf of Alaska down toward the western coast of the U.S. and Canada. Where the age of formation of these seamounts is known, they generally are older toward the northwest and younger toward the southeast. It turns out that there is a single logical explanation for why these seamounts occur in long chains and why they get younger toward the southeast: They formed as the Pacific Plate moved over a group of "hotspots" that are now off the coast of Oregon, Washington, and British Columbia.

A hotspot is a point of frequent volcanic activity that persists over millions of years. They appear to remain at fixed locations on the earth, while the tectonic plates on the surface move over them. So as the Pacific Plate moves toward the northwest it acts as a conveyor belt and carries the seamounts with it as shown in Fig. 3. As one seamount is carried away from the hotspot another forms in its place, so the older the seamounts are, the farther they have been carried by the plate. Over millions of years this process results in the long seamount chains we see today in the Gulf of Alaska, with the oldest seamounts at the northwest ends of these chains and the youngest at the southeast ends.

A seamount might stay volcanically active for 2 or 3 million years while it is above a hotspot: lava streams out of it summit and down its flanks, building up a volcanic mountain much as is happening today on the island

[1] Robert Sinclair Dietz (1914–1995) was a Professor of Geology at Arizona State University. Dietz was a geophysicist and oceanographer who conducted pioneering research along with Harry Hess concerning seafloor spreading as early as 1960–1961. While at the Scripps Institute of Oceanography he observed the nature of "the Emperor chain of seamounts that extended from the northwest end of the Hawaiian Island-Midway chain and speculated over lunch with Robert Fisher in 1953 that something must be carrying these old volcanic mountains northward like a conveyer belt.

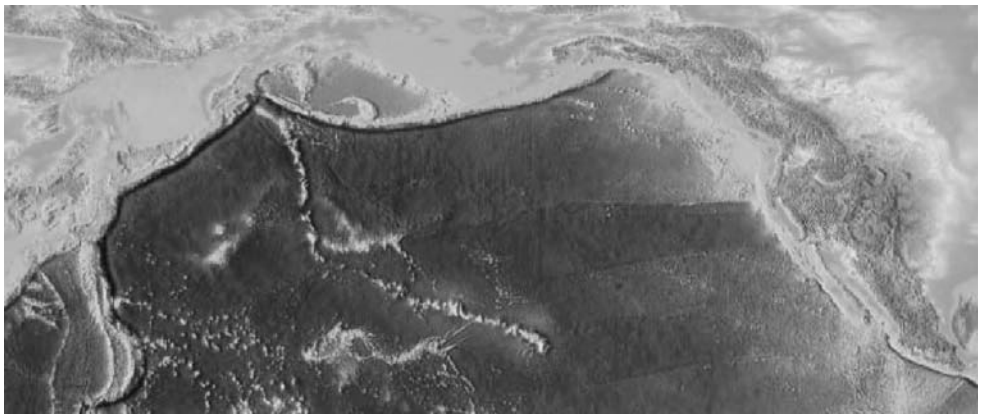

Fig. 1. The trail of underwater mountains created as the tectonic plate moved across the Hawaii hotspot over millions of years, known as the Hawaiian-Emperor seamount chain, or the Emperor Seamounts. (*NOAA*).

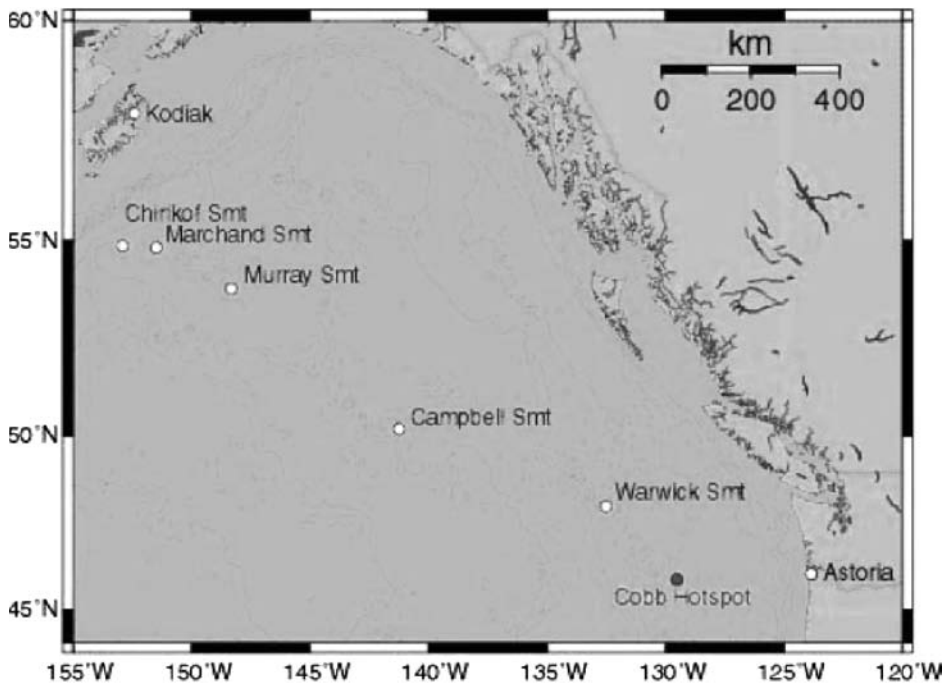

Fig. 2. Many of the volcanic seamounts in the Gulf of Alaska are visible on this bathymetric map. (*NOAA*).

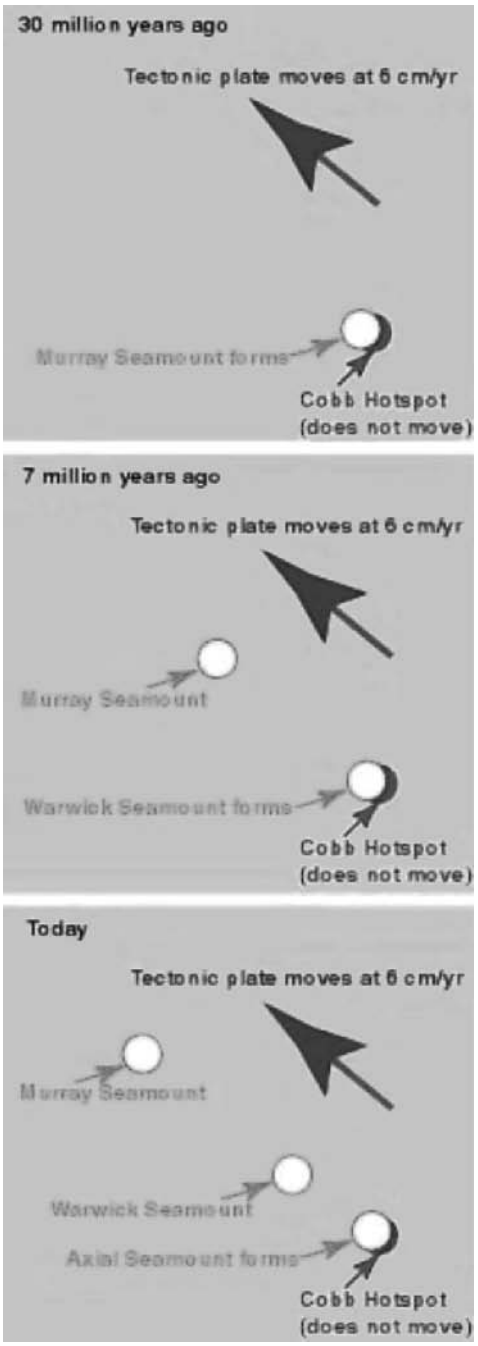

Fig. 3. Hotspot Volcanism and the Plate Conveyor Belt. This series of plate tectonic "snapshots" from 30 million years ago, 7 million years ago, and today, shows how volcanic activity at a stationary hotspot can create a trail of volcanic seamounts as a tectonic plate passes over the hotspot. Murray seamount formed 27–30 million years ago, whereas Warwick seamount formed about 7 million years ago. (*NOAA*).

of Hawaii. But as it is carried away by the moving plate its volcanic activity begins to wane and eventually goes quiet, only to be replaced by volcanic activity at a new seamount being born on the ocean floor that has moved on top of the hotspot. This is occurring today in Hawaii (another example of a hotspot) as volcanic activity on the island of Hawaii is slowly being replaced by activity on nearby Loihi seamount.

The most obvious and complete example of a seamount trail in the Gulf of Alaska is the one created by the Cobb hotspot. This "trail" of hotspot activity extends from the presently active Axial Seamount, now above the Cobb hotspot, all the way to the northern Gulf of Alaska just south of Kodiak Island. Warwick Seamount formed about 7 million years ago; Murray Seamount formed about 27 million years ago, and Marchand and Chirikof seamounts formed about 30–35 million years ago.

New England Seamounts. The New England seamounts form a southeast-trending chain of underwater peaks, running from Bear Seamount (located 200 miles (322 kilometers from Woods Hole, MA) to Nashville Seamount — a distance of about 700 miles (1,127 kilometers). (Fig. 4).

See also **Ocean**.

West Coast Seamounts. In the spring of 1998 the Monterey Bay Aquarium Research Institute http://www.mbari.org/ (MBARI) completed surveys of seamounts and ridges offshore Northern California and Oregon. See Fig. 5.

Axial Volcano. The Axial Volcano rises 700 meters (2,297 feet) above the mean level of the ridge crest and is the most magmatically robust and seismically active site on the Juan de Fuca Ridge between the Blanco Fracture Zone and the Cobb offset. It represents the product of intense volcanic activity from the Cobb-Eikelberg hotspot juxtaposed on the extensional field of the spreading center. Axial Volcano was first studied in the late 1970s and then mapped in greater detail by NOAA/VENTS with SeaBeam in the early 1980s. Following the initial discovery of venting in the northern portion of the caldera in 1983, a concentrated mapping and sampling effort was made in the mid-late 1980s. The summit is characterized by a horseshoe-shaped caldera 1.9×5 miles (3×8 kilometers) that is open towards the southeast. Hydrothermal vents and deposits are common inside the caldera. An eruption took place on the southeastern edge of the caldera in 1998.

Davidson Seamount. Located 120 kilometers (75 miles) to the southwest of Monterey, Davidson Seamount is 42 kilometers (26 miles) long and rises 2,400 meters (7,874 feet) from the ocean floor, yet is still 1,256 meters (4,120 feet) below the sea surface. This large geographic feature was the first to be characterized as a *seamount* and was named after scientist George Davidson of the Coast and Geodetic Survey (forerunner to National Ocean Service of the National Oceanic and Atmospheric Administration). Davidson Seamount, like Guide, Pioneer, and Gumdrop Seamounts to the north and Rodriguez Seamount to the south, is an elongated structure with a distinctive northeast-to-southwest orientation common to many other volcanic edifices near the continental margins of southern and Baja California [Atwater and Severinghaus,1984]. The seamount consists of about six subparallel linear volcanic ridges separated by narrow valleys that contain sediment. These ridges are aligned parallel to magnetic anomalies in the underlying ocean crust. Davidson is flanked on both sides by the same magnetic anomaly of Chron 6 [Lonsdale,1981; Atwater and Severinghaus,1989], indicating that it formed astride a mid-ocean ridge abandoned about 20 million years ago. The southwest end of Davidson is intersected at a right angle by the Morro Fracture Zone, a fossil transform fault (Lonsdale).

Davidson Seamount, with an estimated volume of 320 km^3 (199 mi^3), is almost as large as Guide, Pioneer, and Gumdrop Seamounts combined. At the southeast end of the seamount, a large cone, about 5.8 kilometers (3.6 miles) across at the base and with a volume of nearly 13 km^3 (8 mi^3), is partly surrounded by small satellite cones. The volcano consists mainly of alkalic basalt, hawaiite, and mugearite lavas, with some pyroclastic deposits occurring near the summit [Davis et al., in press]. The seamount is 12.2 ± 0.4 million years old and formed about 8 million years after the underlying mid-ocean ridge was abandoned [Davis et al., in press].

In addition to its unique shape and geology, Davidson Seamount has remarkable biological communities consisting mainly of abundant large sponges and gorgonians, particularly near the tops of volcanic cones. The waters above its surface are very productive feeding grounds for a wide variety of fishes, marine mammals, and seabirds.

Guide Seamount. The Guide Seamount is about 16.6 ± 0.5 million years old (Davis et al.). The seamount consists of four, nearly parallel volcanic ridges, separated by sediment-filled troughs, aligned parallel to magnetic anomalies in the underlying ocean crust and therefore parallel to the abandoned mid-ocean ridge that formed the crust. Guide Seamount looks virtually identical to Davidson Seamount, except it is smaller (approximately 16.5 kilometers by 5 kilometers (10 miles by 3 miles). It rises about 1,440 meters (4,724 feet) above the surrounding seafloor and reaches a minimum water depth of 1,682 meters (5,518 feet). The volume above the surrounding seafloor is about 130 km^3 (87 mi^3). The lavas from Guide are alkalic basalt, hawaiite and mugearite composition with some pyroclastic deposits near the summit.

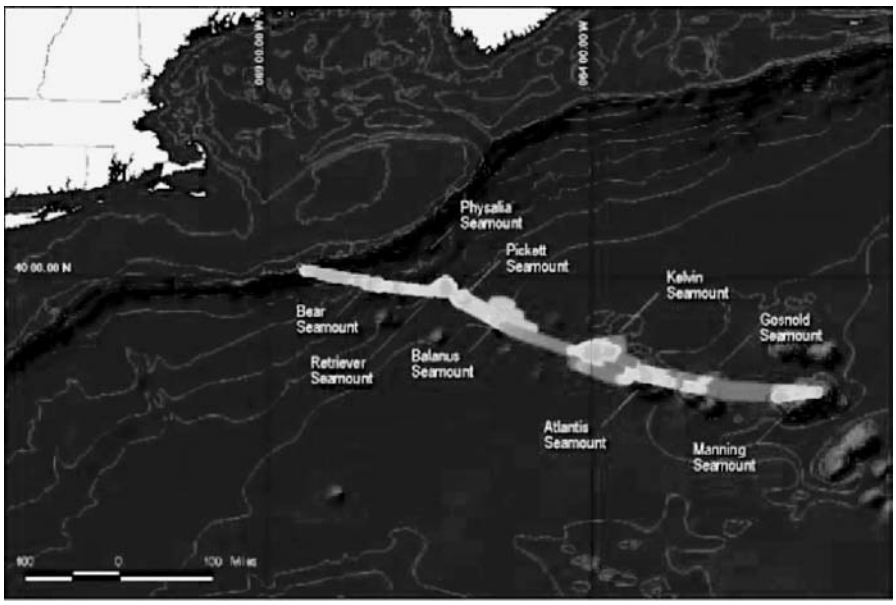

Fig. 4. New England Seamounts (*courtesy of NOAA*).

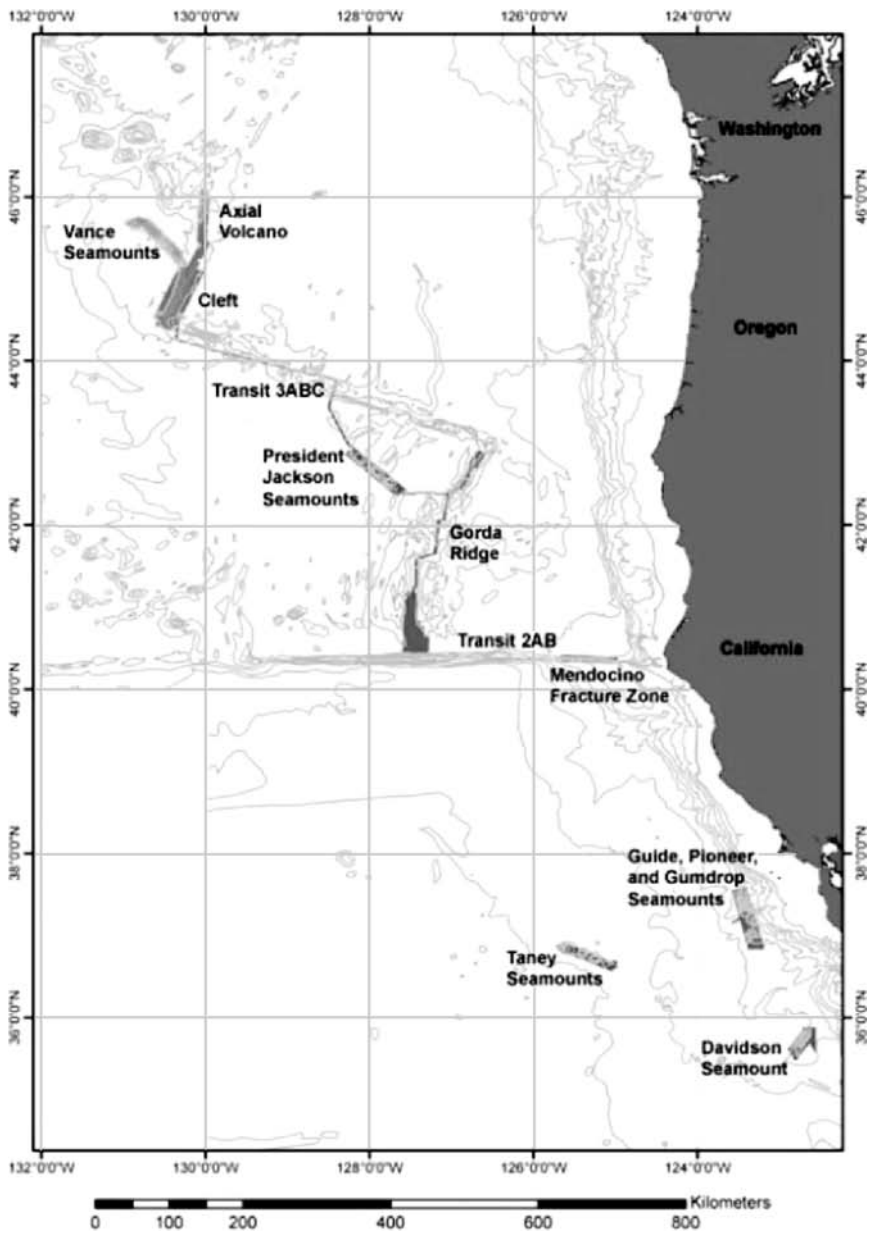

Fig. 5. West Coast Seamounts and Ridges Survey Areas. (*courtesy of NOAA*).

Gumdrop, Pioneer, and Guide Seamounts. These seamounts are located about 120 kilometers (75 miles) off the California margin, north of Monterey Bay. They and other seamounts along the California and Baja California margin, including Davidson Seamount and Rodriguez Seamount, have a similar structure and origin. Magnetic anomalies near Guide and Pioneer Seamounts are not symmetrical but correspond to Chron 6B and 6 C, respectively, indicating ocean crust of about 22 to 24 million years old. Formation of these complex, northeast-trending seamounts offshore central California, including Davidson Seamount to the south, is incompatible with a hot spot model or formation as near-mid-ocean ridge seamounts. All may have been formed by eruption through structurally weak zones at abandoned spreading centers, with volcanism occurring as much as 8 million years after the ridge stopped spreading. Lavas apparently originated and partly crystallized in the shallow mantle [Davis et al.., in press]. Trace element ratios and isotopic compositions suggest origin by small degrees of melting from a mildly but variably-enriched mid-ocean ridge source.

Gumdrop, the northernmost of the three seamounts, has a series of aligned cones separated by sediment-filled troughs, but these structures are poorly defined. The shallowest cone rises to 1,207 meters (3,960 feet) below sea level. The volume is difficult to estimate because the base of the seamount is poorly defined. However, we estimate its volume at about 100 km^3 (62 mi^3). Samples recovered from Gumdrop are highly vesicular, alkalic basalt, hawaiite, and mugearite, but their age is not determined.

Pioneer Seamount. The Pioneer Seamount is 11.0 ± 0.1 million years old [Davis et al.., in press] and is nearly equidimensional with width and length of about 12.8 kilometers (8 miles). It rises about 1,930 meters (6,332 feet) above the surrounding seafloor to a minimum water depth of 820 meters (2,690 feet). It has a volume of about 135 km^3 (84 mi^3). Samples recovered from Pioneer are alkalic basalt, hawaiite, and mugearite. Like samples from Davidson Seamount, all samples are highly vesicular.

President Jackson Seamount. The only near-ridge seamount chain off the Gorda Ridge is the President Jackson Seamounts, located on the Pacific Plate. The chain consists of eight volcanoes, of which four are isolated volcanoes, less than 10 kilometers (6 miles) in diameter and nearly circular in plan view Fig. 6. The other four form two morphologically complex, coalesced flat-topped structures. In addition, a transit line to our survey crossed an elevated hummocky area of volcanic cones and flows about 13 kilometers (8 miles) southeast of the southeastern central volcano. The volcanoes form a linear chain and are all relatively small. The summits of all but the second from the northwestern end are flat, and most are modified by nested or crosscutting calderas and smaller pit craters (29 in total), some of which embay the flanks of the volcanoes. In many cases the younger calderas have removed all but small remnants of the earlier crater walls. The third volcano from the southeast has a trapdoor caldera whose floor slopes down towards the southeast. The flanks and tops of many of the central volcanoes have numerous small cones. Large hummocky aprons, probably of debris, extend away from several volcanoes. The flanks of several volcanoes are also fluted or embayed by erosional gullies or landslide chutes.

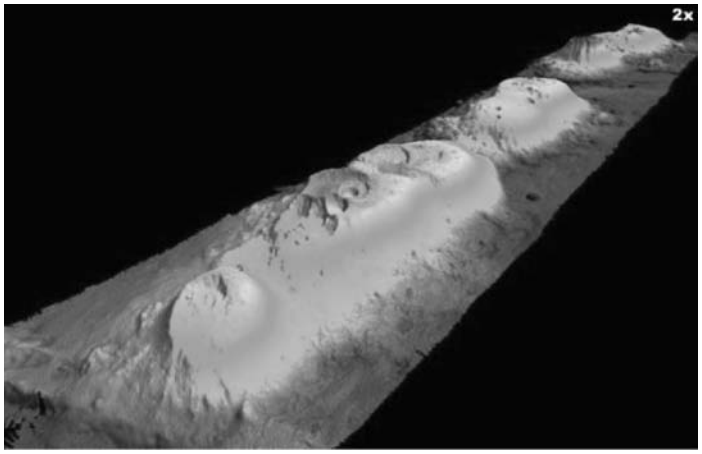

Fig. 6. President Jackson Seamounts perspective view from the east. (NOAA).

Taney Seamounts. The Taney Seamounts are located on the Pacific Plate, west of San Francisco. It is unknown whether a symmetrical chain of volcanoes existed on the subducted Farallon Plate.

The Taney Seamounts consist of five aligned volcanoes. The volcanoes have an average volume of 86 ± 64 km^3, range 11 to 187 km^3 (7 to 116 mi^3). The northwestern volcano is by far the largest volcano in the chain, with a calculated volume of 187 km^3 (116 mi^3). The volcano has been so severely modified by three successive caldera collapses that most of the summit platform has been destroyed. The southeastern portion of the floor of the third and southeastern caldera has been modified by eruptions that formed many 0.5–1.0 kilometer (0.3–0.6 mile) diameter cones and several roughly 1-kilometer (0.6 mile) diameter low, flat-topped shields. The large embayment north of the southeastern caldera may be caused by a landslide or by faulting along a ridge-parallel fault.

The summit of the next volcano to the southeast is an unusual large caldera, about 6.5 by 4.5 kilometers (4 by 2.8 miles). The volcano is oval, with the long axis parallel to the chain. The rim of the large caldera varies in height up to about 150 meters (492 ft) tall. The east-southeastern rim has been overtopped by lava flows erupted within the caldera that flowed from the floor down the flank, and then ponded at the base of the slope to form a lava delta. A small step on the southern flank of the volcano, seen as an illuminated band about halfway up the flank, may be a somma — the rim of an even earlier, and larger, caldera that was almost entirely filled by a subsequent shield. The next volcano to the southeast has three oval calderas with their long dimension parallel to the chain. The southeastern caldera dropped the southeastern rim of the summit by about 575 meters (1,886 feet). The eastern rim of the summit platform is scalloped, apparently by several landslides. A pit crater in the northwestern part of the flat summit of the fourth volcano from the northwest is less than 100 meters (328 feet) across and about 60 meters (197 feet) deep. Unlike the other 13 calderas, this is the only collapse feature in the Taney Seamounts that is less than 1.5 kilometers (0.9 mile) in diameter. See Fig. 7.

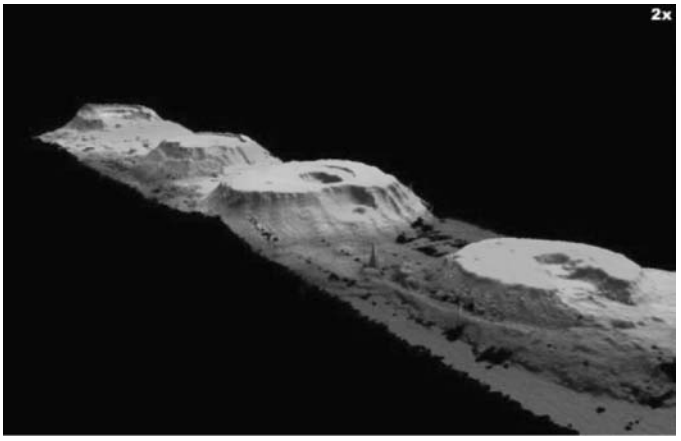

Fig. 7. Taney Seamounts perspective view from the south-southeast. (NOAA).

Vance Seamounts. The Vance Seamounts comprise the southernmost of several near-ridge chains located on the Pacific Plate near the Juan de Fuca Ridge. No symmetrical seamount chain occurs on the Juan de Fuca Plate.

Six of the seven volcanoes Fig. 8 form a roughly linear array of cones that are nearly circular in plan view. The second volcano from the northwest is not a discrete cone like the rest, but rather a region of rough, elevated seafloor consisting of lava cones and flows, covering an area at least 25 by 10 kilometers (15.5 by 6 miles). The six conical volcanoes have an average volume of 34 ± 15 km^3 with a range of 15 to 67 km^3 (9 to 42 mi^3). Most of their gently-domed summit plateaus have been modified by the collapse of nested calderas (11 in total) that appear to step down to the southeast. Several of the volcanoes also have low shield volcanoes on their summits, commonly modified by calderas. Some calderas are very shallow, having been flooded and filled almost completely by subsequent flows, preserving only portions of their rims. Some calderas have hummocky landslide deposits on the nearly flat floors

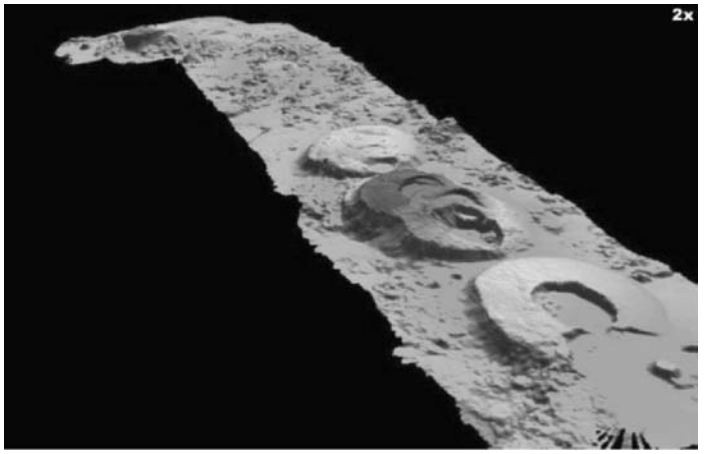

Fig. 8. Vance Seamounts perspective view from the south-southeast.

near the base of the steep caldera walls. The nearly flat tops of several of the volcanoes slope gently down to the southeast and several of the calderas are breached on the southeast side. Small cones and shields dot the seafloor around some of the volcanoes. Ridge-parallel faults cut the summit platforms of several of the southeastern volcanoes. These faults have only low relief — on the order of a few tens of meters — and do not step systematically down to the southeast.

The constructional volcanic region consists of high-backscatter material, presumably lava that forms a broad 700-meter-high (2,297 feet) rise with superposed roughness. Much of the roughness can be resolved into individual cones, some with summit craters, and small volcanic ridges aligned parallel to the ridge axis. The largest of the cones is nearly 2 kilometers (1.2 miles) across and the smallest appear to be only a few hundred meters across. The volume of the dome and cones (67 km^3) (42 mi^3) is roughly equivalent to any two of the circular volcanoes in the Vance chain, but the volcanic activity was less centralized.

SEA MOUSE *(Annelida, Polychaeta)*. A marine worm, *Aphrodite* (*A. hastata* in American waters and *A. aculeata* in British waters), of compact oval form, covered above and on the sides with a felt-like material. It is recorded from Vineyard Sound on the Atlantic coast.

SEA OTTER. See **Mustelines**.

SEA RAVEN. See **Sculpins**.

SEA ROBINS *(Osteichthyes)*. Of the suborder *Polynemoidea*, family *Triglidae*, sea robins occur in American Atlantic waters from Nova Scotia south to Venezuela. They attain a length of about 16 inches (40 centimeters), are highly colorful, with bony heads well protected with spines. Separate fanlike pectoral fins help the sea robin "walk" on the bottom. They are carnivorous, mollusks and small crustaceans comprising their main diet. Some of the larger members can attain a length of some 2 to 3 feet (0.6 to 0.9 meter). It is believed that all triglids are capable of noise-making and, as with other "acoustic" fish, such as croakers and grunts, their sounds are created by vibrating muscles with the assistance of a large air bladder which acts as a sounding box. The tubfish (*Trigla hirundo*), also known as the yellow gurnard, is found in the waters off Europe and the African coasts. It is a very striking fish, featuring bright blue-edged pectorals. There is also a group of armored sea robins (*Peristediidae*) whose entire bodies are protected by bony projections. They prefer the deep tropical waters. Some of the larger triglids are considered good as food.

SEASAT. *Seasat* was the first Earth-orbiting satellite designed for remote sensing of the Earth's oceans and had onboard the first spaceborne synthetic aperture radar (SAR). The mission was designed to demonstrate the feasibility of global satellite monitoring of oceanographic phenomena and to help determine the requirements for an operational ocean remote sensing satellite system. Specific objectives were to collect data on sea-surface winds, sea-surface temperatures, wave heights, internal waves, atmospheric water, sea ice features and ocean topography.

Seasat was managed by JPL and was launched on June 28, 1978, at 01:12:00 UTC on an Atlas Agena rocket from Vandenberg Air Force Base, California, into a nearly circular 800 kilometers (497 miles) orbit with an inclination of 108 degrees. Fourteen Earth orbits were completed each day.

The instrument payload consisted of (1) an X-band compressed pulse radar altimeter (ALT) to measure spacecraft height above the ocean surface, (2) a coherent synthetic aperture radar (SAR) L-band, HH polarization, fixed look angle to monitor the global surface wave field and polar sea ice conditions, (3) a Seasat-A scatterometer system (SASS) to measure wind speed and direction, (4) a scanning multichannel microwave radiometer (SMMR) to measure sea surface temperature, and (5) a visible and infrared radiometer (VIRR) to identify cloud, land and water features. The accuracies obtained were distance between spacecraft and ocean surface to 10 centimeters (4 inches), wind speeds to 2 m/s (4.5 mph), and surface temperatures to 1 °C (34 °F). For more information about *Seasat* 1, see "*Seasat* mission overview," *Science*, **204**, p 1405–1424 (1979), and a special issue on the Seasat 1 sensors, *IEEE J. of Oceanic Eng*., v. OE-5, 1980. On October 10, 1978, Seasat 1 failed due to a massive short circuit in its electrical system. During most of its 105 days in orbit, Seasat 1 returned a unique and extensive set of observations of the earth's oceans. During Seasat operations, approximately 42 hours of data were collected.

http://www.earth.nasa.gov/history/seasat/seasat.html

SEA SLUG *(Mollusca, Gasteropoda)*. Marine mollusks with compact bodies and without shells. Some species have branching processes on the surface of the body by which they breathe. The creeping habits and general form are similar to those of the terrestrial slugs, although there is no closer relationship between the two. The sea slugs make up the order *Nudibranchiata*.

SEA SNAKES. See **Snakes**.

SEASON CRACKING. Spontaneous cracking of brass and other metals on standing. Intergranular cracks result from the action of residual internal stresses from cold-working operations aided by surface corrosion. Cold-worked high-zinc brasses sometimes fail during storage in ordinary atmosphere. Ammonia salts and other specific reagents greatly accelerate cracking in brasses subject to this defect. Many other metals, including stainless steels, are subject to cracking under certain conditions of stress and corrosion.

SEASTAR SATELLITE. A satellite system jointly developed by NASA and private industry to measure ocean color for research and operations.

Ocean color reveals the presence and concentration of phytoplankton, sediments, and dissolved organic chemicals in the uppermost layers of the ocean. Measurements are made with SeaWiFS.

The *SeaStar* spacecraft (Fig. 1), developed by Orbital Sciences Corporation (OSC), carries the SeaWiFS instrument and was launched to low Earth orbit on board an extended Pegasus launch vehicle on August 1, 1997. See Fig. 2. The SeaWiFS instrument will be the only scientific payload on the *SeaStar* spacecraft. OSC has the sole responsibility for the development, launch, and command and control of the satellite. The development of the SeaWiFS instrument was subcontracted to Hughes/SBRC, but OSC maintains ultimate responsibility for the instrument. See also **Sea-Viewing Wide Field-of-View Sensor (SeaWiFS)**.

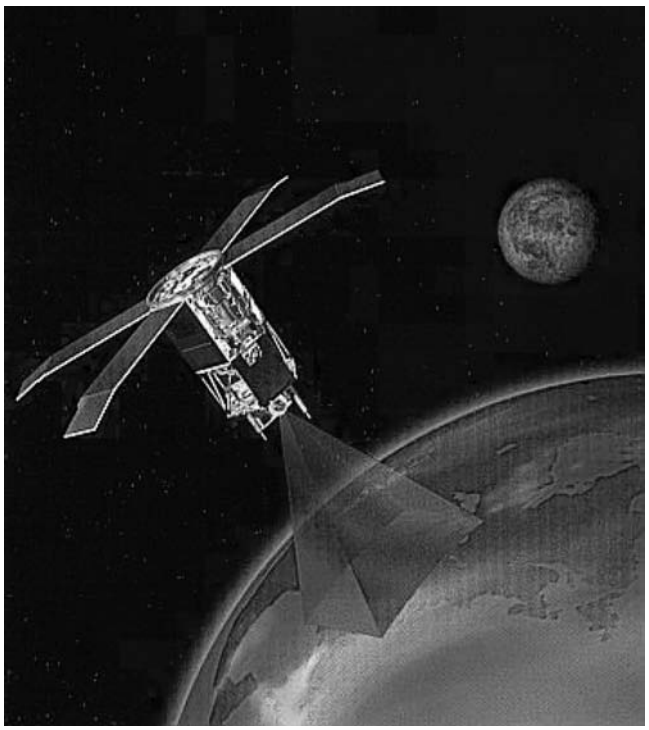

Fig. 1. *SeaStar* Spacecraft in orbit

Fig. 2. Photo of a Pegasus launch

Currently, the Pegasus is flown aloft under the body of a modified Lockheed L-1011 aircraft and released at an altitude of about 39,000 ft (11,887 meters), whereupon the launch vehicle engages and lifts the spacecraft to a low Earth, circular, parking orbit of 278 kilometers (173 miles) with an inclination of 98 degree 20 minute. The solar panels are deployed at this time which along with the batteries, are the sensor's power source.

The *SeaStar* spacecraft has an onboard hydrazine propulsion system that is then used to raise the satellite to its final 705 kilometers (439 miles) (circular, noon, sun-synchronous orbit. The final orbit is reached approximately 20 days following launch. At 25 days after launch, the SeaWiFS instrument is powered up and checked out. At launch plus 30 days, data collection operations commence.

The attitude control system (ACS) must be capable of maintaining the 705 kilometers (439 miles) noon, sun-synchronous orbit, performing lunar and solar calibration maneuvers, and providing attitude knowledge within one SeaWiFS pixel. The three-axis stabilized system consists of orthogonal magnetic torque rods for roll and yaw control and two momentum wheels for pitch stabilization. Sensors include redundant sun sensors, horizon sensors, and magnetometers.

The propulsion system consists of two subsystems, a reaction control system, band a hydrazine propulsion system. The reaction control system uses nitrogen and provides third stage stabilization during the launch. The hydrazine propulsion system is used for raising the orbit from the nominal 278 km (173 miles) parking orbit to the 705 km (439 miles) sun-synchronous operational orbit. In addition, it is used for orbit trim requirements over the life of the mission. Four Hamilton Standard one pound thrusters were used.

Two telemetry streams are transmitted. The first is real-time LAC data merged with spacecraft health and instrument telemetry at 665.4 kbps. This is transmitted at L-band with a frequency of 1702.56 MHz. The other telemetry stream consists of stored GAC and selected LAC, along with spacecraft health and instrument telemetry, at 2.0 Mbps. This is transmitted at S-band with a frequency of 2287.5 MHz. The command system uses S-band with an uplink of 19.2 kbaud at 2092.59 MHz.

Redundant global positioning system (GPS) receivers are used for orbit determination. The orbit state derived from this is included in the spacecraft health telemetry.

See also **Satellites (Scientific and Reconnaissance)**.

SEA-VIEWING WIDE FIELD-OF-VIEW SENSOR (SEAWIFS). The purpose of the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) Project is to provide quantitative data on global ocean bio-optical properties to the Earth science community. Subtle changes in ocean color signify various types and quantities of marine phytoplankton (microscopic marine plants), the knowledge of which has both scientific and practical applications. It became apparent to the oceanographic community that because of the dynamic nature of the world's oceans and climate, and the importance of the ocean's role in global change, a follow-on sensor to the Coastal Zone Color Scanner (CZCS) should be flown. From a scientific perspective, obtaining ocean color data from space in the early 1990s is a high priority goal that has been recognized in reports of the National Research Council of the National Academy of Sciences.

The SeaWiFS Project was designated to develop and operate a research data system to gather, process, archive, and distribute data received from an ocean color sensor. The principal objective has been to acquire data that are critical for the study of the role of oceans, including the exchange of critical elements and gases between the atmosphere and ocean, and how these exchanges affect phytoplankton production.

The data was procured as a "data buy" from a private contractor, Orbital Sciences Corporation (OSC), which subcontracted with the Hughes Santa Barbara Research Center (SBRC) to build the SeaWiFS ocean color sensor (Fig. 1). OSC built and launched the SeaStar satellite (Fig. 2), carrying the sensor on August 1, 1997. Following launch, the satellite's name was changed to OrbView-2(OV-2), and operations were turned over to ORBIMAGE, a spinoff of OCS. See also **SeaStar Satellite**.

Objectives

Program Objectives. The purpose of SeaWiFS data is to examine oceanic factors that affect global change and to assess the oceans' role in the global carbon cycle, as well as other biogeochemical cycles, through a comprehensive research program.

SeaWiFS data are being used to help clarify the magnitude and variability of chlorophyll and primary production by marine phytoplankton,

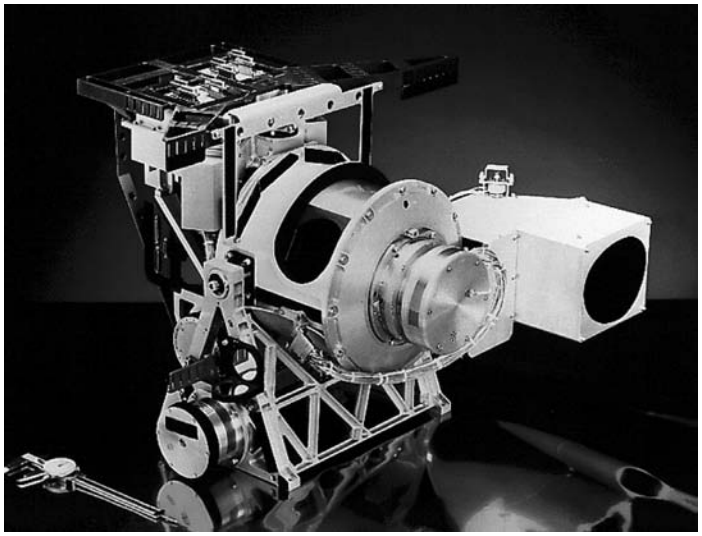

Fig. 1. Photograph of the SeaWiFS scanner assembly, which scans from west to east (left to right in the figure).

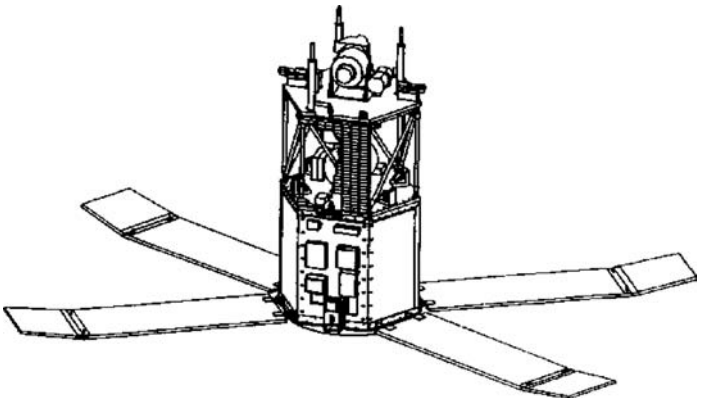

Fig. 2. SeaStar satellite with its solar panels deployed.

and to determine the distribution and timing of spring blooms, i.e., the time of highly abundant growth. The scientific and technical experience gained in the SeaWiFS mission have been valuable preparation for the design and application of the Earth Observing System's MODerate resolution Imaging Spectroradiometer (MODIS) instruments, as well as future sensors such as the National Polar-orbiting Operational Environmental Satellite System (NPOESS) Visible/Infrared Imager/Radiometer Suite (VIIRS).

Project Objectives. The purpose of the SeaWiFS Project has been to obtain accurate ocean color data from the world's oceans for a 5-year (minimum) period; to process these data in conjunction with ancillary data into meaningful biological parameters, such as photosynthesis rates; and to make these data readily available to researchers. Goddard Space Flight Center (GSFC) developed the data processing and archiving system and oversaw the effort to ensure the integrity of the final products. See also http://oceancolor.gsfc.nasa.gov/SeaWiFS/BACKGROUND/.

Project Overview. The success of the SeaWiFS mission is determined by the quality of the ocean color data and their availability. Inherent in any space flight mission for scientific applications are Project elements that assure this success. Figure 3 shows the SeaWiFS Project elements within an end-to-end system overview. The OV-2 satellite broadcasts SeaWiFS data in real time to the GSFC High-Resolution Picture Transmission (HRPT) station, as well as to other stations, and recorded data — Global Area Coverage (GAC) and Local Area Coverage (LAC) — to GSFC, Wallops Flight Facility (WFF), and ORBIMAGE. These HRPT, GAC, and LAC data are then transferred to the SeaWiFS Data Processing System

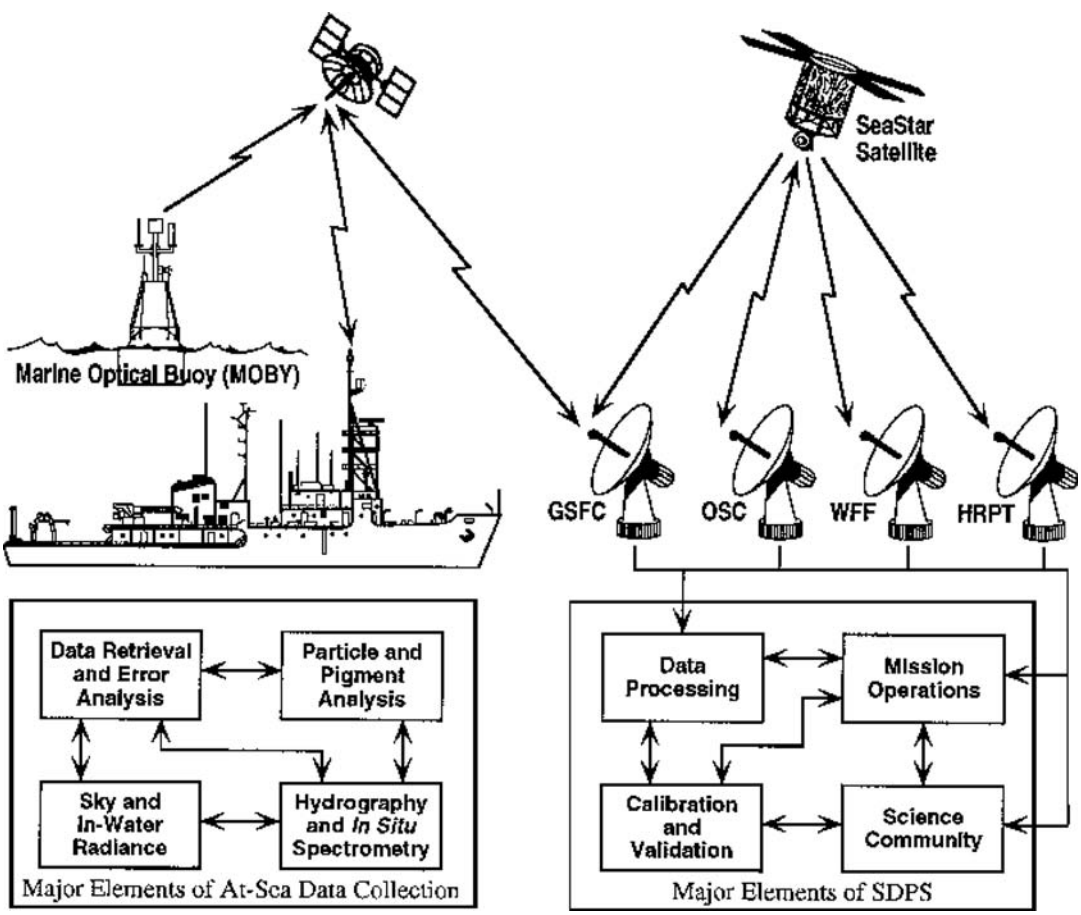

Fig. 3. SeaWiFS Project schematic showing major elements of shore and at-sea data processing.

(SDPS). The SDPS comprises a number of elements: namely, SeaWiFS data processing; calibration, validation, and data quality; data capture; and GSFC mission operations.

The data processing element receives raw spacecraft data and generates standard global ocean color data products. The standard products go to the GSFC EOS Data and Information System (EOSDIS) Distributed Active Archive Center (DAAC) which is responsible for archiving and distributing SeaWiFS data to the scientific community.

The calibration and validation element is responsible for establishing and updating calibration procedures for SeaWiFS data, using correlative data for validating higher-level products; analyzing trends and deviations; and collecting ancillary data sets such as winds, ozone, and atmospheric pressure that are used in data processing.

The mission planning element serves as the link between ORBIMAGE and the SeaWiFS Project Office (SPO) for the purposes of reporting problems, monitoring the automatic data measurements and transmission (telemetry), and scheduling the scientific aspects of mission operations. It also provides navigation information and the orbital elements required for data processing and data collection. ORBIMAGE is responsible for the space segment, mission management, and the command and data acquisition station.

Data Calibration, Processing, and Validation

The data calibration, processing, and validation program calibrates the SeaWiFS data; develops the mathematical procedures (algorithms) for operational atmospheric correction and for derived data; and validates the accuracy of the derived products, such as the concentration of chlorophyll a. The atmospheric correction is critical because only about 5% of the light seen at the satellite is reflected from within the ocean (water-leaving radiances). NASA and the SPO have placed the highest priority on assuring the accuracy of calculated water-leaving radiances, globally, over the life of the mission. Although meeting these requirements is an ongoing process, the accuracy and stability of the radiances has been well established, and development of global and regional biogeochemical algorithms has proceeded on many fronts. Some of this work has been done at GSFC, while the remainder has been done externally, by members of the ocean science community.

Included in the processing program has been the development of atmospheric correction and biooptical algorithms required to produce the derived products. The atmospheric correction algorithms for processing SeaWiFS data include a number of improvements over the CZCS algorithms. Data sets from field studies have been collected to validate these improvements.

The field studies mentioned above have been external activities. Internal activities included the development of biooptical databases and the comparison of atmospheric correction and biooptical algorithms. Investigators funded by NASA to assist with algorithm development have had access to these databases.

Atmospheric correction algorithms use external data such as ozone concentration sand surface pressure fields. The quality of these fields has been assessed before the data were incorporated into the processing. Finally, prior to the release of the derived products, quality assessment and control functions have been performed by comparison of historical and simultaneous field observations submitted to the SPO by field programs and individual investigators.

Data Collection

SeaWiFS has produced scientific data of two spatial resolutions: LAC have been broadcast continuously and recorded selectively, while GAC have been recorded continuously onboard the spacecraft. GSFC has received LAC direct broadcasts routinely for the east coast of the U.S., and various HRPT stations around the world have received other real-time LAC broadcasts. The NASA WFF has received recorded GAC and LAC data, which it has forwarded to the SDPS at GSFC.

In order to meet the science goals, the SPO objectives have been to obtain full GAC data every two days, which has required nearly complete use of onboard recording capability and transmission time to GSFC. The limited space for LAC recording has been allocated, in priority order, to 1) monitoring essential sensor functions; 2) covering key optical calibration and validation activities; and 3) science studies which require full-resolution data.

Data Distribution

The SeaWiFS mission has been made affordable and timely because of its unique private vendor, data purchase structure. As part of the contract between NASA and OSC, NASA retains all rights to data for research purposes, and ORBIMAGE retains all rights for commercial and operational purposes. There has been an embargo period of 2 weeks from collection for general distribution of data to research users to protect ORBIMAGE's commercial interest. Three exceptions to the 2-week embargo are a) field experiments requiring data for ship positioning, b) operational demonstrations to prove feasibility and usefulness, and c) assessment of calibration/validation and instrument performance by NASA. Access to the NASA data archive has been permitted for research purposes by authorized users only. After five years, the data may be used without restriction.

SEAWATER (Desalination). See **Desalination**.

SEAWATER (Elements In). See **Ocean**; and **Ocean Water**.

SEAWEEDS. The production of edible seaweeds is a significant industry in the Orient. It is particularly well established in Japan where seaweed "farming" is practiced on a large scale. China and Korea are also notable producers of edible seaweeds, and improved hybrids have been reported from China. Increased demand for seaweeds has focused attention on methods of cultivating selected species. In the late 1950s, the Japanese *Gelidum* beds, which had proved adequate for centuries, declined rather mysteriously and caused a world shortage. This resulted in the large-scale exploitation of supplies of suitable seaweeds for the manufacture of agar in Chile and Portugal. By the early 1960s, the demand for carrageenin, and to a lesser extent for furcellaran, by the food processing industry caused a shortage of other red seaweeds. The main producers of these products constructed drying units in Nova Scotia and Prince Edward Island to encourage the collection of seaweed.

The economically important seaweeds fall into two main groups: (1) that which grows in the inter-tidal fringe; and (2) that which is permanently submerged. This apparently simple distinction is, however, complicated by many factors. The extent of the intertidal zone is partly controlled by the gradient of the beach, and it also increases with latitude and tidal range. There are considerable local variations in tidal range, varying from less than 3 meters (10 feet) in Shetland (British Isles) to nearly 10 meters (30 feet) on parts of the west coast of the isles. One prominent seaweed of the intertidal zone (*Chondrus crispus*) extends into the sublittoral; and a substantial part of the Canadian harvest grows sublittorally. (Littoral refers to of, on, or along the shore.) The important free-floating seaweeds are *Furcellaria fastigiata*, harvested in the central Kattegat; and *Gracilaria* spp., found off the coasts of Chile and Portugal. These forms are usually harvested by netting.

The cast seaweeds are important in some areas, such as the cast red seaweeds of Prince Edward Island and the cast stripes (*Laminaria hyperborea*) of the Scottish coasts.

Apart from edible uses, seaweed is essentially the raw material for the extraction of a range of carbohydrates, such as agar, carrageenin, and furcelleran from the red seaweeds; and sodium alginate from brown seaweeds — all products used in food processing. Edible seaweeds produced in Japan include: *Konbu* (*Laminaria* spp.); *wakeme* (*Undaria pinnatifida*); *amanori* (*Porphyra* spp.); and *aonori* (*Monostroma* spp. and *Enteromorpha* spp.). The production of amanori approximates upwards of 7000 sheets in Japan; and about one-third of that quantity in Korea, much of which is exported to Japan. Converted into weight, this production represents about 300,000 tons (270,000 metric tons) annually.

SEAWINDS (ADEOS-II). See **Space Science Missions: Earth**.

SEBACEOUS CYST. A cystic structure developing in the skin, due to plugging of a duct leading from a sebaceous gland. The cyst may increase in size, and some become infected. Sebaceous cysts are commonly called wens, and they are often seen on the scalp and face as well as other parts of the body. They always contain a white cheesy material.

Treatment is by surgical excision. If the entire cyst wall is not removed, recurrence is likely.

SEBACEOUS GLAND. A gland of the skin of mammals which secretes an oily substance (sebum). These glands are usually associated with hair follicles and in man are especially abundant in the scalp, although they occur all over the body with the exception of the palms of the hands and soles of the feet. Their secretion keeps the skin pliable and anoints the hair.

In structure these glands are of the compound alveolar type. Their secretory parts are saccular, discharging to a common duct, which often opens in the hair follicle.

SEBORRHEA. A variety of disorders of sebaceous glands are included in this clinical term. The dry, scaling form, "dandruff," is characterized by the presence of fine, branny, slightly greasy scales, which are readily shed. It is common on the scalp but may spread down over the face, neck and ears, and may even be a generalized dermatitis. The oily variety is associated with an excess secretion of oil by the sebaceous glands of the scalp and skin. The scalp is covered with a greasy layer which may mat the hair together; this type is associated with permanent baldness.

In some cases, psoriasis of the scalp may be involved. This disorder usually forms discrete plaques covered by silvery scales, whereas seborrheic dermatitis characteristically is diffuse and patchy and is associated with a greasy scale.

See also **Dermatitis and Dermatosis**.

SECONDARY EMISSION. This term refers to the result of any of several different processes, in each of which some kind of "primary" emission, when it encounters some form of matter, gives rise to another emission of the same or of different character.

The most familiar example of a secondary emission is the x-rays, which have their origin in the impacts of high-speed electrons (cathode rays) upon atoms of matter. The resulting x-rays may themselves act, in turn, as the primary emission and, falling upon solid bodies, cause a secondary x-ray emission. Or they may fall upon a fluorescent substance (see also **Luminescence**) and give rise to a secondary radiation of visible light. X-rays, or any other photons, falling upon a photosensitive metal, may cause a secondary emission of photoelectrons. See also **Photoelectric Effect**. The "recoil" electrons from the Compton scattering of x-rays constitute one form of secondary emission. See also **Compton Effect**.

The most common use of the term denotes the emission of electrons from a solid as the result of the collision of higher energy electrons with the solid. Since the energy levels of the emitted electrons depend upon the atoms emitting them, as well as upon the initial energy, a method of surface layer analysis (i.e., analysis of atoms at the surface or several atomic layers below) has been based upon secondary electron emission. The method consists of placing the solid sample in a vacuum chamber and bombarding it with a beam of relatively low-energy electrons. The secondary electrons emitted (see also **Auger Effect**) are recorded according to their characteristic energies, which correspond to the atoms emitting them. The method is especially useful in detecting impurities of the lighter elements.

SECONDARY RAINBOW. Distinguished from other rainbows by its angular radius, color order, and brightness. The bow is seen between about 50° and 54° from the antisolar point (shadow of the observer's head) or, equivalently, between 130° and 134° from a light source (such as the sun). Reds are found to the inside of the bow (closest to the primary bow) with the blues to the outside. The secondary bow is usually dimmer than the primary bow. Any theory of the bow that approximates the behavior of light as a ray attributes the secondary bow to light that has undergone two internal reflections. The losses accompanying the additional reflection account for the bow being fainter than the primary bow. This may mean that the bow has insufficient contrast to be distinguished from the background. It is sometimes incorrectly asserted that the extra reflection, by itself, is responsible for the reversal of colors from those of the primary bow. See also **Atmospheric Optical Phenomena**.

SECONDARY SEXUAL CHARACTERISTICS. The characteristics of living things whose appearance is definitely associated with the sex of the individual, although the characteristics have no direct connection with the process of reproduction.

The different colors and patterns of the two sexes in many species of birds and insects are familiar examples of secondary sexual characteristics. Horns of some males, the manes of many male mammals, and the spurs of cocks are also in this category. In some species the differences resulting from such characteristics are so great that the two sexes can scarcely be associated by appearance. Cases are on record among the insects of the classification of males and females of the same species in different genera prior to the discovery of their relationship through other evidence. See also **Gonads**; and **Hormones**.

SECOND ORDER REACTION. See **Chemical Reaction Rate**.

SECOND ORDER SYSTEM. A system whose performance characteristics are presented in the form of a second order differential equation

$$r(t) = k_1 \frac{f^2 C(t)}{dt^2} + k_2 \frac{dC(t)}{dt} + k_3 C(t) \ldots$$

where $r =$ system input
$C =$ system output
$t =$ time

k_1, k_2 and k_3 are coefficients.

If all coefficients are constants, then the Laplace transform of foregoing equation also should be second order:

$$\frac{C(S)}{R(S)} = \frac{1}{k_1 S^2 + k_2 S + k_3} \ldots$$

For simplicity, all initial conditions were assumed zero. The time response of a second order system subjected to a step input, r_0, is shown graphically in Fig. 1.

SECOND (UNIT OF TIME). The unit of time, the second, was defined originally as the fraction 1/86,400 of the mean solar day. The exact definition of "mean solar day" was left to astronomical theories. However, measurement showed that irregularities in the rotation of the Earth could not be taken into account by the theory and have the effect that this definition does not allow the required accuracy to be achieved. In order to define the unit of time more precisely, the 11th CGPM (1960) adopted a definition given by the International Astronomical Union which was based on the tropical year. Experimental work had, however, already shown that an atomic standard of time-interval, based on a transition between two energy levels of an atom or a molecule, could be realized and reproduced much more precisely. Considering that a very precise definition of the unit of time is indispensable for the International System, the 13th CGPM (1967) decided to replace the definition of the second by the following (affirmed by the CIPM in 1997 that this definition refers to a cesium atom in its ground state at a temperature of 0 K):

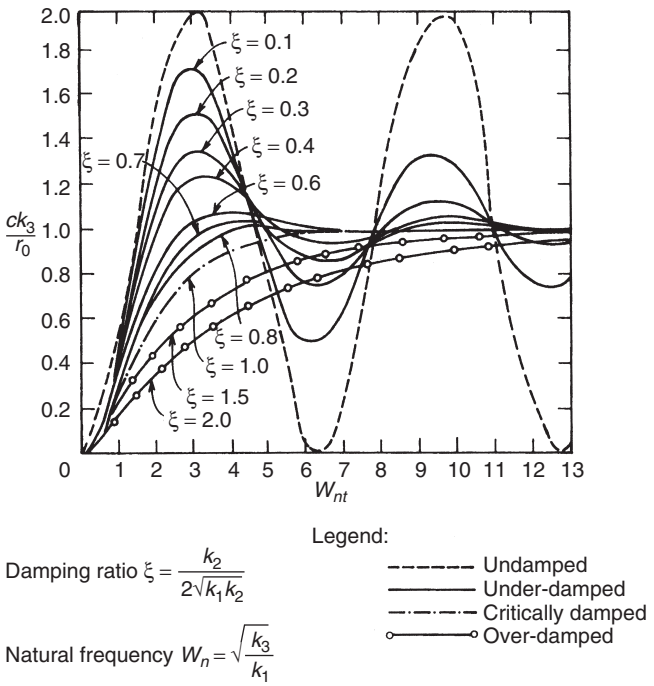

Fig. 1. Time response curve of a second order system subjected to a step input.

The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom.

See also **Units and Standards**.

SECRETARY BIRD. See **Eagle**.

SECRETION. See **Kidney and Urinary Tract**; and **Urine**.

SECTILE. Capable of being cut. In mineralogy, sectile refers to substances, such as talc, mica, and steatite, which can be cut smoothly by a knife.

SECTION MODULUS. An inspection of flexure will reveal that the maximum stress in a member subjected to a transverse bending is directly proportional to the external bending moment, and inversely proportional to the ratio of

$$\frac{\text{moment of inertia}}{\text{Distance of the farthest stressed element from the neutral axis}}$$

It is apparent that this ratio is entirely a property of the shape and size of the cross section of the structural member. This ratio is known as the section modulus, and is an important property of rolled steel sections and other shapes used as structural members. When the bending moment to be withstood by a beam or column is divided by this section modulus, the quotient is the maximum bending stress which will exist in that member.

SECULAR DETERMINANT. An equation of the form

$$K(\lambda) = |a_{ij} - b_{ij}\lambda| = 0$$

which becomes a polynomial in λ when the determinant is expanded. In matrix algebra it is the determinant of the characteristic matrix of A, $[\lambda E - A]$ where E is a unit matrix. In this case,

$$K(\lambda) = \lambda^n + a_1\lambda^{n-1} + \cdot + a_n = 0$$

is the characteristic equation or function, the coefficients a_i involve the elements of A, and the n roots of $K(\lambda)$ are the eigenvalues, latent or characteristic roots. All of them need not be different; if two or more of them are equal they are said to be degenerate. An important property of the latent roots is the following. Suppose two matrices A and B are related by a similarity transformation, $B = Q^{-1}AQ$, then the latent roots of A are identical with those of B.

See also **Determinant**.

SECULAR PARALLAX. The parallactic motion of a star due to the sun's motion through space. See also **Stellar Parallax**.

SECULAR TERMS. In the mathematical expression of an orbit, terms for very long period perturbations, in contrast to periodic terms, terms of short period.

SEDGE *(Cyperaceae)*. This family of monocotyledons is composed of grass-like plants which are found chiefly in marshy places. Most of its members are perennials with creeping rhizomes and grass-like leaves. The basal portion of the leaf is a sheath which completely surrounds the stem. The stem is generally solid and triangular in cross section. The inflorescence is a spike or a panicle, composed of one- to many-flowered spikelets. Each flower, borne in the axil of a bract, has three stamens and a single pistil; in some sedges there is also a perianth of six or many bristles. The fruit is an achene. All sedges are wind-pollinated.

Few of the sedges are of any importance. Some of them yield a coarse hay which may be fed to livestock, and is sometimes used for packing material. Papyrus, used as paper by the ancient peoples, was made from the stems of *Cyperus papyrus*. The erect stems and leaves of species of *Scirpus* are sometimes dried and woven to form chair seats; chairs finished with this material are called rush-bottomed chairs. The plants are sometimes called bulrushes. Several sedges form tubers, which are sometimes used for food.

SEDIMENTATION. The settling out by gravity of solid particles suspended in a liquid, the rate of settling being defined by Stoke's law. See also **Stoke's Law**. This method is used industrially in water purification. It is also an analytical procedure for separation of solids of different particle size, as well as for molecular weight determination. The sedimentation of large molecules in a strong centrifugal field permits determination of both average molecular weights and the distribution of molecular weights in certain systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250,000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary that progressively moves toward the bottom of the cell. An optical system is provided for viewing this boundary, and a study as a function of the time of centrifuging yields the rate of sedimentation for the single component, or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. The result of this work is the distribution of molecular weights in the sample, which is attainable by few other methods. See also **Precipitate**.

The uses of sedimentation in industry fall into the following categories: solid–liquid separation; solid–solid separation; liquid–liquid (immiscible) separation; particle-size measurement by sedimentation; and other operations, such as mass transfer and washing.

In solid–liquid separation, the solids are removed from the liquid either because the solids or the liquid are valuable or because these have to be separated before disposal. If the primary purpose is to produce the solids in a highly concentrated slurry, the process is called thickening. If the purpose is to clarify the liquid, the process is called clarification. Usually, the feed concentration to a thickener is higher than that to a clarifier. Some types of equipment, if correctly designed and operated, can accomplish both clarification and thickening in one stage. See also **Extraction, Liquid–Solid**. In an overwhelming majority of applications in industry the solids to be separated are denser than the suspending liquid. However, where the solids are lighter and, therefore, settle upword (or float), this has some obvious design consequences.

In solid–solid separation, the solids are separated into fractions according to size, density, shape, or other particle property. Sedimentation is also used for size separation, ie, classification of solids. See also **Separation, Size Separation**. One of the simplest ways to remove the coarse or dense solids from a feed suspension is by sedimentation. Successive decantation in a batch system produces closely controlled size fractions of the product. Generally, however, particle classification by sedimentation does not give sharp separation.

Where emulsions are to be resolved or other mixtures of immiscible liquids of different density are to be separated by sedimentation, the principles are the same as for solids, but some specific challenges present themselves. For example, the dispersed phase must not be emulsified by violent pumping or flow shear because this obviously reduces the particle size and makes the subsequent separation more difficult. Another specific feature of such systems is the possibility of coalescence. Where this is possible it is actively promoted because it can greatly improve the efficiency of the separation by effectively locking out of the continuous phase from the coalescing dispersed phase. If coalescence occurs during sedimentation this leads to increases in particle size and the consequent increase in the settling rate. Applications of liquid–liquid separation by sedimentation can be found in many chemical, pharmaceutical, nuclear, petrochemical, and petroleum industries.

In particle-size measurement, gravity sedimentation at low solids concentrations (<0.5% by vol) is used to determine particle-size distributions of equivalent Stokes' diameters in the range from 2 to 80 μm. Particle size is deduced from the height and time of fall using Stokes' law, whereas the corresponding fractions are measured gravimetrically, by light, or by X-rays. Some commercial instruments measure particles coarser than 80 μm by sedimentation when Stokes' law cannot be applied.

Sedimentation is also used for other purposes. For example, relative motion of particles and liquid increases the mass-transfer coefficient. This motion is particularly useful in solvent extraction in immiscible liquid–liquid systems. See also **Extraction, Liquid-Liquid**. An important commercial use of sedimentation is in continuous countercurrent washing, where a series of continuous thickeners is used in a countercurrent mode in conjunction with reslurrying to remove mother liquor or to wash soluble substances from the solids. Most applications of sedimentation are, however, in straight solid–liquid separation.

Principles

Gravity Settling of a Single Particle. If a particle moves relative to the fluid in which it is suspended, the force opposing the motion is known as the drag force. Knowledge of the magnitude of this force is essential if the particle motion is to be studied. Conventionally, the drag force F_D is expressed according to Newton:

$$F_{\mathrm{D}} = C_{\mathrm{D}} \cdot A \cdot \frac{\rho v^2}{2} \tag{1}$$

where v is the particle–fluid relative velocity, ρ is the fluid density, A is the area of the particle projected in the direction of the motion, and C_D is a coefficient of proportionality known as the drag coefficient. Newton assumed that the drag force results from the inertia of the fluid and that C_D is then constant.

Dimensional analysis shows that C_D is generally a function of the particle Reynolds number (Re):

$$Re_{\mathrm{p}} = \frac{v \cdot x \cdot \rho}{\mu} \tag{2}$$

where x is the particle size and μ is the liquid viscosity. The form of the function depends on the regime of the flow. This relationship for rigid spherical particles is shown in Figure 1. At low Re, under laminar flow conditions when viscous forces prevail, C_D can be determined theoretically from Navier–Stokes equations; the solution is known as Stokes' law:

$$F_{\mathrm{D}} = 3\pi\mu v x \tag{3}$$

This is an approximation that gives the best results for Re_p®0. The upper limit of its validity depends on the error that can be accepted. The usually quoted limit for the Stokes' region of $Re_p = 0.2$ is based on the error of ~2%.

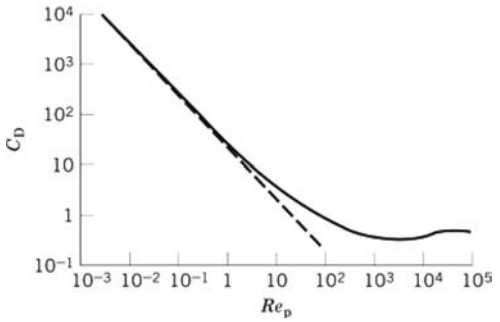

Fig. 1. Drag coefficient versus particle Re for spherical particles where (———) corresponds to the theoretical value of $C_D = 24/Re_p$ (eq. 4)

Elimination of F_D between equations 1, 2 and 3 gives another form of Stokes' law, as shown in Figure 1 as a straight line.

$$C_{\mathrm{D}} = \frac{24}{Re_{\mathrm{p}}} Re_{\mathrm{p}} < 0.2 \tag{4}$$

For $Re > 1000$, the flow is fully turbulent. Inertial forces prevail and C_D becomes constant and equal to 0.44, the Newton region. The region in between $Re_p = 0.2$ and 1000 is known as the transition region and C_D is either described in a graph or by one or more empirical equations.

In solid–fluid separation, the fine particles are most difficult to separate, ie, Re_p is low, almost inevitably <0.2, owing to low values of x and v. Therefore, only the Stokes' region has to be considered.

A single particle settling in a gravity field is subjected primarily to drag force, F_D; gravity force, $m \cdot g$; and buoyancy, $(m \cdot g)\ \rho/\rho_s$; which have to be in equilibrium with the inertial force:

$$m\frac{dv}{dt} = (m \cdot g) - (m \cdot g)\frac{\rho}{\rho_{\mathrm{s}}} - F\mathrm{D} \tag{5}$$

assuming positive downward forces, where m is particle mass, g is gravity acceleration, ρ_s is particle density, and t is time. Equation 5 can be solved, assuming Stokes' law:

$$v(t) = \frac{g x^2(\rho_{\mathrm{s}} - \rho)}{18\mu}\left[1 - \exp\left(-\frac{t 18\mu}{x^2\rho_{\mathrm{s}}}\right)\right] \tag{6}$$

This relationship is exponential with respect to time t and with increasing time quickly approaches equation 7, where v_g known as the terminal settling velocity under gravity.

$$v_{\mathrm{g}} = \frac{g x^2(\rho_{\mathrm{s}} - \rho)}{18\mu} \tag{7}$$

The terminal velocity in the case of fine particles is approached so quickly that in practical engineering calculations the settling is taken as a constant velocity motion and the acceleration period is neglected. Equation 7 can also be applied to nonspherical particles if the particle size x is the equivalent Stokes' diameter as determined by sedimentation or elutriation methods of particle-size measurement.

Note that equation 7 essentially applies to settling at low particle concentrations (<0.5% by volume) in Newtonian liquids, which have a constant viscosity. In principle, it can be used also in non-Newtonian fluids, where viscosity then becomes the apparent viscosity but, depending on the type of non-Newtonian behavior, its determination may require an iterative procedure. Not only is such behavior shear dependent (ie, the apparent viscosity depends on how fast the particle is settling), but it may also be time dependent and the model may contain a zero shear viscosity as a parameter. Svarovsky Ref. section 18.4 reviews the state of the art to 2000 with a specific reference to research that is still in progress, eg, on particle settling in the Carreau model fluids (eg, polymeric liquids).

Settling of Suspensions. As the concentration of the suspension increases, particles get closer together and interfere with each other. If the

particles are not distributed uniformly, the overall effect is a net increase in settling velocity because the return flow caused by volume displacement predominates in particle-sparse regions. This is the well-known effect of cluster formation that is significant only in nearly monosized suspensions. For most practical widely dispersed suspensions, clusters do not survive long enough to affect the settling behavior and, as the return flow is more uniformly distributed, the settling rate steadily declines with increasing concentration. This phenomenon is referred to as hindered settling and can be theoretically approached from three premises: as a Stokes' law correction by introduction of a multiplying factor; by adopting effective fluid properties for the suspension different from those of the pure fluid; and by determination of bed expansion using a modified Carman-Kozeny equation. These three approaches yield essentially identical results:

$$\frac{v_p}{v_g} = \varepsilon^2 f(\varepsilon) \tag{8}$$

where v_p is the hindered settling velocity of a particle, v_g is the terminal settling velocity of a single particle as calculated from Stokes' law (eq. 7), ε is volume fraction of the fluid (voidage), and $f(\varepsilon)$ is a voidage function, which for Newtonian fluids has different forms, depending on the theoretical approach adopted. The differences between the available expressions for $f(\varepsilon)$ are not great and are frequently within experimental accuracy. The most important forms are as follows. From the Carman-Kozeny equation 6,

$$f(\varepsilon) = \frac{\varepsilon}{10(1-\varepsilon)} \tag{9}$$

from Brinkman's theory, applied to Einstein's viscosity equation,

$$f(\varepsilon) = \varepsilon^{2.5} \tag{10}$$

and from the well-known Richardson and Zaki equation,

$$f(\varepsilon) = \varepsilon^{2.65} \tag{11}$$

For irregular or nonrigid particles, eg, flocs, the Einstein constant (2.5) and the Richardson and Zaki exponent (2.65) can be considerably larger than for spheres.

Strictly speaking, these correlations apply only to the cases where flocculation is absent, such as for coarse mineral suspensions. Suspensions of fine particles, because of the very high specific surface of the particles, often flocculate, and therefore show different behavior. With increasing concentration, C, of such suspensions, at a particular concentration, C_1, an interface is observed that becomes sharper at $C > C_1$. The slurry is then said to be in the zone-settling region. The particles below the interface, if the size range is not $> 6:1$, settle en masse, ie, all at the same velocity irrespective of size. There are two possible reasons for this: either the flocs become similar in size and settle at the same velocity, or they are joined and fall as a web. Interestingly enough, the settling rates of the interface and of the solids below it, of many practical suspensions, can still be described by the Richardson and Zaki equation (eq. 11), but the value of v_g has to be determined by extrapolation of the experimental log–linear plot for $\varepsilon = 1$. The value of this intercept has in fact been used for indirect size measurement of the flocs. The slope of the plot determines the exponent.

The concentration C_1 at which zone settling is first observed depends on the material and its state of flocculation and no guidance can be given. Addition of flocculating agents or dispersants drastically changes this concentration and only experimental evaluation can yield its value. If the concentration is increased still higher, a point is reached when the flocs become significantly supported mechanically from underneath, as well as hydraulically, and the suspension is then known to be in compression or compression settling. The solids in compression continue to consolidate. The consolidation rate depends not only on the concentration, but also on the structure of the solids, which in turn depends on the pressure and flow conditions. This is a complex problem closely related to cake filtration and expression. See also **Filtration**. At intermediate concentrations between those of zone settling and fully established uniform compression, channeling is sometimes observed, which particularly occurs in slowly raked large-scale thickeners. Under these conditions, a coarser structure of pores becomes interconnected in the form of channels. See also **Dispersants**; and **Flocculating Agents**.

Most authors who have studied the consolidation process of solids in compression use the basic model of a porous medium having point contacts that yield a general equation of the mass-and-momentum balances. This must be supplemented by a model describing filtration and deformation properties. Probably the best model to date uses two parameters to define characteristic behavior of suspensions. This model can be potentially applied to sedimentation, thickening, cake filtration, and expression.

Coagulation and Flocculation. Both coagulation and flocculation are classical pretreatment methods used to increase the effective particle size, thereby improving sedimentation settling rates. Although these two terms are often used interchangeably, coagulation is sometimes defined as agglomeration of the primary particles into particles up to 1 mm in diameter. Flocculation, on the other hand, not only agglomerates particles, but also interconnects them by means of long-chain molecules of the flocculating agent into giant loose flocs up to 1 cm in size. See also **Flocculating Agents**. The term flocculation is used here to include coagulation as defined. Chemical agents create favorable conditions for flocculation by neutralization of surface charges and thus reduce interparticle repulsion. Mineral coagulants are in the form of electrolytes, such as alum or lime, whereas flocculation agents are mostly synthetic polyelectrolytes of high molecular weight. Development of the latter group since the 1970s has resulted in a remarkable improvement in sedimentation equipment. Such agents are relatively expensive and the correct dosage has to be carefully optimized. Overdosage is not only uneconomical, but may inhibit the flocculation process and cause operating problems. Because surface charges are also affected by pH, control of this variable is essential in pretreatment.

Although reduction or elimination of the repulsion barrier is a necessary prerequisite of successful flocculation, the actual flocculation in such a destabilized suspension is effected by particle–particle collisions. Depending on the mechanism that induces the collisions, the flocculation process may be either perikinetic or orthokinetic.

Perikinetic flocculation is the first stage of flocculation, induced by the Brownian motion. It is a second-order process that quickly diminishes with time, and therefore is largely completed in a few seconds. The higher the initial concentration of the solids, the faster is the flocculation.

The well-known DLVO theory of colloid stability attributes the state of flocculation to the balance between the van der Waals attractive forces and the repulsive electric double-layer forces at the liquid–solid interface. The potential at the double layer, called the zeta potential, is measured indirectly by electrophoretic mobility or streaming potential. The bridging flocculation by which polymer molecules are adsorbed on more than one particle results from charge effects, van der Waals forces, or hydrogen bonding. See also **Colloid System**.

The flocculation rate is determined from the Smoluchowski rate law, which states that the rate is proportional to the square of the particle concentration by number; inversely proportional to the fluid viscosity, and independent of particle size.

Orthokinetic flocculation is induced by the motion of the liquid obtained, eg, by paddle stirring or any other means that produces shear within the suspension. Orthokinetic flocculation leads to exponential growth, which is a function of shear rate and particle concentration. Large-scale one-pass clarifiers used in water installations employ orthokinetic flocculators before introducing the suspension into the settling tank. See also **Water**. Scale-up of orthokinetic flocculators, generally in the form of paddle devices, are based on the product of mean velocity gradient and time, for a constant volume concentration of the flocculating particles.

Another type of flocculation results from particle–particle collisions caused by differential settlement. This effect is quite pronounced in full-size plants where large rapidly falling particles capture small particles that settle more slowly.

A third type of flocculation, mechanical syneresis, has been defined. This is the process of shrinkage and densification of loose and bulky flocs through uneven application of local fluctuating mechanical forces leading to exudation of the liquid from the floc. It is achieved by slowly stirring the blanket zones with rotating paddles in sludge-blanket clarifiers. Pellet-like flocs can be produced by this process allowing higher overflow rates than

those obtained using conventional blanket clarifiers. So far, the process has been applied successfully to only a few suspensions in water treatment.

Settling Tests

For the simplest case of particulate clarification, where no flocculation takes place during settling, ie, either the flocculation process is completed before entering the settling tank or the suspension is entirely nonflocculant, the basic test is the so-called short-tube procedure. A sample settles in and is decanted from a large measuring cylinder in order to evaluate the settling rate, ie, the specific overflow rate that produces a satisfactory clarity of the overflow. The long-tube procedure is designed for systems where flocculation (or deflocculation) takes place during settling, thus the settling tank's performance depends not only on the specific overflow rate, but also on the residence time in the tank. Tests are conducted in a vertical tube that is as long as the expected depth of the clarifier, under the ideal assumption that a vertical element of a suspension that has been clarified maintains its shape as it moves across the tank.

When the overflow clarity is independent of overflow rate and depends only on detention time, as in the case for high solids removal from a flocculating suspension, the required time is determined by simple laboratory testing of residual solid concentrations in the supernatant versus detention time under the conditions of mild shear. This determination is sometimes called the second-order test procedure because the flocculation process follows a second-order reaction rate.

The design of the sludge-blanket clarifiers used primarily in the water industry is based on the jar test and a simple measurement of the blanket expansion and settling rate. Different versions of the jar test exist, but essentially it consists of a bank of stirred beakers used as a series flocculator to optimize the flocculant addition that produces the maximum floc-settling rate. Visual floc-size evaluation is usually included.

The critical settling flux essential for evaluating the requirement of the zone-settling layer area of a gravity thickener is measured either using the Coe and Clevenger method or the simpler Talmage and Fitch procedure. The former consists of a series of settling tests in a measuring cylinder where the initial settling rates of a visible interface within the settling suspension are measured for different initial solids concentrations. The Talmage and Fitch procedure is simpler because it requires only one test at any concentration, providing it is in the zone-settling regime. Theoretically, the two methods should give an identical critical settling flux, and therefore identical pool areas, but this is not so in practice. Usually, the Coe and Clevenger method leads to underdesign of the thickener area, whereas the Talmage and Fitch procedure leads to overdesign. For highly flocculant slurries, the area requirement of the compression layer may exceed that of the zone-settling layer; the compression zone also has a depth requirement. A laboratory test for the latter, employing a multiple batch upflow test for compression-zone evaluation, has been described [Kos Ref.]. This test is by no means generally accepted and its reliability remains to be demonstrated.

Design Methods

The simplest case of a gravity settling tank without coagulation or flocculation in clarification applications, ie, when removing small amounts of solids, is based on the identical principle as laminar settling chambers for cleaning gases. The grade-efficiency curve $G(x)$ is given by equation 12:

$$G(x) = \frac{v_g A}{Q} \tag{12}$$

where v_g is the terminal settling velocity of a particle of size x (see eq. 7), Q is the feed flow rate that is equal to the overflow rate, and A is the plan area of the tank. Equation 12 was derived assuming laminar flow in the tank and no end effects. The tank area is the only design parameter affecting the theoretical separational performance irrespective of the shape or depth of the pool. Equation 12 can be expressed in terms of the more conventional dimensionless groups:

$$Stk.Fr = G(x) \tag{13}$$

if Stokes' law is assumed for the particle-settling velocity, and therefore the Stokes' number, *Stk*, is defined as follows:

$$Stk = \frac{x^2 \Delta\rho}{18\mu} \cdot \frac{Q}{A \cdot H} \tag{14}$$

and the Froude number, *Fr*, as in equation 15:

$$Fr = \frac{HgA^2}{Q^2} \tag{15}$$

where H is a characteristic dimension of the pool, eg, the height, which in equation 13 cancels; $\Delta\rho$ is the particle–fluid density difference; μ is the liquid viscosity; and g is the acceleration of gravity.

Scale-up can be calculated with the help of equation 12, based on a simple specific overflow rate model: for the same performance, the flow rate is proportional to the area, or vice-versa. Because of the long residence time involved during which the feed solids must remain constant, it is difficult to measure the grade-efficiency curve of a settling tank, particularly on a large scale. It is therefore more practical to measure the specific overflow rate (or overflow volume flux) Q/A that gives satisfactory overflow clarity from simple settling tests. If the clarification is not completely particulate, ie, when flocculation takes place and has not been completed before the suspension enters the settling tank, the overflow clarity depends not only on the overflow rate, but also on the detention time. The scale-up under such conditions is based on the long-tube procedure. Sometimes the effect of the detention time is so strong that the overflow rate can be ignored and the scale-up is based on the detention procedure. For the whole range of coagulation clarifiers used predominantly in the water industry, the scale-up is usually based on the overflow rate determined from jar tests primarily designed to select the best flocculant and determine the settling rates that give a clear supernatant.

Probably more relevant to the chemical industry is the scale-up of thickeners. Thickeners are basically gravity settling tanks that, apart from producing a clear overflow, are designed to have a thick underflow with as little water content as possible. The feed into a thickener is generally more concentrated than the feed into a clarifier, and quite often exhibits zone-settling behavior because of the application of flocculants.

An operating thickener has basically three layers: the topmost clarification layer, the zone-settling layer, and the compression layer at the bottom. Each of the three layers requires a certain area. Ideally, the largest of these governs the design of the thickener. In most cases, it is the function of the clarification layer to prevent those particles that have escaped from the zone-settling layer or the feed from leaving with the overflow. This function is frequently less important than the thickening function and thus the thickener area is usually chosen on the basis of the zone-settling or compression layer requirement.

The conventional design and scale-up of thickeners operated with mineral or certain metallurgical slurries is based on the area requirement of the zone-settling layer and assumes that the compression zone only imposes a solids-detention (hence depth) demand and has no independent demand on area, with the exception of the empirical 3-ft (1 m) rule, which if applicable, introduces an area demand. It is the basic principle of this method that the solids on their way downward from the feed layer to the underflow continuously increase in concentration from that of the feed to that of the underflow, usually determined by a time-retention test. The total solids flux (mass flow rate of solids per unit area), which different layers in the thickener are capable of accommodating, usually goes through a minimum between the feed zone and the underflow. This critical solids flux, G_c, determines the minimum design area of the thickener. The zone-settling layer does not form under these conditions and makes no depth demand. The thickener is then in no danger of overflowing solids. The area of the thickener, A, is calculated from the critical solids flux, G_c; the feed flow rate, Q; and concentration, C_f, using a simple mass balance, which assumes a complete separation of all feed solids.

$$G_c A = Q \cdot C_f \tag{16}$$

Thus the design and scale-up of the thickeners in this category centers around the determination of the critical solids flux, G_c. This value cannot be estimated from the primary properties of the particulate system

because of the unpredictable effect of flocculation. It must be obtained experimentally from large- or pilot-scale thickeners. However, with a few exceptions, this method is impracticable because of the scale and cost of such experiments. If the settling velocity of the solids is assumed to be a function of concentration only, ie, $v = v(c)$, then this function should be unique for a given suspension and should be the same in batch-settling and continuous operations. This is the basis of the conventional Coe and Clevenger, and Talmage and Fitch methods that only differ in the way in which G_c is determined from experimental tests. The latter method requires simpler tests. According to Coe and Clevenger, if the function of $v = v(c)$ is known, the critical flux G_c corresponds to the minimum on the total flux G curve, which is as follows:

$$G = v/\left(\frac{1}{C} - \frac{1}{C_v}\right) \tag{17}$$

where the underflow concentration, C_v, is determined by time-detention tests. The thickness of the compression zone is also determined by time-detention tests, assuming that the solids concentration reached in the compression layer in a batch test after a given time is the same as in the compression layer of a thickener.

Equipment

Sedimentation equipment can be divided into batch-operated settling tanks and continuously operated *thickeners* or *clarifiers*. The operation of the former is simple. Whereas use has diminished, the batch settling tanks are employed when small quantities of liquids are to be treated, eg, in the cleaning and reclamation of lubricating oil. Furthermore, batch settling as repeated decantation is an effective and well-predictable particle classification process for small quantities of products. Most sedimentation processes, however, are operated in continuous units. See also **Clarifiers**; **Clarifying Agents**; **Classifying (Process)**; and **Thickeners**.

SEEBECK EFFECT. Production of electromotive force as a result of a circuit containing two conducting materials having two junctions between the materials at different temperatures. This effect is the basis of all thermocouples. The Seebeck effect is one of a number of related thermoelectric phenomena, is the inverse of the Peltier effect, and is closely related to the Thomson effect. See also **Thermocouple**.

SEED. In the vegetable kingdom, seeds are a vital link to the past and to the future. For the majority of food plants, of all factors, including climate, water management, fertilizers, insecticides, etc., that are required to ensure a successful crop, healthy, vigorous seeds are, without qualification, the singular indispensable requirement. Seed requirements for planting are a significant cost factor and support a major seed growing, processing, and supply industry, as is evidenced by Table 1.

Seeds per se are consumed as food items and the oils and proteins they contain are expressed, extracted, and separated from them to yield edible fats and oils and vegetable protein. The grain industry is based upon seed processing. See also **Protein**; and **Vegetable Oils (Edible)**.

TABLE 1. QUANTITY OF SEED REQUIRED FOR PLANTING SELECTED MAJOR CROPS[1]

Crop	Pounds/Acre	Kilograms/Hectare
Barley	80	90
Beans (dry edible)	54	60
Groundnuts (peanuts)	136	152
Maize (corn)	13.4	15
Oats	83	93
Peas (dry field)	167	187
Potatoes (Irish)	1830	1050
Rice	142	159
Rye	90	101
Sorghum	6.76	7.57
Soybeans	63	71
Sweet potatoes	600	672
Wheat (Durum)	89	100
Wheat (winter)	69	77

[1] Average of entire United States plantings.

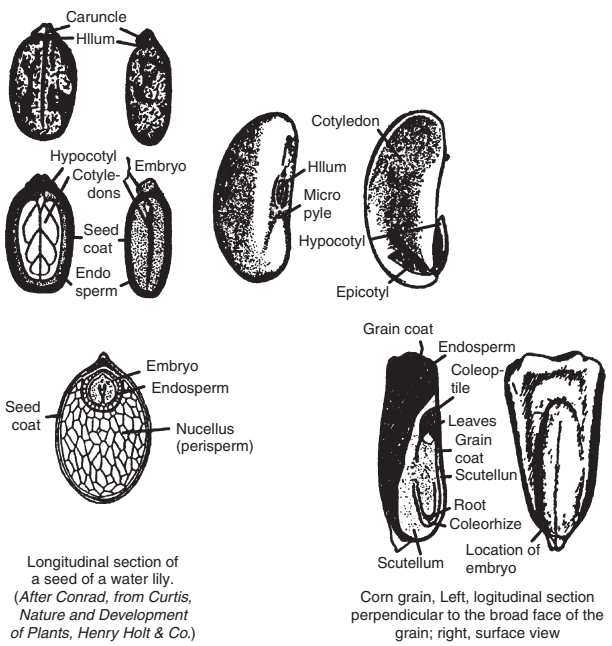
The collection and preservation of seeds as a source of germ plasm for improving crops in numerous ways (yields, resistance to disease, insects, and severe climates) are extremely important scientific undertakings.

Botanical Factors A seed consists of a dormant embryo, together with a quantity of stored food that may be absorbed in the embryo, or may surround it, and one or two seed coats or integuments. The seed develops from an ovule. In angiosperms, the seed is completely enclosed by the ovary wall. In gymnosperms, the seed lies exposed on the surface of a scale of the cone. Representative seeds are shown in Fig. 1.



Longitudinal section of a seed of a water lily. (*After Conrad, from Curtis, Nature and Development of Plants, Henry Holt & Co.*)

Corn grain, Left, logitudinal section perpendicular to the broad face of the grain; right, surface view

Fig. 1. Representative types of seeds.

The fertilized egg develops into the embryo, which is a young plant contained in a seed. This embryo may be an undifferentiated mass of cells, as it is in the orchid family, but usually is more highly organized. It then consists of a short axis called the hypocotyl. At one end of the hypocotyl there is a primitive root called the radicle. At the other end is a terminal bud, called the plumule. This plumule may be nothing more than a small mass of undifferentiated cells, recognizable only as a small bulge at the apex of the hypocotyl, or it may be a well-developed shoot having a short internode and two distinct leaves. Borne laterally at the apex of the hypocotyl there are one or more seed leaves or cotyledons. In many seeds these cotyledons are thin and more or less leaf-like, while in others

they are very fleshy, filled with stored food material, and form the greater part of the seed. The number of cotyledons varies. In monocotyledons there is usually only one cotyledon, in dicotyledons there are two, and in gymnosperms there are often many.

In angiosperms the endosperm is the tissue which results from the endosperm nucleus. It is a tissue rich in stored food. The food reserves stored in the seed are carbohydrates, especially starches and sugars, fats and proteins. The developing embryo gets its food from the endosperm. In many seeds, the embryo uses only a part of the endosperm during its development, so that the mature seed contains much endosperm surrounding the embryo. These are called albuminous seeds. In other plants, the food reserves of the endosperm have been entirely absorbed and restored in the embryo, especially in the cotyledons, which then becomes very fleshy. Such seeds are exalbuminous.

The embryo sac of the ovule is surrounded by a mass of tissue called the nucellus. In most plants, this is completely absorbed before the seed reaches maturity. In some seeds, it persists and it becomes much enlarged. It is then known as the perisperm, and serves as an additional source of stored food.

Surrounding all these are the seed coats, which develop from the integuments of the ovule. The outer coat may be variously modified to aid in the dissemination of the seeds. On the seeds of many plants there is a fleshy structure called the aril. This grows up around, and more or less covers, the outer integument. In some seeds, the outer coat produces an outgrowth called the caruncle, which seems to aid in absorbing water from the soil and passing it on to the seed. Passing through the integuments is a minute hole called the micropyle. It is through this that the pollen tube entered the young ovule; the radicle generally points directly toward it. The seed is attached to the ovary wall by a small stalk or funiculus which, when the seed falls off, leaves a scar called the hilum on the seed coats.

Natural Broadcasting of Seeds. Once started, without human intervention the plant must remain in a fixed position throughout its life. In higher plants, the vegetative parts are very rarely able to colonize new territories. The fruit, or less frequently the seed, is the part which is carried to new regions. There are several agents effecting this transfer. The most important is wind. Sometimes the seeds of a plant are very small and light, and so easily carried by the wind. The minute seeds of orchids are carried by this means; in these seeds, additional buoyancy is gained by a loose, thin case, which surrounds the embryo tissue within and acts as a float. In other plants the seeds are carried away by hairs that grow from the seeds. Milkweed seeds are provided with a tuft of long silky hairs attached at one end of the thin light seed. Cotton fibers serve the same purpose; they completely cover the cotton seed. In other plants the seed is provided with a wing, a flat thin outgrowth from the seed coats. Catalpa seeds are thus equipped, as also are pine seeds. The distances to which the wind carries seeds is considerable. By this means, plants are disseminated over many square miles or kilometers.

Another way in which new land is reached is by ejecting seeds violently from the fruit. When the fruit of the witch hazel is ripe, the dry, thick wall of the ovary suddenly snaps and hurls the seeds violently to a distance of many feet (several meters). The common Jewelweed or Touch-me-not scatters its seeds in similar fashion. At maturity the fruit abruptly splits open, and the valves roll back, throwing the seeds many feet away. In similar fashion the pods of many legumes split apart forcefully and scatter the seeds within. Seeds scattered by this means cannot attain the wide dispersal which wind-borne seeds do.

A few plants form seeds that float readily on water for some time without harm. Currents of water may carry the seeds to new shores. Other seeds are provided with hooks or barbs or have a sticky surface, which causes them to adhere to the bodies of passing animals that scatter them. In most plants, however, it is the fruit that is so carried. Such fruits, as beggar's lice, burdock, goldenrod and many others, are commonly mistaken for seeds.

Germination and Dormancy. Having reached an environment where suitable conditions exist, the seed germinates. The seeds of many plants must reach such a place in a very short time or perish, since they remain viable but a very short time. Those of the willow, for example, live only a few days after falling from the parent plant. The seeds of most garden vegetables grow best if planted within a year from the time they ripen, though they may retain their vitality for three or four years with decreasing vigor. On the other hand, some seeds lie dormant for a long time before germinating. Seeds of many weeds, including the common ragweed, the pollen of which causes hay-fever, may live for years before germinating, making it very difficult to eradicate the species by pulling up the plants for a single season. Tests show that the seeds of some plants may remain viable for 20–50 years. It is recorded that the seeds of the Asiatic lotus have germinated after lying dormant for 200 years. But records of viable seeds found in ancient vaults, such as contained the mummies of Egypt, are entirely unfounded.

Certain conditions favor the continued vitality of dormant seeds. Sometimes the seed has a very thick wall that is impervious to water or to oxygen gas, and so excludes two things necessary to start germination. Until the wall has softened or rotted the seed does not germinate. In other seeds the thick wall resists the pressure of the developing embryo within. Many important crop plants have seeds that germinate slowly because of their thick coats. To hasten germination and to insure a uniform stand of plants the seeds are scarified before planting; that is, the seed coat is rubbed with abrasive substances that break down the impervious wall layers. Often the wall of the seed is sufficiently damaged during mechanical threshing to insure prompt germination when planted. Prolonged soaking sometimes hastens germination.

In other seeds, dormancy is inherent in the embryo itself. The embryo may be entirely undeveloped, requiring a long period of slow development before it can break the seed coats. Other seeds germinate only after a period of "after-ripening" which varies from a single winter to many years. The changes occurring during this period are as yet not well understood. The time of "after-ripening" may be considerably shortened by burying the seeds in sand or other suitable material and by keeping them cold and moist.

The external conditions necessary to cause germination are adequate water, suitable temperature and oxygen. With some seeds, light is an important factor. Most seeds contain very little water, which is one of the reasons why they can survive under adverse conditions such as cold and drought. To germinate they must receive additional water. This added water favors digestion, a process that makes available to the plant the stored food. Both water and oxygen are needed by the germinating embryo, because of the great increase in respiration, the process which frees to the plant the energy stored in the carbohydrates and other compounds.

The temperature at which a seed will germinate varies with different plants. For each there is a considerable range of temperature. The lowest temperature at which germination occurs is called the minimum temperature, and varies from 0–10 °C or even higher. The maximum or highest temperature at which germination takes place is usually between 45 and 50 °C. The most favorable temperature, or optimum, is about 30 °C. Light favors the germination of many common plants, such as many grasses and troublesome weeds. Other plants, including many common crop plants, are unaffected by light.

Germination is the development of the embryo into a young plant. It becomes completed when the young plant is independent of the food stored in the seed. In most seeds the first visible change is swelling of the seed. This is a result of the increased water content. Often the seed coats are ruptured by the swelling of the contents of the seed. Respiration increases greatly, and much energy is made available in those regions where active growth occurs, that is, the hypocotyl and plumule. The radicle pushes out of the seed and attaches itself, by means of root hairs, to the soil particles. These then begin absorbing water from the soil. In some seeds, the hypocotyl elongates considerably, often forming an arch which subsequently straightens, lifting the cotyledons and plumule out of the soil and into the air. In other seeds, the cotyledons remain permanently underground, the plumule elongating and pushing out into the air. There the first leaves of the plant appear. With their formation the plant becomes independent.

Many foodstuffs are seeds, especially those of the cereal grains, rice, wheat, corn, barley, and oats. But seeds are used in many other ways. Many medicinal products are obtained from seeds. Linseed oil, soybean oil, and coconut oil are but a few of the many oils that come from seeds. Poppy seeds, caraway seeds, and mustard add flavor to other foods. Clothing is made from the hairy covering of the cotton seed. Beads, buttons, and ornaments of various kinds are also often made from seeds.

SEEDING (Gas Conductivity). Introduction of atoms, such as sodium, with a low ionization potential into a hot gas for the purpose of increasing the electrical conductivity.

SEEING (Astronomy). A term used by ground-based optical astronomers to describe image quality.

When describing stellar (point source) images, good seeing means the images are small and stationary; bad seeing means the images are large (sometimes changing in size in a rapid and irregular fashion) and unsteady. When describing images of extended objects (such as planets or nebulae), good seeing means the images are sharp and steady; bad seeing means the images are blurred and unsteady.

Seeing quality is determined by motions of air masses of differing index of refraction (due to differences in density and/or humidity) so that light rays are refracted or bent in a time-variable fashion. These motions can be both near the telescope or at some distance from it. A similar phenomenon is observed in viewing a distant object over a nearby fire or other source of heat. The heat causes rising currents of warmer air which produce time variable refraction so that the object's image is seen to "shimmer" or be blurred.

For most astronomical observations, the better the seeing, the fainter one can observe. Hence, seeing quality is an important criterion in selecting the site of a ground-based observatory. (Other important criteria are the number of clear hours, absence of anthropogenic night time illumination, and, for infrared observations, dryness of the atmosphere.) The sites with the best seeing are generally islands and mountains near oceans or in isolated flat areas. This is generally believed to be because the large-scale motions of the atmosphere in such places are largely laminar rather than turbulent. Local conditions, such as local topography, height of dome, temperature of dome floor, among other factors, can be very important and much effort is made to control these conditions.

SEGER CONE. Seger Cones are conical shaped ceramic objects of differing compositions. When heated to different temperatures, these cones will slump as they soften in response to the temperature, with the degree of slumping being dependent on the composition. A similar cone shaped object is made from the material to be measured and heated along with standard Seger cones. After the conclusion of the heating cycle, the sample material is compared to the Seger cones to gain a comparative measure of its refractoriness. However, it should be noted that when a material is subject to a mechanical load, it may well soften at well below the temperature indicated by the Seger cone test.

A series of substances having different fusion temperatures might serve roughly to measure the temperature of high-temperature regions such as furnaces, since, with a series of substances having progressively increasing fusing temperatures, the temperature naturally lies between the fusion temperature of the last substance fused, and that of the next not yet fused. A series of artificially prepared mixtures, mostly of the oxides such as clays, lime, feldspar, have been designed to form a series of "Seger cones." There are 60 mixtures covering a temperature range from 590° to 2,000 °C (1,094° to 3,632 °F).

SEICHE. 1. A standing wave oscillation of an enclosed water body that continues, pendulum fashion, after the cessation of the originating force, which may have been either seismic or atmospheric.

2. An oscillation of a fluid body in response to a disturbing force having the same frequency as the natural frequency of the fluid system. Tides are now considered to be seiches induced primarily by the periodic forces caused by the sun and moon.

3. In the Great Lakes area, any sudden rise in the water of a harbor or a lake, whether or not it is oscillatory. Although inaccurate in a strict sense, this usage is well established in the Great Lakes area. See also **Estuary**.

SEISMIC SEA WAVE. See **Tsunami**.

SEISMOGRAPH. An instrument used to measure and record earthquake vibrations and other earth tremors. It consists essentially of a heavy pendulum hung so that it can swing freely in one direction. A pen is attached to the end of the pendulum so that the pendulum's motion, relative to a recorder fixed solidly to the earth, may be determined. A seismological observatory requires three seismographs in order to measure the three component directions of the tremors and to fix approximately their origin. A study of the records of sensitive seismographs has shown that some of the tremors may be attributed to oceanographic and atmospheric phenomena. See also **Earth Tectonics and Earthquakes**.

SEISMOLOGY. See **Earth Tectonics and Earthquakes**.

SEISTAN. See **Winds and Air Movement**.

SEIZURE (Neurological). Epilepsy is characterized by sudden, brief disturbances in brain function. A clinical seizure may be defined as one resulting from the excessive discharge of aggregates of neurons, which in some manner become depolarized in a synchronous fashion. Epilepsy is not a disease in the usual sense, but rather it is a disorder, the root causes of which remain poorly understood. Some researchers have suggested that the paroxysmal depolarization of neurons may derive from abnormalities of neuronal membranes, disturbances in synaptic transmission, or defective functioning of glial cells. The causative factors will probably be revealed when there is a better understanding of the fundamental biochemistry and bioelectronics of the brain and the nervous system. Epilepsy may be divided into two broad categories: (1) *idiopathic epilepsy*, where there is no known organic injury to the brain prior to the first seizure; and (2) *symptomatic epilepsy*, where such damage has been confirmed. The genetics of seizure disorders (epilepsy) are poorly understood and difficult to research because of the probable large number of causative factors and, from a statistical standpoint, because of the prevalence of the disorder. It is estimated that a minimum of 0.5% of the population suffer from recurrent seizures. This, in a country of the size of the United States, translates into 1 million persons. It is generally concluded that the close relatives of persons with idiopathic epilepsy may experience a seizure incidence rate of three times that of the general population. Of course, where seizures are the result of injury (accidents to the brain and spine during and after birth — at any time of life), genetic factors do not enter.

Even though there is a poor understanding of the biochemistry and mechanics which precipitate seizures, over the years very effective treatment regimens have been developed empirically.

Types of Seizures

Some authorities have classified seizures on the basis of symptoms as follows:

Generalized Seizures
- Grand Mal (*tonic-clonic*)
- Petit Mal

Drop Attack (*akinetic*)
Myoclonic
Partial Seizures
Psychomotor
Focal Cortical
Continual (continuing *status epilepticus*)

The treatment, including the drugs of choice, varies from one type to the next.

Grand Mal Epilepsy. In this type of seizure, the patient may feel unusually good or poor for a day or two prior to the attack. This vague state warns the patient of an impending attack. It is peculiar to the individual and identical in different attacks. There may be queer sensations in some part of the body. Flashes of light or color may be seen, strange sounds may be heard, and pleasant or disturbing emotions may be experienced. Consciousness is swiftly lost, often with a wild, harsh cry. Breathing stops; the legs and body stiffen; and the patient falls to the ground, the elbows bent at rigid right angles. During this part of the spasm, which lasts from 10 to 30 seconds, the bladder or bowel, or both, may empty. The face becomes blue as the features contort, and the patient seems about to die when the spasm breaks. Rhythmic muscular contractions, at first small and rapid, begin and then become slower and more powerful. Gasps for breath come through heavy froth, often blood-stained from a bitten tongue or cheek. The contractions become less and less frequent. This phase usually lasts 2 to 3 minutes, but may persist longer. At the end, the patient may sleep heavily for several hours or rouse with aimless, thrashing movements, dazed and forgetful and unable to understand what is said to him. There is often a severe headache for several hours. Occasionally, the patient may have one convulsion after another without regaining consciousness. The dangerous state is called *status epilepticus* and demands immediate attention by the physician, since it can result in death from exhaustion.

In summary, the clinical features of grand mal are generalized major motor convulsions with a loss of consciousness and a depression of cerebral function.

Petit Mal. In petit mal attacks, a milder form of epilepsy, the loss of consciousness is fleeting and variable — from 1 to 40 to 50 times per day. It may be so short that it goes unnoticed. The head may nod momentarily, the flow of speech may halt a second or two and then may be normally resumed; or perhaps only a vacant stare marks the attack. Sometimes there are one or two contractions of the arms flickering of the eyelids. In petit mal, an electroencephalogram a spike-and-wave pattern, which occurs at the rate of 3 per second.

Drop Attack. In this type of attack, there is a brief loss of consciousness and loss of muscle tone.

Myoclonic Type. The clinical features include isolated muscle jerks, which may be precipitated by various sensory stimuli. This condition is frequently associated with degenerative and metabolic brain disease.

Psychomotor Epilepsy. This manifestation may follow grand or petit mal seizures or occur independently. These attacks last from a few minutes to a day or two. The patient may remember nothing of the episode on recovery. The behavior is confused and unusual. There may be uncontrollable emotional outbursts, which may be violently destructive, or the patient may be dazed and apathetic. There is also evidence that some psychomotor cases may be the result of subtle injury to the brain at the time of birth. In this state, there is some impairment of consciousness.

Focal Seizures. Also known as Jacksonian epilepsy, these seizures assume two forms. There may be unusual sensations or uncontrolled movements remaining localized to one part of the body, while consciousness is undisturbed. Thus, the head and eyes may turn irresistibly to one side despite the patient's awareness. In the other form, the movements or sensations which begin in one part of the body may spread upward in a slow, orderly fashion, or they may cross to the other side. This form may develop into a typical grand mal attack with loss of consciousness. Many convulsive seizures resulting from brain injury are of the Jacksonian type.

Continual Seizures. There is incomplete recovery between attacks, which may be generalized or partial. Drugs of choice in treatment include phenytoin and phenobarbital. Patients are treated for *status epilepticus*. This condition is considered a medical emergency and invariably results in death when not treated. Factors which the physician and other emergency personnel must consider include: (1) measures for ensuring an unblocked airway and measures for ensuring adequate fluids, such as intravenous infusion with 5% dextrose; and (2) administration of drug of choice.

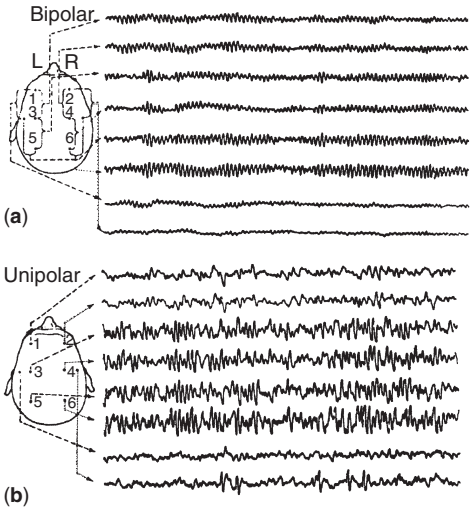

Fig. 1. Electroencephalograms. (**a**) Normal adult, showing the low amplitude of the tracings that are obtained from electrodes variously placed on the head. (**b**) A 4-year-old child suffering from a convulsive disorder, showing high-amplitude waves, in marked contrast to those of the normal individual. (*Photography by F.W. Schmidth.*)

Electroencephalographic tracings can be of considerable value in the assessment of various seizure disorders. See Fig. 1. See also **Central and Peripheral Nervous Systems**.

SELACHII. See **Sharks**.

SELECTION RULES (Energy Levels). It was found early in the study of atomic spectra that radiative transitions between certain pairs of energy levels seldom or never occur. A set of rules which are expressed in terms of the differences of the quantum numbers of the two states involved allow a prediction of allowed transitions and forbidden transitions. The conditions for allowed transitions are:

$$\Delta L \text{ (orbital angular momentum)} = \pm 1$$

$$\Delta J \text{ (total angular momentum)} = 0 \text{ or } \pm 1$$

$$\Delta M \text{ (magnetic orientation)} = 0 \text{ or } \pm 1$$

The selection rules are not rigorously obeyed. In atoms that do not exhibit Russell-Saunders coupling, the quantum numbers L and S are not defined.

Even in atoms that do have this type of coupling, forbidden transitions are merely of lower probability than allowed ones, and they may occur from a state from which no transitions are allowed by the rules, if conditions are such that collisions of the second kind do not remove the atom from the initial state before it radiates (e.g., at extremely low pressures).

Similar selection rules hold for molecular spectra. In fact, let ψ_i and ψ_j be wave functions for two levels in any quantum mechanical system. Then if P is the appropriate operator, a transition between levels i and j is permitted if the matrix element

$$\int \psi_i^* P \psi_j \, d\tau$$

does not vanish. Here ψ_i^* is the complex conjugate of ψ_i, $d\tau$ is a volume element including all of the variables involved in the two wave functions, and the operator may refer to electric or magnetic dipole radiation, quadrupole radiation, polarizability, etc. If the integral vanishes, the transition is forbidden. Frequently, symmetry properties and group theory may be used to determine whether the matrix element does or does not vanish. This is very helpful since evaluation of the integral itself may be difficult or impossible.

SELECTION RULES (Nuclear). A set of statements that serves to classify transitions of a given type (emission or absorption of radiation, beta decay, and so forth) in terms of the spin and parity (I and π) quantum numbers of the initial and final states of the systems involved in the transitions, in such a way that transitions of a given order of inherent probability (after making allowance for the influence of varying energy, charge and size of system, and so forth) are grouped together. The group having highest probability of taking place per unit time is said to consist of allowed transitions; all others are called forbidden transitions. Table 1 lists the selection rules for radiative transitions: each entry gives the character (E = electric, M = magnetic) and the multipole order (1 for dipole, 2 for quadrupole, 3 for octopole, ...) of the predominant radiation mechanism for the indicated spin change ΔI and parity change $\Delta\pi$; the entry "none" means that radiative transitions are strictly forbidden.

TABLE 1. SELECTIVE RULES FOR RADIATIVE TRANSITIONS

	ΔI						
$\Delta\pi$	0 $I = 0$	0 $I \neq 0$	1	2	3	4	5
No	None	$M1$	$M1$	$E2$	$M3$	$E4$	$M5$
Yes	None	$E1$	$E1$	$M2$	$E3$	$M4$	$E5$

Fermi selection rules and Gamow-Teller (GT) selection rules are alternative sets of rules for allowed beta transitions; both are currently believed to be valid, so that a transition allowed according to either set is actually allowed.

TABLE 2. SELECTION RULES FOR BETA DECAY

	ΔI						
$\Delta\pi$	0	1	2	3	4	5	6
No	A	A	II	II	IV	IV	VI
Yes	I	I	I	III	III	V	V

Table 2 lists the selection rules for beta decay: the entry A means that for the indicated spin and parity change the transition is allowed; I, means that it is first forbidden; II, second forbidden ...

SELECTIVE CHOPPER RADIOMETER (SCR). See **Nimbus Satellite Program**.

SELENIUM. [CAS: 7782-49-2]. Chemical element, symbol Se, at no. 34, at. wt. 78.96, periodic table group 16, mp 217 °C (423 °F), bp 685 °C (1,265 °F), density 4.82 g/cm^3 (solid), 4.86 (single crystal). Selenium has a large number of allotropes, some of which have not been fully investigated. On heating selenium above its melting point and cooling it, a red vitreous mass is formed, probably a mixture of allotropes. A red, amorphous allotrope is precipitated by sulfur dioxide [CAS: 7446-09-5] SO_2 from selenous acid [CAS: 7783-00-8] H_2O_3Se solutions. On heating at above 150 °C (302 °F), the red vitreous form changes to a gray hexagonal form, the stable form at ordinary temperatures, with metallic properties, one of which is photo-conductivity. By evaporation of a carbon disulfide [CAS: 75-15-0] CS_2 solution of the red vitreous form below 72 °C (162 °F), a red α-monoclinic form is obtained; evaporation above 72 °C (162 °F) gives β-monoclinic selenium. Black hexagonal selenium, believed to have a ring structure, is produced by heating amorphous selenium to near its melting point. Unlike sulfur, liquid selenium apparently has only one form.

There are six natural occurring isotopes: ^{74}Se, ^{76}Se through ^{78}Se, ^{80}Se, and ^{82}Se, and seven known radioactive isotopes ^{72}Se, ^{73}Se, ^{75}Se, ^{79}Se, ^{81}Se, ^{83}Se, and ^{84}Se. With exception of ^{79}Se which has a half-life of something less than 6×10^4 years, the half-lives of the other isotopes are comparatively short, measured in minutes, hours, or days. In terms of abundance, selenium ranks 34th among the elements occurring in the earth's crust. It is estimated that a cubic mile of seawater contains about 14 tons (3 metric tons per cubic kilometer) of selenium. First ionization potential 9.75 eV; second 21.3 eV; third, 33.9 eV; fourth, 42.72 eV; fifth, 72.8 eV. Oxidation potentials $H_2Se(aq) \rightarrow Se + 2H^+ + 2e^-$, 0.36 V; $Se + 3H_2O \rightarrow H_2SeO_3 + 4H^+ + 4e^-$, −.740 V; $H_2SeO_3 + H_2O \rightarrow SeO_4^{2-} + 4H^+ + 2e^-$, −1.15 V; $Se^{2-} \rightarrow Se + 2e^-$, 0.78 V; $Se + 6OH^- \rightarrow SeO_3^{2-} + 3H_2O + 4e^-$, 0.36 V; $SeO_3^{2-} + 2OH^- \rightarrow SeO_4^{2-} + H_2O + 2e^-$, −0.03 V. Other important physical properties of selenium are given under **Chemical Elements**.

Selenium was first identified by the Swedish chemist Jons Jacob Berzelius (Stockholm, Sweden) in 1817. The element is found associated with volcanic activity, as for example in cavities of Vesuvian lavas and in the volcanic tuff of Wyoming (about 150 parts per million). See also **Chemical Elements: The History of the Origin**.

Selenium occurs as selenide in many sulfide ores, especially those of copper [CAS: 22205-45-4] Cu_2S, silver [CAS: 21548-73-2] Ag_2S, lead [CAS: 1314-87-0] PbS, and iron [CAS: 1317-37-9] FeS, and is obtained as a by-product from the anode mud of copper refineries. The mud is (1) fused with sodium nitrate [CAS: 7631-99-4] and silica [CAS: 7631-86-9], or (2) oxidized with nitric acid [CAS: 7697-37-2] HNO_3, and the water [CAS: 7732-18-5] H_2O extract is then treated with hydrochloric acid [CAS: 7647-01-0] HCl and SO_2, whereupon free selenium is separated.

Uses. Selenium is widely used in photoelectric cells. The element alters its electrical resistance upon exposure to light. The response is proportional to the square root of incident energy. Selenium cells are most sensitive in the red portion of the spectrum. Although an external emf must be applied, the resistance is low and amplification is easy. In the selenium photovoltaic cell configuration, a thin film of vitreous or metallic selenium is coated onto a metal surface. Then, a transparent film of another metal, often platinum, is placed over the selenium. A cell of this type generates its own emf, with a decrease in internal resistance with increasing irradiation. The response essentially is proportional to incident energy. The cells are not importantly sensitive to small temperature changes.

Advantage of the unipolar conduction characteristic of selenium is taken in arc rectifiers. In a typical unit, a nickel or nickel-plated steel or an aluminum disk with a thin layer of selenium applied to one side is used. Selenium also is added to copper alloys and to stainless steel to increase machinability. Advantages claimed for selenium copper are high machinability, combined with hot-working properties and high electrical conductivity. As a decolorizer in glass, selenium counteracts green shades arising from ferrous ingredients. Sodium selenite [CAS: 10102-18-8] Na_2O_3Se is used in the production of red enamels and in the manufacture of clear red glass. Addition of from 1 to 3% selenium to vulcanized rubber increases abrasion resistance. The element also is used in photographic and printing reproduction chemicals.

Selenium is also used as an additive to lead-antimony battery grid metal and as a vulcanizing agent to improve temperature and abrasion resistance of rubber.

Chemistry and Compounds. Due to its $4s^2 4p^4$ electron configuration, selenium, like sulfur, forms many divalent compounds with two covalent bonds and two lone pairs, and *d* hybridization is quite common, to form compounds with Se oxidation states of 4+ and 6+.

While selenium dioxide, [CAS: 7446-08-4] SeO_2, can be produced by direct reaction of the element with oxygen activated by passage through HNO_3, the compound is easily made by heating selenious acid, H_2SeO_3. Selenium dioxide sublimes at 315–317 °C (599–603 °F), and is readily reduced by SO_2 to elemental selenium. Selenium trioxide, [CAS: 13768-86-0] SeO_3, is not prepared from the dioxide by oxidation, although selenium does react with oxygen to form SeO_3 and SeO_2 in an electric discharge. Preferred method of preparing SeO_3 is by refluxing potassium selenate [CAS: 7790-59-2] K_2O_4Se with sulfur trioxide [CAS: 7446-11-9] O_3S. The reverse reaction, hydration of SeO_3 to selenic acid, CAS: 7783-08-6, H_2SeO_4, occurs easily. Selenous acid, H_2SeO_3, produced by hydration of SeO_2, is a stronger oxidizing agent than sulfurous acid as judged by its quantitative oxidation of iodide ion in acid solution, but is a weaker acid (ionization constants 2.4×10^{-3} and 4.8×10^{-9} at 25 °C (77 °F). It forms salts, the selenites, many of which, especially those of the heavy metals, are reduced to selenides by hydrazine. Many of the selenites, e.g., those of nickel, mercury, and ferric ion, are very slightly soluble in H_2O. Selenous acid is readily oxidized by halogens in the presence of silver ion or 30% hydrogen peroxide [CAS: 7722-84-1] H_2O_2 to selenic acid, H_2SeO_4. Selenic acid is as strong an acid as H_2SO_4, and it is more readily reduced, reacting with hydrobromic acid [CAS: 10035-10-6] BrH and hydriodic acid [CAS: 10034-85-2] HI to form selenous acid or (at high concentration) elemental selenium. Like sulfate ion, SO_4^{2-}, SeO_4^{2-} is tetrahedral in crystals.

Hydrogen selenide, [CAS: 7783-07-5] H_2Se, is a stronger acid than H_2S (ionization constants of H_2Se, 1.88×10^{-4} and about 10^{-10}) and is less readily obtained from selenides than H_2S from sulfides (the selenides of aluminum, iron and magnesium, Al_2Se_3 [CAS: 1302-82-5], FeSe [CAS: 1310-32-3], and MgSe [CAS: 1313-04-8], require heating with H_2O or dilute acids). In general, the metal selenides are prepared by direct combination of the elements. Those of transition groups 3–8, 1 and 2 and main groups 3 and 4 exhibit many instances of well-defined compounds, berthollide compounds, and substitutional solid solutions. Thus, four intermediate phases are found in the palladium-selenium system, Pd_4Se, $Pd_{2.8}Se$, $Pd_{1.1}Se$, and $PdSe_2$ [CAS: 60672-19-7].

Selenium hexafluoride, [CAS: 7783-79-1] SeF_6, the only clearly defined hexahalide, is formed by reaction of fluorine with molten selenium. It is more reactive than the corresponding sulfur compound, sulfur hexafluoride [CAS: 2551-62-4] SF_6, undergoing slow hydrolysis. Selenium forms tetrahalides with fluorine, chlorine, and bromine, and dihalides with chlorine and bromine. However, other halides can be found in complexes, e.g., treatment of the pyridine complex of selenium tetrafluoride SeF_4 [CAS: 13465-66-2] in ether solution with HBr yields $(py)_2SeBr_6$. Selenium tetrafluoride also forms complexes with metal fluorides, giving $MSeF_5$ complexes with the alkali metals.

Selenium forms several oxyhalides, e.g., $SeOF_2$, selenium oxychloride [CAS: 7791-23-3] $SeOCl_2$, and selenium oxybromide [CAS: 7789-51-7] $SeOBr_2$, the first two being liquids and the last a crystalline solid, mp 41.6 °C (107 °F). Selenium also forms tetraselenium tetranitride, Se_4N_4 [CAS: 12033-88-4].

Selenocyanates, M^ISeCN, corresponding to the thiocyanates, are prepared by addition of selenium to soluble cyanides. They are similar to the thiocyanates except that HSeCN immediately decomposes in acid to selenium and hydrogen cyanide. The heavy metal selenocyanates are less soluble than the corresponding thiocyanates.

Selenium forms "thio"-type compounds, such as $SeSO_3$ by reaction of selenium and sulfur trioxide, $SeSO_3^{2-}$ (selenosulfates) by reaction of selenium and sulfites, SeS^{2-} (selenosulfides) by reaction of selenium with sulfides, as well as diselenides, Se_2^{2-}, and polyselenides, Se_x^{2-}.

Carbon diselenide is an evil-smelling liquid, and COSe carbonyl selenide [CAS: 1603-84-5] and CSSe thiocarbonyl selenide [CAS: 5951-19-9] are also known.

Biological Role of Selenium. Some very interesting examples of the effect of soils on the nutritional quality of plants are associated with selenium. The element has not been found to be required by plants, but it is required in very small amounts by warm-blooded animals and probably by humans. However, selenium in larger quantities can be very toxic to animals and humans.

In large areas of the world, the soils contain very little selenium in forms that can be taken up by plants. Crops produced in these areas are, therefore, very low in selenium. A selenium deficiency in livestock is a serious problem. A deficiency causes a form of muscular dystrophy in younger animals and poor reproductive qualities in the adult animals. For prevention, sodium selenate or sodium selenite, sometimes augmented with vitamin E, is added in proper proportions to feedstuffs. Some areas, including the Plains and Rocky Mountain states in the United States have soils that are rich in available selenium. In regions like these, selenium toxicity is a problem. The situation is particularly serious in Arizona, California, Montana, Nevada, New Mexico, and South Dakota.

An interesting feature of selenium is that it occurs naturally in several compounds and these vary greatly in their toxicity and in their value in preventing selenium-deficiency diseases. In its elemental form, selenium is essentially insoluble and biologically inactive. Inorganic selenates or selenites and some of the selenoamino acids in plants are very active biologically, whereas some of their metabolites that are excreted by animals are not biologically active. In well-drained alkaline soils, selenium tends to be oxidized to selenates and these are readily taken up by plants, even to levels that may be toxic to the animals that eat them. In acid and neutral soils, selenium tends to form selenites and these are insoluble and unavailable to plants. Selenium deficiency in livestock is most often found in areas with acid soils and especially soils formed from rocks low in selenium.

In 1934, the mysterious livestock maladies on certain farms and ranches of the Plains and Rocky Mountain states were discovered to be due to plants with so much selenium that they were poisoning grazing animals. Affected animals had sore feet and lost some of their hair; many died. Over the next 20 years, researchers found that the high levels of selenium occurred only in soils derived from certain geological formations of high selenium content. They also found that a group of plants, called *selenium accumulators*, had an extraordinary ability to extract selenium from the soil. These accumulators were mainly shrubs or weeds native to semiarid and desert range lands. They usually contained about 50 parts per million (ppm) or more of selenium, whereas range grasses and field crops growing nearby contained less than 5 ppm selenium. These findings helped ranchers to avoid the most dangerous areas when grazing livestock.

In 1957, selenium was found to be essential in preventing liver degeneration of laboratory rats. Since then, research workers have found that certain selenium compounds, either added to the diet or injected into the animal, would prevent some serious disease of lambs, calves, and chicks. That selenium is an essential nutrient element for birds and animals has been established.

In most diets used in livestock production, from 0.04 to 0.10 ppm of selenium protects the animal from deficiency diseases. If the diet is very high in vitamin E, the required level of selenium may be lower.

In terms of human dietary requirements, much of the wheat for bread-making in the United States is produced in selenium-adequate sections of the country. Bread is generally a good source of dietary selenium.

Selenomethionine decomposes lipid peroxides and inhibits in vivo lipid peroxidation in tissues of vitamin-E-deficient chicks. Selenocystine catalyzes the decomposition of organic hydroperoxides. Selenoproteins show a high degree of inhibition of lipid peroxidation in livers of sheep, chickens, and rats. Thus, some forms of selenium exhibit in vivo antioxidant behavior.

Health and Safety Factors. Commercial elemental selenium along with the stable metallic selenides are considered relatively nontoxic. However, other selenium compounds which include the reactive selenides; the gaseous, volatile, and soluble compounds; and particularly hydrogen selenide, the halides, oxides, and the organics are highly toxic and must

be handled with care. Selenium can enter the body through inhalation, ingestion, or absorption through the skin where it accumulates primarily in the liver and kidney. Symptoms of selenium poisoning include bronchial irritation, gastrointestinal distress, nasopharyngeal irritation, and garlic on the breath.

Selenium plays a dual role in a living organism, depending on the compound and the amount adsorbed. Controlled small doses of some compounds are used in medicine and as diet supplements, for example, ca 0.1 ppm of diet dry matter for livestock. Larger amounts can be toxic.

SELENOGRAPHIC. 1. Of or pertaining to the physical geography of the moon.

2. Specifically, referring to positions on the moon measured in latitude from the moon's equator and in longitude from a reference meridian.

SELENOLOGY. That branch of astronomy that treats of the moon, its magnitude, motion, constitution, and the like. *Selene* is Greek for *moon*.

SELF-DIAGNOSTICS. A term commonly used in the sensors, instrumentation, process control, and computer field to designate separate circuitry and instructions (self-contained) to test and sometimes recalibrate an electronic measurement and supervisory piece of equipment.

SELF-ENERGY (Particle). Classically, the energy of interaction between different parts of the particle (considered, for example, as a ball of charge). In quantized field theory (see also **Field Theory**) the contribution to the Hamiltonian arising from the virtual emission and absorption of other particles, especially photons or mesons. In terms of mass-energy equivalence, the energy equivalent of the rest mass of the particle.

SELF-INDUCTANCE. The ratio of the magnetic flux linking a circuit to the flux-producing current in that circuit.

SELF-OPERATED CONTROLLER. Often termed a *regulator*, a self-operated controller requires no external power for automatically controlling a variable, notably pressure, temperature, liquid level, or flow. Some of the styles of self-operated controllers are: (1) *directly actuated* (DA), where the valve is positioned directly by the measuring element; (2) *pilot-actuated* (PA), where the measuring element controls a pilot valve. The latter admits supply-line pressure to a piston or diaphragm to move the main valve; (3) *self-contained* (SC), where the measuring element is an intimate part of the valve structure. This type of device responds only to variations, such as pressure, temperature, or flow, that occur in the flowing medium; and (4) *remote-sensing* (RS), where the measuring element is separated from the valve.

Usually, regulators are furnished with only a proportional control action, with the proportional band established by the manufacturer. Control accuracy obtainable with self-operated controllers is on the order of: temperature regulators, $\pm 1\,^{\circ}$F; pressure regulators, ± 0.5 psi; level regulators, $\pm 1\%$. Self-operated controllers are advantageous where control specifications can be met because of their simplicity, ease of service, general ruggedness, comparatively low cost, no need for external power (hence extra wiring or piping), and normally long useful life. Limitations include the rather coarse accuracy performance previously mentioned, allowable pressure drop through the valve, limited availability of ranges, and the usually relatively large measuring element.

With reference to Fig. 1, the direct-actuated, remote-sensing temperature regulator employs a vapor-filled thermal system. When the temperature at the bulb rises, vapor pressure in the system is increased and this, in turn, is transmitted to the bellows. When the force produced equals the adjustable spring force, further pressure increase will cause a downward movement of the stem, thus causing the valve to commence closing. The reverse process occurs, of course, upon a drop in temperature.

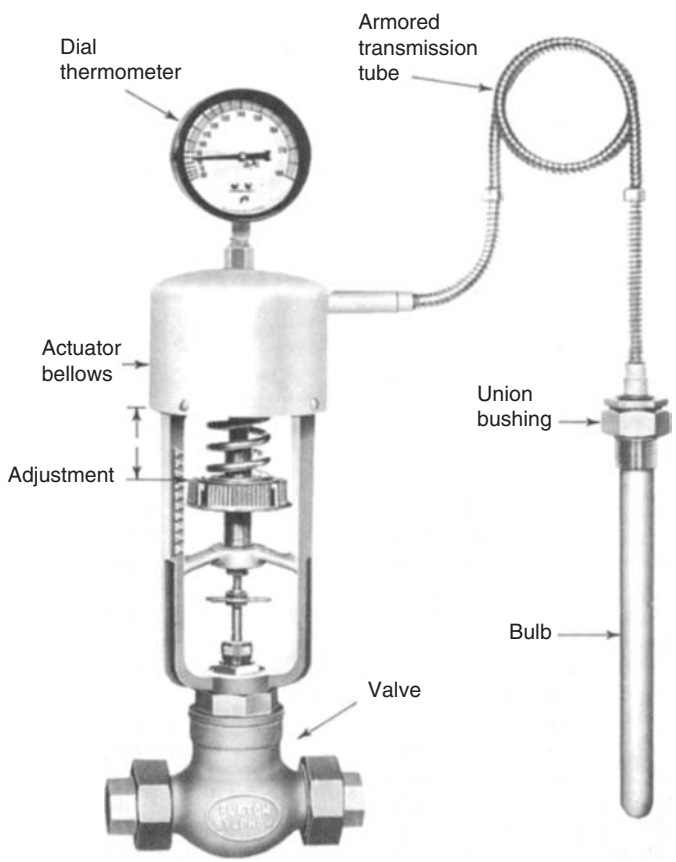

Fig. 1. Direct-actuated remote-sensing self-operated temperature controller or regulator. (*Robertshaw*.)

SELLMEIER EQUATION. An equation often used for media that show anomalous dispersion

$$n^2 = 1 + \sum \frac{A\lambda^2}{\lambda^2 - \lambda_1^2} + \frac{B\lambda^2}{\lambda^2 - \lambda_2^2} + \cdots$$

where n is the refractive index, λ the wavelength of the light, λ_1 and λ_2 are the wavelengths of absorption lines, and $A, B, \ldots$ are constants to be determined from experimental data. If the equation is expanded in a series

it becomes

$$n^2 = a + \frac{b}{\lambda^2} + \frac{c}{\lambda^4} \cdots$$

which has the same form as the Cauchy dispersion formula (but note that n occurs to the first power there).

SELSYN. (A trade name, from self-synchronous; often capitalized). An electrical remote indicating instrument operating on direct current, in which the angular position of the transmitter shaft, carrying a contact arm moving on a resistance strip, controls the pointer on the indicator dial.

SEMENOV, NIKOLAY N. (1896–1986). A Russian chemist and physicist who won the Nobel Prize in 1956 together with Sir Cyril Norman Hinshelwood for their researches into the mechanism of chemical reactions. Semenov graduated from Petrograd University in 1917 and in 1920 he took charge of the electron phenomena laboratory of the Leningrad Physico-Technical Institute. He received his doctorate at Leningrad State University.

Semyonov's outstanding work on the mechanism of chemical transformation includes an exhaustive analysis of the application of the chain theory to varied reactions (1934–1954) and, more significantly, to combustion processes. He proposed a theory of degenerate branching, which led to a better understanding of the phenomena associated with the induction periods of oxidation processes.

Semenov wrote two important books concerned with his work. *Chemical Kinetics and Chain Reactions* was published in 1934 with an English edition in 1935. It was the first book in the U.S.S.R. to develop a detailed theory of unbranched and branched chain reactions in chemistry. *Some Problems of Chemical Kinetics and Reactivity*, first published in 1954, was revised in 1958; there are also English, American, German, and Chinese editions.

SEMIARID ZONE. Aridity is a climatological condition in which the amount of precipitation received (supply) is exceeded, on average, by potential evapotranspiration (demand). A number of physically based indices have been proposed to describe this deficiency that relate precipitation to temperature and humidity. For practical purposes, in the temperate and tropical zones, semiarid climates generally receive between 200 and 500 millimeters (8 and 20 inches) of precipitation per year on average, and arid climates receive less than 200 millimeters (8 inches). However, definitions based on mean precipitation are not always satisfactory, because they do not express variability or the likelihood of drought. Rainfall in arid climates is extremely variable, with coefficients of variation for arid climates exceeding 50%, and coefficients for semiarid climates ranging between 30% and 50%. In broad economic terms, variability restricts the potential use of these lands. Arid climates are unsuitable for growing crops using rainfall alone, because crops may fail three or more years out of ten. Semiarid climates often support grasses that are suitable for grazing animals. Thus, livestock raising is often more appropriate, less risky, and more common than rainfed agriculture in semiarid areas.

SEMICARBAZONES. The products of the reaction between an aldehyde or a ketone with semicarbazide are termed *semicarbazones*.

$$\underset{\text{(acetaldehyde)}}{CH_3 \cdot CHO} + \underset{\text{(semicarbazide)}}{NH_2 \cdot CO \cdot NHNH_2} \longrightarrow \underset{\text{(acetaldehyde semicarbazone)}}{CH_3 \cdot CH : N \cdot NH \cdot CONH_2} + H_2O$$

$$\underset{\text{(acetone)}}{(CH_3)_2CO} + NH_2 \cdot CO \cdot NH \cdot NH_2 \longrightarrow \underset{\text{(acetone semicarbazone)}}{(CH_3)_2C : N \cdot NH \cdot CO \cdot NH_2} + H_2O$$

SEMICONDUCTORS: AMORPHOUS SEMICONDUCTORS. Since 1970 the subject of amorphous semiconductors, in particular silicon, has progressed from obscurity to product commercialization such as active matrix liquid-crystal displays, linear sensor arrays for facsimile machines, inexpensive solar panels, electrophotography, etc. Many other applications are at the developmental stage such as medical imaging, spatial light modulators for optical computing, and optical filters.

The success has been primarily due to the developments that occurred in the early 1970s at the University of Dundee (United Kingdom) where it was demonstrated that a device-quality amorphous silicon semiconductor (*a*-Si) could be produced with the following features: low concentration of defects, high photosensitivity, ability to be doped, and no size limitation.

There is another class of amorphous semiconductors based on chalcogens that predate the developments that have occurred in *a*-Si. Because their use has been limited, e.g., to switching types of devices and optical memories, this discussion is restricted to the optoelectronic properties of *a*-Si-based alloys and their role in some applications.

Classification

Amorphous semiconductors are solids in which the atoms retain well-defined local, or nearest neighbor, order, but lack long-range periodic order of crystalline solids, and the local bonding between atoms is characterized predominantly by covalent forces. These types of semiconductors are normally synthesized as metastable thin solid films and are to be distinguished from glass that is formed by continuous hardening of a cooled liquid. Amorphous material is a solid in internal equilibrium in which there is, just as in crystalline solids, a definite set of equilibrium positions about which the atoms oscillate. However, in contrast to crystalline solids, the amorphous materials do not exhibit translational symmetry, ie, there is no long-range order.

The tetrahedrally bonded materials, such as Si and Ge, possess only positional disorder; however, materials of this type exhibit high density of defect states (DOS). It is only with the addition of elements, such as hydrogen and/or a halogen, typically fluorine, that the DOS is reduced to a point such that electronic device applications emerge. These materials contain up to ~10 atomic % hydrogen, commonly called hydrogenated amorphous silicon (*a*-Si:H).

Growth of Amorphous Silicon

By far, the most widely studied and used deposition technique for preparing amorphous silicon is the plasma-enhanced chemical vapor deposition (PECVD) technique, which typically utilizes a capacitively coupled multichamber system, A gas, such as SiH_4, is allowed to pass at a controlled rate between the two plates and the plasma is generated using direct current (dc), audio, radio frequency (rf), or microwave frequencies. A variety of species are produced, such as atoms, free radicals, and stable and unstable ions. The mean energy of the electron is on the order of a few electron volts and electron temperature can be up to 100 times higher than that of the gas. Hence, the electrons possess enough energy to break down the molecular bonds.

The defect state density within the gap or the DOS is critically controlled by the deposition temperature, T_s, of the substrates; the DOS decreases by several orders of magnitude when T_s is raised from 300 to 570 K (80 °F to 566 °F) (27 °C to 297 °C). This change in DOS has been attributed to basic structural change from a polymeric-type (SiH_n) structure, for samples deposited at low temperature, to a monohydride (SiH) structure for higher T_s samples. The pressure of the gases during deposition also affects the properties of the film because gas-phase polymerization is encouraged at high pressures with the consequence that SiH_2 and SiH_3 grouping within the film becomes more pronounced and again DOS increases in the film.

The relative abundance of neutral SiH_4 and H_2 species have been measured as a function of power, pressure, flow rate, and dilution. For low power levels, eg, 5 W, up to 50% of the SiH_4 gas is dissociated and the percentage increases to 80% for a power of 50 W. The decomposition of SiH_4 gas proceeds more readily with lower flow rates. These observations, coupled with infrared (IR) measurements performed on the films, suggest that deposition under conditions in which the silane gas is not entirely decomposed leads to a majority of SiH units, whereas those deposited under conditions in which silane is strongly dissociated contain a majority of dihydride units leading to a deterioration of the semiconductor. Also, when the dwell time of SiH_4 in the plasma region increases, the resultant film exhibits a pronounced peak at 2090 cm^{-1} from the ir spectra corresponding to SiH_2 inclusion.

TABLE 1. REACTIONS WITHIN PLASMA DURING TRANSPORT OF SPECIES PRODUCED BY ELECTRON IMPACT DISSOCIATION OF SILANE

Reaction	Enthalpy of reaction DH, eV
SiH_4+H SiH_3+H_2	−0.5
SiH_2+SiH_4 Si_2H_6	−2.1
SiH_2+H_2 SiH_4	−2.2
SiH_3+SiH_3 Si_2H_6	−3.2
Si_2H_6 SiH_2+SiH_4	2.1
$SiH^+{}_2+SiH_4$ $SiH_3+SiH^+{}_3$	−0.04
$SiH^+{}_3+SiH_4$ $Si_2H^+{}_5H_2$	−0.12

The primary process of SiH_4 decomposition is electron impact that produces a large number of different neutral and ionic species.

Table 1 shows the predominant reactions that take place during the transport of the species produced by electron impact dissociation to the substrate.

Properties

An inclusion of an element, such as H, plays a crucial role in determining the properties of the *a*-Si:H material. This can be illustrated by considering the results of sputtered Si prepared in a reactive H environment. Figure 1 shows the effect of H on the electronic properties of *a*-Si with all the samples prepared at 200 °C (392 °F). In Fig. 1 the dark conductivity, σ_D, is plotted as a function of $10^3/T$ with hydrogen pressure. The hydrogen content of the films increases from curves A to F. With the addition of 20 atomic % H to the films, curve F, an activated behavior over several orders of magnitude in the conductivity, results that corresponds to extended state conduction above E_c. This change in the conduction behavior is due to the reduced DOS within the μ-gap.

The optoelectronic properties of the *a*-Si:H films depend on many deposition parameters, such as the pressure of the gas, flow rate, substrate temperature, power dissipation in the plasma, excitation frequency, anode–cathode distance, gas composition, and electrode configuration. Deposition conditions that are generally employed to produce device-quality hydrogenated amorphous Si (*a*-SiH) are as follows: gas composition = 100% SiH_4 or diluted in H_2; flow rate is high, ∼40 sccm; pressure is low, 26–80 Pa (200–600 mtorr); deposition temperature = 250 °C; rf power is low, <25 mW/cm^2; and the anode–cathode distance is ∼1–4 cm.

Another parameter of relevance to some device applications is the absorption characteristics of the films. Because the k quantum is no longer valid for amorphous semiconductors, *a*-Si:H exhibits a direct band gap (∼1.70 eV) in contrast to the indirect band gap nature in crystalline Si. Therefore, *a*-Si:H possesses a high absorption coefficient such that to fully absorb the visible portion of the sun's spectrum only 1 μm is required in comparison with >100μm for crystalline Si. Further improvements in the material are expected to result from a better understanding of the relationship between the processing conditions and the specific chemical reactions taking place in the plasma and at the surfaces that promote film growth.

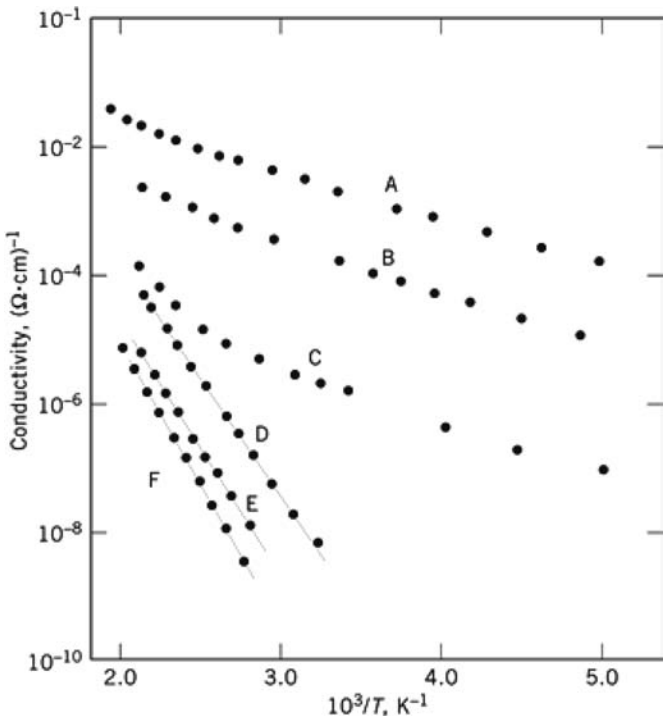

Fig. 1. Dark conductivity, σ_D, versus $10^3/T$ for sputtered *a*-Si:H samples prepared at T_s of 200 °C (392 °F) using partial hydrogen pressure between 0 and 0.13 Pa (0–1 mtorr). Hydrogen content (atomic %) and hydrogen partial pressure are as follows for each curve: A, 0 atomic (at) %; B, 1 at%, 0.002 Pa; C, 2 at%, 0.0067 Pa; D, 10 at%, 0.02 Pa; E, 15 at%, 0.05 Pa; and F, 20 at%, 0.133 Pa. To convert Pa to mtorr, multiply by 7.5.

Applications of a-Si-Based Semiconductors

Inherent disorder possessed by *a*-Si:H alloy limits the mobility of the free carriers (electrons and holes) to ∼10 cm^2/(s· V); this is compared with crystalline Si, in which the electron mobility is 1500 cm^2/(s· V). However, crystalline Si is expensive to manufacture and its size is limited to about 30 cm in diameter. Many applications discussed have either emerged or been identified which preclude the use of crystalline Si because of cost, size, or both. The basic commonality in these applications is the ability to fabricate devices on areas much larger than can be addressed by crystalline Si. Furthermore, these applications are not demanding in terms of speed, which then provides *a*-Si:H alloy with a distinct competitive advantage.

Figure 2 shows the basic construction of the devices used in different applications, involving the deposition of multilayers of *a*-Si:H of intrinsic (*i*), doped (n^+,p^+), and closely allied films, such as amorphous silicon nitride, SiN, and transparent conducting oxide (TCO). As in crystalline semiconductors, the basic building block is a junction (p–n) or thin-film transistor. Attempts to fabricate p–n junctions (using *a*-Si:H) have thus far exhibited insignificant rectification. The reason is that during the process of doping with B or P, extra defect states are introduced within the gap, which leads to an increase in the generation–recombination current, thus precluding viable rectification. Instead of this type of junction, an *i*-layer is inserted between the p^+ and n^+ layers with the charge separation occurring within the intrinsic layer; a basic requirement being that the p^+ and n^+ layers should be thick enough to sustain a depletion width.

The fact that excellent rectification can be demonstrated with p–i–n junctions, together with high photosensitivity and the ability to deposit over large areas, leads to natural usage as a solar cell. See also **Photovoltaic Cells**. The three primary parameters of a solar cell are the open-circuit voltage (V_{oc}), the short-circuit current (J_{sc}), and the fill factor (FF) with a theoretical maximum of 1.1 V, 22 mA/cm^2, and 0.8, respectively, which leads to a conversion efficiency, η, of ∼19%. The solar cell is generally constructed on a transparent conducting oxide, SnO_2.

The p–i–n junctions are also used as contact linear array image sensors in facsimile machines. An advantage is that they eliminate the need for magnification lenses that are used in conjunction with charge coupled device (CCD) sensors, constructed from crystalline Si devices. In a facsimile machine, the sensor unit consists of an illuminator, a compact optical guide, and a long photosensor array connected to the scanner. Light from the light-emitting diode (LED) arrays illuminates the document and the reflected signal is guided by the rod lens array onto the *a*-Si:H p–i–n junction photosensor array. The p–i–n junctions are constructed in a pixelized fashion with the number dictated by the resolution requirements, eg, 200 dots/in. (80 dots/cm) necessitates an excess of 1800 pixels for a page width array. The junctions are operated in reverse bias, with typical off-current of ∼10^{-13} amps, and under illumination the current rises by several orders of magnitude to excess of 10^{-9}amps. The photocurrent generated is proportional to the light intensity reaching the pixels. By operating the devices in the charge collection mode and with use of appropriate circuitry, the output of the device is proportional to light intensity. The elements are attached to read-out integrated circuits which then transmit the data to the receiver.

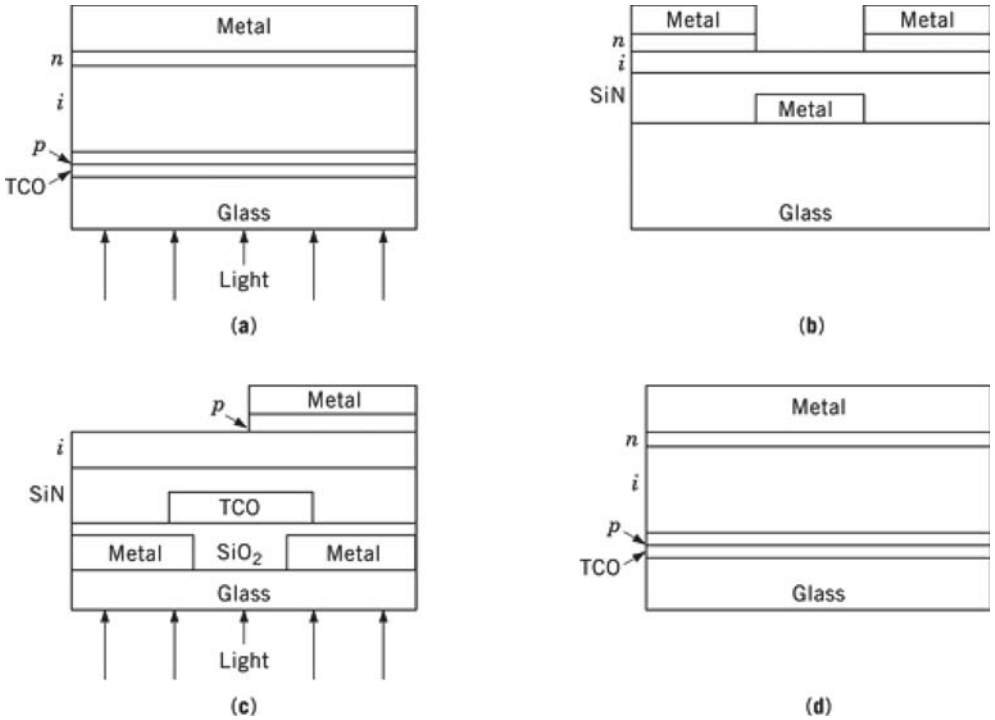

Fig. 2. Some electronic device applications using amorphous silicon: (**a**) solar cell, (**b**) thin-film transistor, (**c**) image sensor, and (**d**) nuclear particle detector. TCO = transparent conducting oxide.

In an active matrix liquid crystal (LC) display application, a single TFT for each picture element (pixel) is incorporated.

Stability of Amorphous Silicon

Stability is one of the principal issues confronting the eventual commercialization of solar cells for large-scale power applications. There has been an increasing amount of data showing that good stability can be attained in *a*-Si alloy devices. In a solar cell device configuration, the degradation is seen primarily as a decrease in the fill factor and J_{sc}, but the device can be restored to its original performance level upon annealing at 175 °C (347 °F) for 30 min. The amount of degradation is a function of the operating conditions: it is greatest at V_{oc}, reduces at J_{sc}, and is virtually eliminated under far reverse bias conditions. These observations have been associated with the so-called Staebler-Wronski effect (SW), where the application of light can significantly degrade the electronic properties of the material. Two types of states can be distinguished: a fully annealed state attained by slowly cooling the material from ∼500 K (∼440 °F) to room temperature in the dark (state A); and a light-soaked state attained after application of $\sim 10^{21}$ photons/cm^2 to the material (state B).

There have been many investigations of photoinduced effects in *a*-Si:H films linked to material parameters. Changes have been observed in the carrier diffusion length, unpaired spin density, density of states in the gap, and ir transmission. The transition from state A to B seems to be induced by any process that creates free carriers, including X-ray radiation and injection (double) from the electrodes. Because degradation in a solar cell is accentuated at the open-circuit voltage conditions, the A to B transition occurs upon recombination of excess free carriers in which the energy involved is less than the band gap. It has been pointed out that this transition is a relatively inefficient one and the increase in spin density takes place at a rate of 10^{-8} spins per absorbed photon.

The recovery from state B to A seems to be complete upon annealing, suggesting that state B is metastable and that the photoinduced defects are distinct from the defects present in state A. Various explanations for the SW effect have been put forth but no clear consensus has yet emerged. This degradation remains the major impediment for large-scale usage of amorphous silicon solar cells. The degradation under light illumination is strongly dependant on the thickness of the device used and can be circumvented to a certain extant by the use of multijunction (MJ) devices at the expense of complexity in fabrication. As discussed above, there are several thin cells stacked on top of each other with differing band gaps to absorb a wider portion of the solar spectra (such as *a*-SiH/*a*-SiGeH/*a*-SiGeH). Since they are constructed in a two terminal (2-T) device structure, the band gap and thickness of the active layers are adjusted to yield the same current from each constituent cell. This structure necessitates the use of relatively thick *a*-Si:H junctions (∼2500 A), and hence the device exhibits degradation of (∼20%) within the first 1000 h, with primary degradation occurring in <100 h. It should be noted that in the fabrication of the narrow band gap material, such as *a*-SiGe:H, GeH_4 gas is required that is prohibitively expensive. Further as the gas utilization is normally <10%, the cost goals are difficult to meet. Hence, the use of 2-T tandem solar cell with a micro- (or nano) crystalline Si (nc-Si:H) i-layer in the bottom cell and an *a*-Si:H i-layer in the top cell shows a promising technique in terms of providing an increased spectral response over a wide spectral wavelength range. Such solar cells (termed as "micromorph" solar cells) can produce an initial AM1.5 conversion efficiency of ∼13% in small area and ∼12% in large area modules. However, these micromorph solar cells also contain a relatively thick (∼4000 A) *a*-Si:H layers junction (top cell) due to the current matching constraint from the bottom *nc*-SiH device. As a result, majority of the power (∼70%) results from the unstable thick *a*-Si:H portion. This structure also experiences a significant degradation under light illumination. To circumvent the instability problems in a 2-T MJ device structure, another proposal is the use of a much simpler 4 terminal (4-T) thin-film silicon based MJ solar cell configuration, in which the current matching constraint is released from each constituent cell.

SEMICONDUCTORS: COMPOUND SEMICONDUCTORS. In the most general sense, the term compound semiconductor encompasses a large number of materials, most of which crystallize in either the zincblende (cubic), wurtzite (hexagonal), or rock salt (cubic) crystal structures. Prototypes of these structures are GaAs, CdS, and PbS, respectively. More exotic examples of zincblende semiconductors are $ZnSiP_2$ and Ga_2Se_3. The latter crystal is a defect zincblende structure in which one-third of the Ga sites are structural vacancies. Groups 13 and 15 (III–V) and (2, 12) and 16 (II–VI) compounds which crystallize in the zincblende structure are of significant value for electronic and photonic device applications. The III–V nitrides, AlN, GaN, and InN, crystallize in the wurtzite structure and are being developed for blue light-emitting devices and high temperature and high power electronics. The Group (2, 12) and 14 (II–VI) compounds are of value primarily for photonic applications. Blue lasers have been created from ZnMgSSe alloy heterostructures. The HgCdTe alloy system has been extensively studied for infrared photovoltaic detectors. CdTe has a band gap of 1.49 eV, whereas HgTe is a semimetal. Consequently, the band gap of the alloy may be varied smoothly from over 1 eV to zero. Another interesting class of materials are the dilute magnetic semiconductors. The transition-metal Mn, with a half-filled d shell ($3d^5$), may be readily alloyed with all of the simple II–VI semiconductors. These materials have applications in flat-panel displays and are projected to apply to mid-infrared detectors and nonreciprocal optical devices (isolators and circulators). The Group 14–16 (IV–VI) lead salt crystals have a unique niche in mid-infrared detectors and lasers.

Physical Properties

The defining characteristic of a semiconductor is that there is a gap between the completely filled valence states and the lowest excited or conduction states of the crystal which is typically <2.5 eV. The primary advantage of a direct gap semiconductor is its ability to strongly absorb and emit light at the fundamental band gap. The secondary advantage is that a small isotropic electron-effective mass is typically associated with the Γ_c minimum. The effective mass of an electron or hole in a crystal is inversely proportional to the curvature of the band in which it resides. In all zincblende semiconductors the effective mass at Γ_c is nearly isotropic and universally less than the average of the anisotropic mass associated with either the L or X minima. It is also approximately proportional to the magnitude of the band gap. In GaAs the electron effective mass is $0.067\ m_0$ where m_0 is the free-electron mass. This may be compared to the electron conductivity effective mass of Si which is $0.260\ m_0$. For low electric fields the steeper slope for GaAs implies an electron mobility roughly six times greater than in Si. This implies shorter switching transients at lower voltages in field-effect transistors (FETs). At high electric fields, electron transport in GaAs is limited by carrier scattering into the low mobility L minima and much of the speed advantage is lost. However, because the saturated velocity is obtained at much lower fields there is an advantage that GaAs FETs can operate at the same speed as a Si FET while consuming less power. This is significant for high density integrated circuits.

The tertiary advantage of compound semiconductors is the ability to fabricate multilayer structures epitaxially, widely varying the material properties such as band gap and refractive index from layer to layer. Within the constraint that the lattice constants are well matched it is usually possible to grow heterostructures of different III–V and II–VI semiconductors with atomically abrupt interfaces and monolayer thickness control. With some intermixing at the interfaces it is also possible to grow lattice matched heterostructures between elemental, III–V, and II–VI semiconductors. The possible combinations are essentially infinite and combining different alloy layers of variable electronic and optical properties allows for the design of a wide variety of complex devices, many of which are explicitly designed to exploit quantum size effects. The prevalent growth technologies are metal organic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE). In MOCVD, deposition takes place on a heated substrate with the constituent elements transported as alkyls, in a hydrogen carrier gas, and hydrides. In MBE, deposition occurs in an ultrahigh vacuum by evaporating elemental beams from pyrolytic boron nitride crucibles that are resistively heated. Other commercial crystal growth technologies which are less flexible than MOCVD and MBE are hydride vapor-phase epitaxy (VPE) and liquid-phase epitaxy (LPE). These techniques are limited either in the specific materials which can be grown, in their ability to grow thin layers with abrupt junctions, or both.

In the design of heteroepitaxial layers, which are not lattice matched, the elastic constants of the layers are essential to the calculation of the thermodynamically stable maximum layer thickness for elastic deformation as well as the shape of the deformed unit cell. In most cases the ⟨001⟩ surface is the preferred surface for crystal growth. In this case the deformation is purely tetragonal and expressions for the critical layer thickness and the dimensions of the unit cell are readily obtained. For growth on substrates with an arbitrary surface orientation the results are more difficult to obtain. An interesting case of lattice mismatched epitaxy is the case of a strained layer superlattice in which elastically deformed layers under compressive stress alternate with layers under tensile stress. By designing the magnitude of the tensile and compressive stresses to be equal, strained layer superlattices of arbitrary thickness may be grown with zero net stress which are stable against plastic relaxation.

Along with the lattice constant the congruent sublimation temperature is a useful guide as to which pseudobinary alloys, $(AC)_x(BC)_{1-x}$ or $(AC)_y(AD)_{1-y}$, may be easily grown. Similar arguments apply to pseudoternary and pseudoquaternary alloys. When the lattice constants of the end-point binaries are closely matched the alloy is easily obtained for all mole fractions. Large lattice mismatches typically imply a miscibility gap in the alloy phase diagram. A large difference in the congruent evaporation temperatures also implies difficulty in growing high quality material.

This advantage over indirect semiconductors, including Si, diminishes as improvements in processing technology continue to shrink device dimensions.

An extensive compilation of the properties of compound semiconductors may be found in the Landolt-Börnstein reference books. Various subvolumes in the series cover the properties of elemental, III–V, II–V, and other less common semiconductors. Information may also be found concerning semiconductor technology. Another useful source of information is the EMIS data review series. These books describe the properties and technology of GaAs, HgCdTe, InP, AlGaAs, InGaAs, and the III–V nitride compounds.

Metal Organic Chemical Vapor Deposition (MOCVD)

Metal organic chemical vapor deposition (MOCVD) is a technique that has evolved since 1975 into one of the two prime growth methods for compound semiconductor devices. This is because of the capability to grow high quality, very thin layers of most III–V and II–VI semiconductors making it the most versatile of the growth methods in use. MOCVD is also referred to as organometallic vapor-phase epitaxy (OMVPE) as well as MOVPE and OMCVD. Epitaxy is the term used to describe the growth by chemical reaction of a thin layer of semiconductor on the surface of a bulk crystal (wafer) of similar or different material, where the layer has a well-defined crystalline orientation with respect to the bulk crystal. MOCVD growth typically involves decomposition in a cold wall reactor of chemical precursors, usually an organometallic Group III compound and a Group V hydride. For the growth of gallium arsenide [CAS: 1303-00-0] from trimethylgallium and arsine a typical reaction is as follows:

$$Ga(CH_3)_3 + AsH_3 \longrightarrow GaAs + 3CH_4$$

This technique has been extended to all of the important III–V semiconductors such as AlGaAs, InP, InGaAs, and InGaAsP. Semiconductors grown by MOCVD for use as lasers, solar cells, detectors, and high speed transistors are in commercial production. MOCVD is a state-of-the-art technique for preparing epitaxial layers of compound semiconductors. It is a rapidly growing area as reflected by the number of papers and attendees at the biannual international conference. Topics of interest to researchers in MOCVD include the synthesis and use of novel sources, the continued improvement of the materials' purity, understanding of the parameters that limit the sharpness of interfaces in heterostructures, the growth of quantum wires and dots, the reaction kinetics and growth mechanisms of MOCVD, ordered structures and how to control the ordering, the use of *in situ* diagnostics such as x-ray diffraction and optical reflection to control and better understand the MOCVD process, new reactor designs for multi-wafer commercial growth, and extension of the technique to the growth of nonsemiconductors such as superconducting and ferroelectric oxide films.

Chemical Vapor Deposition (CVD). Chemical vapor deposition is usually defined as a technique that involves a chemical reaction which results in the deposition of a solid on a specific surface. Growth techniques such as MOCVD, chloride or hydride vapor-phase epitaxy, and gas source molecular beam epitaxy are considered to be CVD techniques. Growth methods such as liquid-phase epitaxy, molecular beam epitaxy, and sputtering are not considered CVD techniques because they lack one or more of the criteria in the definition. CVD offers the advantages of near equilibrium growth which allows for the precise control of growth rates and improved purity. The use of CVD allows one to utilize a growth pressure from atmospheric down to very low pressures ($<1.3 \times 10^{-3}$ Pa) as well as a large variety of reactants with widely varying chemical reactivities. The capability for using materials that would decompose in the liquid or high temperature gaseous state is also an advantage of CVD. MOCVD has demonstrated very precise and reproducible control of alloy composition, layer thickness, and dopant levels. CVD techniques are generally readily scaled-up for mass production. Some disadvantages of the MOCVD technique include a large number of control variables, reactive atmospheres which can attack substrates and the growth apparatus, and the complexity of the apparatus, the mass transport, and the chemical reactions.

A complete understanding of the MOCVD process at a fundamental level would necessitate knowing the thermodynamic and kinetic parameters for all of the possible species and reactions involved.

Transport Phenomena. One significant though often overlooked kinetic aspect of MOCVD is the influence that gas flow or hydrodynamics has on mass transport and uniformity of deposition. Because of the complexity of these effects, they are not intuitive and are often overlooked in the design of an MOCVD reactor. Both simplified and complete numerical descriptions of the hydrodynamics of certain types of MOCVD reactors have been published. The three types of reactors that are commonly used in MOCVD are commonly referred to as the vertical reactor, the planetary rotation reactor, and the horizontal reactor. The overall gas flow direction is indicated in each reactor. Another type of reactor geometry used in production is the barrel reactor which can hold a large number of substrates. It is configured with a vertical flow, and the substrates are placed on the sides of a rotating substrate holder.

Heterostructures and Superlattices. Although useful devices can be made from binary compound semiconductors, such as GaAs, InP, or InSb, the explosive interest in techniques such as MOCVD and MBE came about from their growth of ternary or quaternary alloy heterostructures and superlattices. For the successful growth of alloys and heterostructures the composition and interfaces must be accurately controlled. The composition of alloys can be predicted from thermodynamics if the flow in the reactor is optimized. Otherwise, composition and growth rate variations are observed across the surface of the substrate. The surface reactions can be complex and lead to deviations from the predicted compositions. The temperature profiles and hydrodynamics of the reactor also affect the resulting composition from the effects of the transport of the reactants to the surface and the incomplete decomposition of the reactants. These effects are well illustrated by the GaAsP system where the amount of P incorporated varies dramatically with temperature due to the large difference in decomposition temperatures of arsine and phosphine.

Electronic Devices

The main advantages that compound semiconductor electronic devices hold over their silicon counterparts lie in the properties of electron transport, excellent heterojunction capabilities, and semi-insulating substrates, which can help minimize parasitic capacitances that can negatively impact device performance. The ability to integrate materials with different band gaps and electronic properties by epitaxy has made it possible to develop advanced devices in compound semiconductors. The hole transport in compound semiconductors is poorer and more similar to silicon. For this reason the majority of products and research has been in *n*-type or electron-based devices.

Some of the original applications of compound semiconductors were in the development of diodes for microwave power and oscillator applications, including impact ionization avalanche transit times (IMPATTs) and transferred electron devices (TEDs). More recently, development efforts have focused on three terminal devices including heterojunction bipolar transistors (HBTs) and field-effect transistors (FETs). Presently, HBTs and FETs are the devices of choice for analogue, microwave, and digital circuit design in compound semiconductors. Much more recently, a newer class of devices called quantum effect devices (QEDs) has been the subject of intense research. QEDs include resonant tunneling diodes (RTDs) and single-electron transistors (SETs). There is a great deal of speculation surrounding the functionality of these devices as present device geometries shrink to the <0.1 μm range, where quantum effects are expected to dominate device behavior.

Quantum-Effect Devices. As modern devices become smaller in pursuit of higher speed and lower power operation, they are entering length scales where quantum effects are expected to become important, if not dominant. Instead of trying to avoid these quantum effects in conventional devices, an alternative approach is to exploit these effects in developing new devices. Although conventional devices often improve with shrinking size, small dimensions are a requirement for the successful operation of quantum-effect devices (QEDs). This field is in its infancy with many issues to be resolved including how best to incorporate quantum effects into devices that can be used in a complete system. Because the behavior of a QED may be significantly different from conventional devices, work is also being carried out in system architecture issues, as the best way to utilize these unconventional devices is unclear. Many QED concepts have increased functionality over the basic on–off behavior of FETs or HBTs. This could allow the design of complicated systems with decreased numbers of devices thereby increasing speed and further reducing power consumption.

Electron tunneling is the basis for the resonant tunneling diode (RTD), a two-terminal device exhibiting on–off–on behavior. The RTD uses epitaxy to achieve the small dimensions necessary to control the tunneling, whereas the lateral dimensions can be >1 μm, allowing conventional lithography to be used for fabrication. Other QEDs which use a horizontal geometry, relying on ultrasmall lithography, include single-electron transistors and electron interference devices. Single-electron transistors (SETs) are devices in which the addition or subtraction of a single electron is sufficient to control the operation. There have been a number of other device technologies proposed in compound semiconductors that have yet to be proven experimentally. These include electron interference devices and a novel technology for quantum cellular automata (QCA).

Single-Electron Transistors. The greatest potential application for single-electron devices lies in digital circuits. However, a number of other applications exist, including current standards and ultrasensitive electrometers. SETs are not unique to compound semiconductors, and in fact a great deal of work has been carried out in other material systems, including Al–AlO_x–Al tunnel junctions.

The basic operating principle of a SET lies in how much energy is required to add or remove a single electron from the system.

There is another class of SETs that do not make use of the energy to add single electrons to a system. These devices use the trapping of individual electrons to modify the conductance of a more conventional FET channel. By trapping charge in polysilicon grain boundaries, these devices have been operated at room temperature with very promising electrical characteristics. This device operates on the electron's ability to electrostatically deplete the channel, not on the energy required to trap the electron.

Photonic Devices

A technology for which compound semiconductors are uniquely suited is that of photonics, which describes devices that generate, amplify, detect, propagate, transmit, or modulate light. This field therefore covers a wide range of systems, including light-emitting diodes (LEDs), lasers and optical amplifiers, detectors, waveguides such as optical fibers, lenses, and other optical components, and optical modulators. Although silicon has contributed much to photonics technology with its applicability to visible and near-infrared (ir) light detection systems, the compound semiconductors, with their wide range of primarily direct bandages, enable the realization of efficient light-emitting devices, namely laser diodes and LEDs, and extension of detector technology into the far ir region of the spectrum.

The relevance of photonics technology is best measured by its omnipresence. Semiconductor lasers, for example, are found in compact disk players, CD-ROM drives, and bar code scanners, as well as in data communication systems such as telephone systems. Compound semiconductor-based

LEDs utilized in multicolor displays, automobile indicators, and most recently in traffic lights represent an even bigger market, with approximately $1 billion in annual sales. The trend to faster and smaller systems with lower power requirements and lower loss has led toward the development of optical communication and computing systems and thus rapid technological advancement in photonics systems is expected for the future. In this section, compound semiconductor photonics technology is reviewed with a focus on three primary photonic devices: LEDs, laser diodes, and detectors.

LEDs. A light-emitting diode (LED) is a forward-biased $p-n$ junction in which the applied bias enables the recombination of electrons and holes at the junction, resulting in the emission of photons. This type of light emission resulting from the injection of charged carriers is referred to as electroluminescence. A direct band gap semiconductor is optimal for efficient light emission and thus the majority of the compound semiconductors are potential candidates for efficient LEDs.

The most simple LEDs are homojunction devices, composed of the same bulk material with n- and p-type doped regions. Greatly increased performance has been achieved with the development of heterojunction devices which combine two or more semiconductor materials of different band gaps. Different band gaps of the heterostructure enable the formation of potential wells in the junction region to better confine the electrons and holes which results in more efficient photon generation. Advances in semiconductor growth technologies such as MOCVD and MBE allow for the growth of more complex structures. In this structure, the center well of the double heterostructure LED is replaced with one or more very thin ($<$10 nm) layers which result in further improved carrier confinement as well as changes in the energy and wavelength of emission.

The fact that compound semiconductors have a wide range of band gaps has enabled the development of LEDs from the ultraviolet (UV) to the mid-IR region of the spectrum. Starting at the shorter wavelengths, GaN is a Group III–V semiconductor material which is suitable for UV and blue-based LEDs. This new technology has overwhelmed the performance of commercial SiC-based blue LEDs with an order of magnitude improvement in output efficiencies (approaching 4%) and estimated device lifetimes as high as 100,000 hours at an emission wavelength of 450 nm. Group II–VI materials based on ZnSe have also been proven to enable efficient LEDs in the blue and green regions of the spectrum, with significantly narrower spectral bandwidths than the GaN LEDs and slightly lower efficiencies. To date, the II–VI LEDs have suffered from shorter lifetimes than the GaN materials, with projected lifetimes of approximately 1000 hours. One of the most important applications for these blue LEDs is that of multicolor displays. The GaN LED is in use as the critical third component of red–blue–green (RBG) multicolor displays, the other wavelengths having been developed previously out of other material systems.

LED technology in the rest of the visible region of the spectrum is dominated by GaP, GaAsP, AlGaAs, and AlGaInP materials. Although both GaP and GaAsP are indirect gap materials, they are often doped with impurities to enhance radiative efficiency, typical examples being nitrogen-doped GaP (GaP:N), zinc and oxygen-doped GaP (GaP:Zn,O), and nitrogen-doped GaAsP (GaAsP:N). These GaP and GaAsP LEDs span the deep red (700 nm for GaP:Zn,O) to the green (555 nm for GaP). Although not extremely efficient (external quantum efficiency for 630 nm red GaAsP:N, 0.1% for 555 nm green GaP), these materials compose up to 90% of the LED market because they can be grown with the mature and cost-effective technique of liquid-phase epitaxy (LPE). AlGaAs-based LEDs are appropriate for long wavelength visible (650–700 nm) LEDs, and are used in traffic lights and car tail-lights. External quantum efficiencies of $>$16% have been achieved at 650 nm. Direct gap AlGaInP materials, which cover the red to green regions of the spectrum, are promising for shorter wavelength visible LED applications. Significant advances in AlGaInP-based LEDs have been made by bonding the material to a transparent GaP substrate to enable light emission from both sides of the device. This technology has resulted in LED performance that exceeds all other commercial technologies for the green to red spectral regime.

The visible LEDs dominate the LED market, but longer wavelength LEDs also have applications. Near-ir LEDs (780–1000 nm) are used in short haul communication systems and are typically made of GaAs, AlGaAs, and InGaAs materials. The 1.1–1.6-μm region of the spectrum is also relevant for optical communication systems and LEDs emitting in this region are based on InGaAsP materials. Finally, InAsSb and related alloy structures have been developed into LEDs covering the mid-ir (2–5 μm) region of the spectrum. These wavelengths are useful for gas monitoring systems, such as those used to monitor pollution.

Other applications such as wavelength division multiplexing (WDM) and some spectroscopic applications require high powers and/or a broader spectral width than typical LEDs. In this case, a superluminescent LED is used, which typically has an edge-emitting geometry with cleaved facets and is essentially the same structure as a laser diode. The difference is that some loss mechanism, usually in the form of a tilted mirror or an absorbing region along the length of the LED, is introduced that prohibits the device from actually lasing. This allows a relatively high level of current injection without lasing, such that much higher powers and broader spectral outputs are achieved than from standard LEDs. Superluminescent LEDs have been reported throughout the near-ir region of the spectrum and are sold commercially. At the communication wavelengths, as an example, 80- and 140-nm linewidths have been achieved at 1.3 and 1.5 μm, respectively. See also **Automotive Electronics**; **Luminescence**; and **Telephony (Telecommunications)**; and **Light-Emitting Diodes (LED)**.

Lasers. First developed in 1962, the semiconductor laser diode has rapidly matured to become the dominant laser source used in photonics technologies, primarily due to its small size, low power requirements, manufacturability, and robustness. Just as for LEDs, the wide array of primarily direct band gap compound semiconductors has enabled semiconductor laser development from the blue to the mid-ir region of the spectrum. The semiconductor laser diode is similar to the LED in that it utilizes the injection of charged carriers to emit light. In addition, the laser diode employs an optical cavity formed by mirrors, often just the cleaved facets of the semiconductor, to allow for optical feedback. The optical feedback enables stimulated emission to occur, in which reflected photons stimulate the emission of additional photons of the same energy and phase. Injecting current into the device provides gain to the system which is the mechanism that allows for the multiplication or amplification of photons. The photons that travel in the cavity also experience a certain loss, due to absorption in the cavity or transmission through the mirrors. When the gain of the laser system is greater than the loss of the system, lasing occurs.

Because lasers are governed by stimulated emission, their properties are distinct from those of LEDs which emit spontaneous emission. In particular, the fact that stimulated emission generates photons of equal phase is responsible for lasers having coherence. This is important for applications such as holography and enables improved focusability of light. As the mirrors of the cavity determine a preferred direction for photon propagation, the laser emission is in the form of a well-defined beam, as opposed to the isotropic emission from LEDs. In contrast to the relatively broad spectral output of the LED, the laser has one or more sharp emission lines, arising from optical modes that propagate due to the boundary conditions imposed by the laser cavity. Finally, the fact that the losses of the cavity must be overcome before lasing can occur results in a well-defined threshold injection current below which lasing cannot occur.

Several heterostructure geometries have been developed since the 1970s to optimize laser performance. Initial homojunction lasers were advanced by the use of heterostructures, specifically the double-heterostructure device where two materials are used. The ability of the materials growth technology to precisely control layer thickness and uniformity has resulted in the development of multiquantum well lasers in which the active layer of the laser consists of one or more thin layers to allow for improved electron and hole confinement as well as optical field confinement.

Like the LED, the laser diode has both edge-emitting and surface-emitting geometries, with edge-emitting lasers being by far the most common. For the edge-emitting laser, light propagates in the plane of the wafer and the mirrors are typically fabricated by cleaving the wafer along a crystallographic plane. Although the reflectivity of these cleaved mirrors is only about 30%, it is sufficient to support lasing in broad area lasers that have high gain. To reduce mirror loss, the facets can be coated with a dielectric multilayer stack to enhance reflectivity of the mirrors. The cavity length of edge-emitting lasers is usually on the order of 250–1000 μm.

Another type of edge-emitting laser commonly used in communications applications is the distributed feedback (DFB) laser. In this device, the

cleaved mirrors that are commonly used are replaced by corrugations fabricated in the semiconductor material. These corrugations result in a periodic refractive index variation that enables coherent feedback of the light propagating in the cavity. This complicated mirror has definite advantages over a cleaved mirror in that it only allows one of the many optical modes of the laser cavity to propagate, resulting in single-mode (therefore single-frequency) output. As the optical fibers used in communication systems have significant wavelength dispersion at 1.55 μm, the sharp spectral profile of the DFB laser results in less distortion of the optical signal.

Compound semiconductor-based laser diodes operate in the blue–green, red, and near- to mid-ir region of the spectrum. One of the areas of most recent developments is that of blue–green laser diodes. Interest in these short wavelength lasers arises primarily from optical data storage applications where the shorter wavelengths translate to the ability to read or write more information on a disk. In early 1996, Nichia Chemical Industries reported the first demonstration of a room temperature GaN-based laser diode, with emission at 415.6 nm in the blue region of the spectrum. The GaN-based materials field is rapidly advancing and improvements in GaN laser diode performance as well as expansion into the uv and green regions of the spectrum may be seen in the near future.

Another material system for which blue and green laser diodes have been demonstrated is that of ZnSe and related Groups II–VI materials. These II–VI materials are primarily grown by molecular beam epitaxy (MBE). The first demonstration of electrically injected blue–green edge-emitting lasers, observed at low temperatures and under pulsed conditions, occurred in 1991. Rapid progress has extended the technology to room temperature continuous wave (CW) emission in the blue–green region of the spectrum (510–520 nm), with pulsed operation down to approximately 463 nm. One problem with these II–VI-based laser diodes is that they suffer irreversible degradation with CW lifetimes on the order of one hour. ZnSe-based VCSELs have been demonstrated with optical pumping.

As of early 1996, commercial laser diodes were restricted to emission in the red region of the spectrum. The dominant material for red laser diodes is AlGaInP, which has demonstrated room temperature pulsed lasing in broad area lasers down to emission wavelengths approaching 610 nm, with longer wavelengths (670–690 nm) giving significantly better performance. AlGaInP high power laser diode arrays have been developed with up to 12 W emitted at 640 nm. Red VCSELs were first achieved from AlGaInP materials in 1993, with more recent performance at 690 nm of up to 8 mW output power. Applications for red lasers include laser printers, bar-code scanners, optical data storage systems, and plastic fiber-based communications systems.

GaAs, AlGaAs, and InGaAs materials are used in laser diodes with emission from 750 to 1000 nm. One of the principal technologies in this wavelength region is that of compact disk players and CD-ROM drives which use 780-nm AlGaAs DH lasers. Although these lasers have become an industry standard, other materials have been developed to generate lasing in this wavelength region. One such material is the quaternary InGaAsP grown on GaAs substrates, which can be grown to cover the same band gap range (1.42–1.92 eV or 870–650 nm) as the AlGaAs materials. Near-ir semiconductors are also employed to pump erbium-doped fiber amplifiers that are used in long distance communication systems. InGaAs lasers are used to supply the 980-nm laser emission wavelength, which is optimal for absorption into the doped fiber. Although the wavelengths of these 780–980-nm lasers are not optimized for fiber-based communication systems, they are routinely used as a low cost solution for short distance communication applications as well.

The most important laser wavelengths for communication applications is the 1.1–1.7 μm region in the near-infrared. This arises from the fact that glass optical fibers used in data communication systems have minimum dispersion at 1.3 μm and minimum loss at 1.55 μm. See also **Optical Fiber Systems**. The primary material system for laser diodes in this wavelength region is InGaAsP.

Laser sources that emit in the mid-IR region of the spectrum (2–5 μm) are useful for detection of trace gases because many molecules have strong absorption bands in that region. Other applications include remote sensing and laser radar. Semiconductor lead–salt (IV–VI) lasers that operate CW at a temperature of 200 K (−99.7 °F) and emission wavelength of 4 μm are commercially available; however, they have relatively low output powers (<1 mW). Group III–V quaternary materials have also been developed as mid-IR laser diodes, with the strained quantum well GaInAsSb–AlGaAsSb laser demonstrating up to 1.3 W CW output power at 2 μm. Many other ternary and quaternary III–V structures have been developed to enable longer wavelength emission. InAsSb–AlInAsSb strained quantum well structures are one example, with CW lasing at 3.9 μm achieved up to an operating temperature of 128 K (−229 °F).

Detectors. Whereas there are several types of photon detectors, the most common compound semiconductor-based devices are photoconductors and photovoltaic devices. With the photoconductive detector, a change in the resistivity of the semiconductor material as light is absorbed is measured. The spectral range of detection is limited on the long wavelength end by the semiconductor band gap (intrinsic detectors) or the binding energy of an impurity in the semiconductor (extrinsic detectors) and the current–voltage characteristics are nominally linear. The photovoltaic devices, often called junction devices or photodiodes, employ a p–n junction. The long wavelength limit of detection is determined by the band gap of the semiconductor material for most types of detectors. The intersubband detector is an exception. The absorption of light results in the generation of electrons and holes which are subsequently swept out of the depletion region of the junction. This carrier transport acts to forward bias the junction and to produce either an open-circuit voltage or a short-circuit current which is measured. The current–voltage characteristic is not linear but rather shows rectifying behavior. Many of the semiconductor materials that are used in detectors, such as InSb, InAs, HgCdTe, PbTe, PbSe, and PbTe, have been developed as both photoconductive and photovoltaic detectors.

The most critical parameters that govern the performance of the detector are quantum efficiency, responsivity, and response time.

Silicon-based detection systems are the dominant technology for single-element and array detectors in the near-uv to near-ir spectral region (350–1000 nm), with a quantum efficiency at least 20% greater than that of compound semiconductors (approaching a value of 1 in the 700–800 nm range). The advantage of compound semiconductors is that they can cover a much wider spectral range than silicon, operating from the UV to the far-IR region of the spectrum. Applications for long wavelength ir (LWir) detectors that operate in the 8–12 μm region are numerous and include systems for navigation, weather, and pollution monitoring, remote sensing, night vision, and navigation. The most commonly used material system is HgCdTe–CdTe that operates in the 3–17-μm region of the infrared and is utilized in commercial imaging arrays. Mid-IR detection is accomplished by InSb arrays, and near-IR detector technologies include InGaAs–InP materials that operate in the 1.3–1.6-μm region. Additional near-ir materials are quaternary materials such as InGaAsP–InP and AlGaAsSb–GaSb which operate in the 0.9–1.7-μm region.

Developments have also been made on GaAs–AlGaAs quantum well infrared photodetectors (QWIPs).

Many of these material systems have been developed into avalanche photodiodes (APDs) which involve not only the generation of carriers with the absorption of light but also the amplification of the generated carriers. This is accomplished by applying a very high reverse bias to the detector, resulting in a high enough internal electric field inside the material to generate additional carriers by impact ionization. These detectors therefore have a higher responsivity than more conventional photodiodes, but suffer from increased noise.

As for LEDs, substantial improvement in detector performance can be achieved by placing the LED structure inside a resonant cavity. In particular, the resonant cavity photodetector can achieve high quantum efficiencies in a relatively narrow spectral region. In one study, a mirror was designed to allow for resonant absorption of two wavelengths: 730 and 910 nm. This type of multiple wavelength detector shows promise for wavelength division multiplexing (WDM) systems where wavelength multiplexing enables enhanced transmission capacity.

SEMICONDUCTORS: ORGANIC SEMICONDUCTORS. Semiconductors are materials that are characterized by resistivities intermediate between those of metals and of insulators. The study of organic semiconductors has grown from research on conductivity mechanisms and structure–property relationships in solids to include applications-based research on working semiconductor junction devices. Organic materials are now used in transistors, photochromic devices, and commercially viable light-emitting diodes, and the utility of organic semiconductors continues to increase.

The study of organic semiconductors and conductors is highly interdisciplinary, involving the fields of chemistry, solid-state physics, engineering, and biology.

The theory of conduction in organic semiconductors conveniently begins with a discussion of bonding in extended solids, since the nature of conduction is intimately related to the extent of delocalization of orbitals in the material to be studied. For inorganic conducting solids, the orbital overlap of the atoms in the crystal lattice results in the atomic energy levels spreading out to form energy bands rather than discrete levels. These energy bands allow for motion of charge carriers over many lattice sites without interruption by trapping events. The interactions between molecules in a molecular organic solid similarly leads to the formation of energy bands, with the extent of interaction between molecules (the extent of overlap of interacting orbitals) determining the width of the bands.

The distinctions between metals, semiconductors, and insulators are based on the band structure of the materials as well as on the electron occupancy of these bands. Figure 1 is a diagram of energy bands and occupancies for various classes of solids. As can be seen in Figure 1, insulators have a filled band formed from the valence orbitals (a "valence band") with a higher lying unfilled band formed from higher energy orbitals (the "conduction" band). The region between these has no allowed states, and the energy difference required to promote an electron from the valence to the conduction band is termed the band gap of the material. For an insulator, the band gap is large, typically >4 eV. Since all of the levels of the valence band are filled, no electrons are able to carry current.

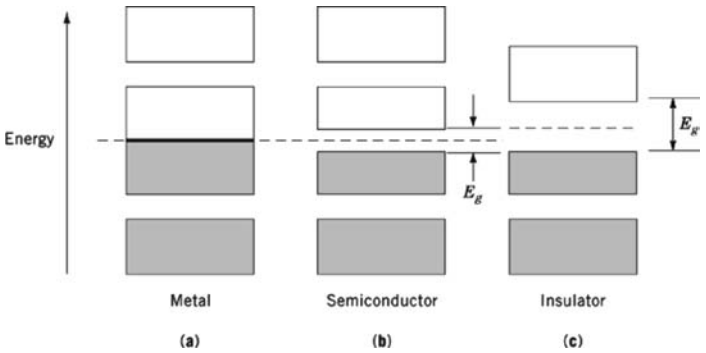

Fig. 1. Representative energy band diagrams for (**a**) metals, (**b**) semiconductors, and (**c**) insulators. The dashed line represents the Fermi Level, and the shaded areas represent filled states of the bands. E_g denotes the band gap of the material.

Metallic behavior is observed for those solids that have partially filled bands (Fig. 1**b**), that is, for materials that have their Fermi level within a band. Since the energy bands are delocalized throughout the crystal, electrons in partially filled bands are free to move in the presence of an electric field, and large conductivity results. Conduction in metals shows a decrease in conductivity at higher temperatures, since scattering mechanisms (lattice phonons, etc) are frozen out at lower temperatures, but become more important as the temperature is raised.

Semiconductors show thermally activated conductivity. The reason can be seen from Figure 1**c**. The band gap of a semiconductor is small relative to that of an insulator. Similar to insulators, pure intrinsic semiconductors have a filled valence band and unfilled conduction band. However, this is strictly true only at absolute zero. At higher temperatures, the energy of the surroundings kT can become large enough to thermally excite electrons from the valence to the conduction band, with the result that semiconductors have partially unfilled orbitals, giving rise to conduction. Typical band gaps for semiconductors are. Increasing temperature causes increased electrical conductivity by providing more carriers in the conduction band.

A variety of organic materials demonstrate reasonable conductivity, and a great deal of study has been devoted to conduction in organic materials. Initial study of conduction in organic materials was focused on molecular crystals (such as anthracene) that have weak intermolecular van der Waals interactions and low conductivities. However, the area of research has broadened and also includes charge-transfer compounds and polymeric materials. Research on new materials has led to synthesis of organic compounds with much larger conductivities than typical molecular crystals. Conducting and superconducting organic solids are now relatively commonplace.

Certain one-dimensional, chain-like organic semiconductors are found to display metallic properties (decreasing conductivity with increasing

temperature) above a certain temperature. The phase transition that occurs in these stacked materials is termed a metal-to-insulator transition and is the result of the highly anisotropic nature of these materials. A stack of equally spaced atoms or molecules is subject to a reorganization to a lower symmetry configuration. This reorganization, termed a *Peierls distortion*, is the condensed matter counterpart of the molecular Jahn-Teller distortion. The Peierls deformation results in pairing of molecules along the chain with the formation of short and long intermolecular spacings. This nuclear deformation causes changes in the electronic distribution of the lattice. The result of this redistribution is the opening of an energy gap at the Fermi level, with resulting semiconductivity.

Interaction of molecules to form charge-transfer complexes occurs via transfer of electron density from one molecule (an electron donor, D) to another (an electron acceptor, A), resulting in a partially ionic ground state. The amount of charge transfer is large when the ionization potential of the donor is low and the electron affinity of the acceptor is high. Orbital descriptions and experimental aspects of charge-transfer complexes have been studied extensively, especially for weak complexes. In a charge-transfer salt, the intermolecular interactions give rise to periodic arrays of donors and acceptors.

Typical charge-transfer salts form as stacks of planar D and A molecules, though the ratio of D:A need not be 1:1, as the interaction can be spread over more than two molecules. The amount of charge transfer (δ) per $D^{\delta+}$ $A^{\delta-}$ unit in the solid may be less than unity, with partial charges residing on the respective stacks. Interactions between stacks are usually weak, and the observed conductivity is, thus, anisotropic, with the preferred direction being along the stacking axis. Anion (A^-) stacks result in electrical conductivity, while cation (D^+) stacks conduct holes. Strongly bound charge-transfer systems are of primary interest for organic semiconducting applications.

Some common single-carrier semiconducting salts are tetracyanoquinodimethane (TCNQ) radicals with alkali or other cations. The study of semiconductivity in these materials led to synthesis of more highly conductive charge-transfer salts based on the strong donor tetrathiafulvalene (TTF) with halogen or other acceptors. Organic materials have been developed with even larger conductivity and superconductivity above liquid helium temperatures.

Electrical Properties

Electrical properties have been the main focus in the study of organic semiconductors, and conductivity studies on organic materials have led to the development of materials with extremely low resistivities and large anisotropies. A discussion of conductivity behaviors for various classes of compounds follows.

Charge-Transfer Salts. Most organic molecular crystals have only weak interactions between molecular units and have resulting low conductivities, with $S < 10^{-10}\ \Omega^{-1}\,\mathrm{cm}^{-1}$. Charge-transfer solids tend to have higher conductivities than the molecular compounds from which they are composed, and semiconducting charge-transfer salts of TCNQ were first synthesized in the early 1960s. The simple metal-ion radical salts of the composition $M^+(TCNQ)^-$ have conductivities of $\sim 10^{-9} - 10^{-4}\ \Omega^{-1}\,\mathrm{cm}^{-1}$ at room temperature, intermediate between conductivity values for insulators and typical metals. A variety of other systems show thermally activated conductivity in the range $10^{-10} - 1\ \Omega^{-1}\,\mathrm{cm}^{-1}$, including phthalocyanines and chloranil or tetracyanoethylene-based charge-transfer complexes.

Proposed conductivity mechanisms and the importance of band motion vs hopping motion in semiconducting organic solids have generated a great deal of controversy. However, it is plausible that for many organic molecular semiconducting materials, the description of the conductivity lies somewhere between the extremes of localized hopping and delocalized band models.

The highly conductive class of solids based on TTF–TCNQ have less than complete charge transfer (~0.6 electrons/unit for TTF–TCNQ) and display metallic behavior above a certain temperature. However, these solids undergo a metal-to-insulator transition and behave as organic semiconductors at lower temperatures. The change from a metallic to semiconducting state in these chain-like one-dimensional (1D) systems is a result of a Peierls instability. Although for true one-dimensional systems this transition should take place at 0 Kelvin, interchain interactions lead to effective non-1D behavior and inhibit the onset of the transition.

The temperature of the metal-to-insulator transition in TTF–TCNQ is 53 K. For systems with increased interchain coupling, the transition temperature for the onset of metallic conduction increases roughly as the square of the interaction between the chains. This behavior is true as long as the coupling between chains remains relatively weak. For compounds with strong interactions between stacks, the material loses its quasi-1D behavior. Thus, the Peierls distortion does not occur even at low temperatures, and the materials remain conductive.

The temperature range of metallic conductivity in organic materials can sometimes be increased by compaction of the compound under large pressures.

Polymers. The use of polymers in semiconducting applications is growing rapidly. In the undoped form, most of these π-conjugated systems are semiconducting, with a small band gap separating filled valence and conduction bands. The dark (nonphotoinduced) conductivity of these systems is typically low and increases with increasing temperature, as a result of thermalization of charge carriers. Doping the material leads to large increases in conductivity, with increases of several orders of magnitude possible. Doping removes electrons from the valence band or adds them to the conduction band. However, the charges are not delocalized along the polymer chain. An extra electron in the conduction band, for example, becomes localized as a result of a local geometry change caused by the excess charge. The result of the charge localization is termed a polaron, which as a result of the local energy minimum gives a state in the bandgap of the material. Conduction can then occur by motion of the polaron through the chain.

Conductivities of polymers of technological interest such as polypyrrole and polythiophene are typically $\sim 100\ \Omega^{-1}\,\mathrm{cm}^{-1}$ in the doped state, and the conductivity can be tuned by reversibly doping and undoping the polymer. Derivatives of these and other polymers have achieved even higher conductivities.

One-dimensional polymers such as polyacetylene which have degenerate ground states are special cases. Conduction in polyacetylene has been extensively studied. The nature of conduction in pure, *trans*-polyacetylene is a result of the alternating single bond–double bond structure that results from the Peierls instability. The energy of the system is the same if the alternating pattern of the bonds is reversed. Conductivity has been described for this system in terms of solitons (mobile kinks in the polymer chain that link alternating bond patterns), excitations that are unique to systems with degenerate ground states. These neutral solitons are mobile, and extend over several bond lengths along the chain. As usually prepared, undoped polyacetylene has *p*-type conductivity as a result of acceptor impurities in the material. The conductivity increases with doping, reaching a plateau value at high doping levels. Highly doped *trans*-polyacetylene can display conductivities as high as $10^5\ \Omega^{-1}\,\mathrm{cm}^{-1}$.

Optical Properties

Charge-Transfer Salts. New strong absorbance bands (charge-transfer bands) are often observed in spectra of donor–acceptor solids. These bands are the result of excitation from a ground state that is predominantly donor in character to an excited state that resides mainly on the acceptor. For a given acceptor, the frequency of this band varies linearly (over a small range) with the ionization potential of the donor molecule. This absorption band can occur at lower energy than absorptions of the isolated D and A molecules, and is often in the infrared region. By a suitable choice of donor and acceptor, it is possible to tune the frequency of this absorption band (and the associated fluorescence) throughout the visible region.

Polymers. Polymers used in semiconducting applications such as light-emitting diode displays are π-conjugated systems with small band gaps of 1–3.5 eV. In the undoped state they give strong $\pi - \pi*$ absorption bands in the visible or ultraviolet region, corresponding to transitions from the valence band to the conduction band levels. By tailoring the nature of the electron-donating and withdrawing substituents on the polymer backbone, absorbance and the resulting emission spectra can be shifted throughout the visible region. Conformational changes due to heating can drastically shift the absorption, suggesting possible uses as molecular switches.

Chemical Properties

Since charge-transfer and mobility of carriers are important features for organic semiconductors and devices, the energies of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) are of interest. The energies of these levels are related to the efficiency of charge injection into a material as well as the degree of charge-transfer between donors and acceptors. Electrochemical measurements provide a convenient means for determining HOMO and LUMO levels by measuring the potentials required for oxidation and reduction of the material, respectively. Redox potentials also provide a quick method for checking energy gap values obtained from conductivity measurements.

Electron donor molecules are oxidized in solution easily.

Reversible oxidation and reduction of polymers is commonly used to increase conductivity in these systems. Ions from the electrolyte are usually incorporated into the polymer as part of this process.

Stability. The materials used in organic semiconducting applications are thermally labile upon exposure to high temperatures. For example, many of the compounds used in fabrication of organic light-emitting diodes (LEDs) are vapor deposited by resistive heating at relatively low temperatures in vacuum. Compounds such as the hole transporter *N,N′*-biphenyl-*N,N′*-bis(3-methylphenyl)-1,1′ biphenyl-4,4′ diamine (TPD) have glass-transition temperatures in the range of 150 °C (302 °F).

As a result of the organic nature of the materials, chemical oxidation is a problem when heating in atmosphere. Polymeric compounds can also oxidize at low temperatures. Polyacetylene is degraded at room temperature by atmospheric oxygen and water vapor. Although other conjugated polymers are typically more thermally stable, most exhibit degradation and decreased conductivity after heating in atmosphere.

Photostability and Atmospheric Stability. The presence of oxygen and water vapor has a profound effect upon the photostability of many organic semiconducting materials. Oxygen and water vapor have also been implicated in dark spot formation in the degradation of light-emitting diodes. As a result, performance lifetimes of these devices can be significantly prolonged by packaging under inert atmosphere. An exception to the general behavior of organic semiconducting systems is observed for $p-n$ solar cells fabricated with the donor chloroaluminum phthalocyanine. These cells exhibit improved performance after exposure to water and oxygen, due to formation of a crystalline hydrate. This provides further evidence for the need for control over impurity and humidity levels during device production.

Structure

A discussion of structure in organic semiconductors includes chemical structure of individual molecules or unit cells, as well as three-dimensional structure of the bulk material. The structure of individual molecules can be tailored by synthetic methods, with molecules designed for specific applications. For example, rigid, planar structures are often used for dyes in photovoltaics, since this increases exciton mobility. Molecular packing and the structure of thin films can be dependent upon the method of fabrication and the structure of individual units. See also **Thin Films**. The nature of molecular and polymeric thin films for semiconducting applications ranges from highly crystalline to amorphous. Challenges ahead are to design better adhesion between organic films and substrates. Better interfacing and orientation are needed for many applications, since these can influence charge injection and transport.

The individual units in a polymer are well-defined, but bulk polymer usually lacks the periodic structure characteristic of inorganic or small molecule crystalline solids. The structure of semiconducting and conducting polymers is determined by the units of the polymer backbone as well as pendant side-groups. Typical conducting polymers are conjugated systems that provide for motion of the electrons through the π-system, and both linear chain (poly-acetylenes) and aryl chain poly(*p*-phenylene) polymers are commonly used. As chain length increases during polymer growth, the long-chain polymers become insoluble and precipitate out during synthesis. The chain length in polymeric solids is thus, influenced by the nature of the solvent and the synthetic process. Although most polymers are fairly amorphous, chemical substitution has been used to design self-assembled oligomeric films with highly ordered structures. Film morphology for linear chain polymers can be affected by stretching of the film to orient the chains, resulting in higher crystallinity. The morphology of electrochemically grown conducting polymer thin films has also been shown to be dependent on the nature of the substrate.

The conducting polymer poly(sulfur nitride) is unusual in that it is crystalline, consisting of chains of sulfur and nitrogen packed in parallel. Individual chains are planar with alternating cis–trans conformation along the chain, and the interaction with neighboring chains leads to a highly ordered matrix.

Although its use as a transparent electrode in diodes has made it one of the most useful of the conductive polymers, the intractable nature of the material made the structure of polyaniline difficult to determine. Recent studies of polyphenyleneamineimines have conclusively shown that the structure of PANI is an exclusively para-linked system.

Uses

Organic semiconductors offer many advantages over inorganic-based materials for use in electronic and optoelectronic devices. Among the advantages are the possibility of tailoring properties through synthetic chemical modifications, the relative ease of generating large-area films, and low cost device manufacture.

Diodes. Organic light emitting diodes (OLEDs) are based on amorphous (glassy) organic films, which can be deposited on virtually any substrate, ranging from rigid supports such as glass or silicon to highly flexible polymer supports. This is in contrast to inorganic LEDs, which require crystalline substrates for epitaxial growth of the active materials. An additional feature of OLEDs is that the organic layers are very thin (ca 50–100 nm, 500–1000 Å), and combined with large Franck-Condon shift between absorption and emission, makes them transparent to their own emission. This transparency may open the door to novel display architectures and applications. Taking these qualities together it is clear that OLEDs have unique characteristics as compared with other potential flat panel display (FPD) technologies. Although technical obstacles must be overcome, OLEDs have potential for certain display applications.

Photovoltaic Devices. For many inorganic semiconductors, absorption of light can be used to create free electrons and holes. In an organic semiconducting solid, however, absorption of a photon leads to the formation of a bound electron–hole pair. Separation of this pair in an electric field can occur due to differing mobilities of the electron and hole, and this separation of the charge particles gives rise to a photovoltage. See also **Photovoltaic Cell**. This photovoltaic effect is of great interest for use in solar cells, since the conversion of light energy from the sun to electrical energy provides a nonpolluting renewable energy source. The photovoltaic effect is also of interest for photodetectors and for memory storage devices. Photocurrents are of great importance in biological systems as well, and there is interest in light-harvesting devices based on protein pigments.

Transistors. The use of molecular materials for transistors is attractive because of the facile processability and low cost of organic thin films. Stable field-effect transistors based on metal phthalocyanines have been developed with mobilities of 10^{-3} cm^2/V·s, much of the research on organic field-effect transistors has focused on semiconducting polymeric materials. Early devices typically generated the polymer electrochemically under inert atmosphere or by spincoating; devices with enhanced performance were fabricated using vacuum deposition of oligomers. Devices from α-conjugated oligomers of polythiophene (α-sexithienyl, α-6T) showed mobility enhancement after heat treatment, with maximum $\mu = 10^{-3}$ cm^2/V·s reported. These *p*-type polycrystalline thin films (thicknesses of 100–200 nm) give on/off current ratios of 10^2–10^3.

"All-organic" transistors based on α-6T were designed with organic materials serving as the semiconductor, insulator, and support (the source and drain contacts were metallic). Aside from being flexible as a result of the organic support, these devices showed very high mobilities. The reported field-effect mobility (4.6×10^{-1}) and transit times are similar to those of amorphous-silicon based transistors. The performance of these devices was noted to be highly dependent on the nature of the semiconductor–insulator interface. Later refinement of α-6T based devices has improved the ratio of source-drain currents in the on and off states, with ratios of $>10^6$ obtained. Improvements in device performance are continuing, and organic transistors are likely to become important in a number of applications ranging from displays to integrated circuits.

Reproduction and Resist Materials. Organic photoreceptors have advantages over inorganic-based systems in cost and flexibility. Organic charge-transfer complexes, polymers, and dyes have found wide use in xerography. See also **Electrophotography**. The role of the photoreceptor is to convert an optical input signal to an electrostatic map on a photoconductive surface. The photoreceptor must accept and hold a surface charge, discharging only in those areas that are exposed to illumination. Oppositely charged toner particles are then attracted to the undischarged areas of the photoconductor to create an image representing the dark regions of the original image.

The photoreceptor must be highly optically absorbing throughout the visible region, must be stable with respect to light and chemicals such as ozone, and must be relatively insulating in the absence of illumination.

The first use of organic charge transfer complexes was of poly(*N*-vinylcarbazole) [CAS: 25067-59-8] (PVK) mixed with the acceptor 2,4,7-trinitro-9-fluorenone [CAS: 129-79-3] (TNF) in a 1:1 ratio. In this device, charge generation through absorption and charge transport both occur in a single layer. This material had good sensitivity throughout the visible region, but the carcinogenic properties of the fluorenone led to the discontinuation of its commercial use. A number of other acceptors have been used as dopants in PVK, including tetracyanoethylene, tetracyanoquinodimethane, and chloranil. Charge-transfer complexes from triarylamine donors and boron diketonate acceptors have also been investigated for use as photoreceptors when doped into a Lexan host. The use of single-layer devices has been supplanted by two-layer systems, with one layer used for charge generation and the other for charge transport. Highly absorbing organic dye molecules are typically usually used for charge-generation and doped polymers serve as transport layers.

Batteries. Many π-conjugated polymers can be reversibly oxidized or reduced. This has led to interest in these materials for charge-storage batteries, since polymers are lightweight compared to metallic electrodes and liquid electrolytes. See also **Batteries**. Research on polymer batteries has focused on the use of polymers as both the electrode and electrolyte. Typical polymer electrolytes are formed from complexes between metal-ion salts and polar polymers such as poly(ethyleneoxide). The conductivity is low at room temperature due to the low mobility of cations through the polymer-matrix, and the batteries work more efficiently when heated above the glass-transition temperature of the polymer. Advances in the development of polymer electrolytes have included polymers poly(ethylene oxide) intercalated into layered silicates. These solid-phase electrolytes exhibit significantly improved conductance at room temperature.

A variety of polymers have been investigated for use as electrodes, including polyacetylene and polyaniline. The stability of polymer electrodes with respect to repeated cycling has been a question. Improvements in polymer battery design should make polymer-based cells attractive, especially for low power applications.

Electrochromics. Oxidation or reduction of organic compounds often results in a color change. Materials exhibiting such changes are termed electrochromics. Typically, the organic is pale in color prior to oxidation or reduction, with intense color change upon application of a voltage as a result of new optical absorption bands. Electrochromic materials are of interest for use in displays as well as for optical shutters. An important parameter in performance of these devices is the read–write efficiency, which is the percentage of electrically generated color that can be removed by reversing the current through the device.

Other solution-based electrochromic systems have been based on tetracyanoquino-dimethane (TCNQ), which is soluble in organic solvents such as acetonitrile. Tetrathiafulvalene (TTF) has also been used in electrochromic devices. TTF-based polymers spin-coated onto transparent electrode surfaces form stable thin films with reproducible electrochromic properties. The slow response of these devices has been attributed to the rate of ion movement through the polymer matrix.

The use of polymeric materials for electrochromic displays is especially promising. A number of conjugated polymer systems can be used as electrochromics, with insulating and doped forms of the polymer exhibiting different absorption spectra. Electrochemical oxidation of aniline results in thin films of polyaniline, which can exist in various redox states. Successive oxidations cause reversible color changes from transparent to yellow–green to deep blue–black. Polythiophene can also be electrochemically generated from the monomer. Though polythiophene electrochromic films suffer a loss in read–write efficiency after a large number of read–write cycles, derivatives of polythiophene have found use as electrochromes in a number of devices including display and memory devices. The colors in the oxidized and reduced forms of these systems depend upon the nature of the substituents on the monomer unit.

Switches and Sensors. The use of conducting polymers has been shown to be promising for chemical sensor technology, with molecular recognition leading to changes in conductivity of the polymer. See also **Sensors**. One approach utilizes polythiophene derivatives which undergo ion-specific conformational changes, resulting in conductivity reductions upon sensing. Switching phenomena in charge-transfer complexes has also been observed. Thin films of metal-organic charge-transfer complexes such as Cu–TCNQ can be switched between low and high conductivity states with application of a suitable field. Conduction in the high conductivity state has been associated with channel formation in the material. One design for optoelectronic gates incorporates a dye molecule as the absorbing chromophore with a series of linked metalloporphyrins serving as a molecular wire. Switching is observed as a result of the change in the porphyrin energy levels (and thus the conduction in the wire) upon reversible oxidation at a designated site. Polymeric systems also show promise as temperature sensors, since thin films of doped polymers such as polyacetylene exhibit temperature dependent color changes.

SEMICONDUCTORS: SILICON-BASED SEMICONDUCTORS. With the invention of the transistor in 1947 semiconductors changed the basis of electronics from vacuum tubes to semiconductor devices. The invention of the integrated circuit in 1958 revolutionized electronic systems. The reason for this can be seen by considering the Intel 8086 (1978), the 16-bit microprocessor used in the first IBM PC. This chip used NMOS technology (MOS = metal/oxide/semiconductor) with 10-μm feature lengths and contained 20,000 transistors in a 25-mm^2 chip. Compare this with the Whirlwind computer (1950), the first large-scale, real-time control system, which contained 15,000 vacuum tubes and occupied a 2500-ft^2 room. Thus, a single semiconductor chip contained the complexity of a large system. As important, the failure rate of the Intel 8080 with 4500 transistors, 220 in 10^9 h, was comparable to the failure rates of reliable, single transistors. Remarkably, this revolution in circuit integration has continued.

The semiconductor industry, which is primarily the manufacturers of silicon-based integrated circuit (IC) chips, has managed to put exponentially increasing numbers of transistors on silicon chips since 1960. This has been driven by Moore's Law, which Gordon Moore defined in 1965

by noting that the number of components on ICs was doubling every 12 months. Since 1970 the number of bits on a DRAM (DRAM = dynamic random access memory) chip has doubled every 18 months, while the number of transistors on a microprocessor chip has doubled every 24 months. Moore's law is a self-fulfilling prophecy because it has provided goals for the (silicon-based) semiconductor industry. These goals are now codified in projections by the International Technology Roadmap for Semiconductors (ITRS) http://public.itrs.net/.

The exponential growth of circuit integration on chips characterized by Moore's law has led to an extraordinary growth in semiconductor device revenue. This has increased by a 13–16% compound annual growth rate (CAGR) from 1960. Allowing for inflation, this corresponds to about a 10% CAGR in constant dollars. Semiconductor device revenue plotted on a semilogarithmic plot as a function of time leads to a curve that is nearly a straight line over the 40-year period from 1960 to 2000. However, this masks the cyclic, precipitous changes in revenue that have characterized the semiconductor industry. In particular, the drop in revenue from $200 billion in 2000 to $140 billion in 2001 was the largest drop in the history of this industry, with corresponding implications for the companies involved.

The semiconductor industry was originally driven by advances in DRAM technology, then by advances in microprocessor technology, as can be seen from the corresponding focus of Intel in the mid-1980s. More recently, there is increasing emphasis on chips for communications and consumer electronics. The present market for the industry is primarily silicon-based ICs containing MOSFETs (MOSFET = metal-oxide-semiconductor field effect transistor). These chips are the foundation for the increasing convergence of the computer, communications, and consumer electronic industries.

The doubling of transistors on chips predicted by Moore's law has been primarily the result of shrinking transistor sizes. Multiplying the length and width of transistors by a factor of 1/Ö2 or 0.7 will double the number of transistors on the same size chip. Technological change is measured in DRAM memory bits or transistors for the microelectronics revolution and in the horsepower of steam engines for the industrial revolution. The result is exponential growth, as shown by straight lines on a semilogarithmic plot. The degree of technological change in the microelectronics revolution is orders of magnitude greater, even though it has taken less than half the time taken by the industrial revolution. Considering the social changes brought by the industrial revolution, one may expect even greater changes from the microelectronics revolution.

As the silicon semiconductor field has matured, its focus has shifted from the development of new devices to the manufacture (fabrication) of the same devices, mostly MOSFETs, made from mostly the same materials, but with ever-smaller dimensions. Each technology generation is identified by a dimension that is the minimum half-pitch of the first metal (M1) interconnect level. Historically, this has been the half-pitch for DRAMs. Note that we are in a deep submicron regime, characterized by quoting half-pitch dimensions in nanometers rather than microns.

Nanometer dimensions give a new meaning to questions of doping and contamination. When semiconductor devices were first developed, they were characterized by extraordinary levels of chemical purity, with typical impurity concentrations on the order of 10^{17} cm^{-3} or 2 parts per million atoms (ppma) because the number density of silicon is 5×10^{22} cm^{-3}. Consider a regular prism with dimensions (100 nm)^2 × 10 nm, not unreasonable for deep submicron device features. It would contain 5000 silicon atoms. An impurity concentration of 2 ppma would mean there was only one impurity atom in 100 such prisms.

The starting material for bulk devices has been a wafer cut from a single crystal of silicon, 200 mm (8 in.) in diameter and ~650 μm thick, with a global flatness variation across the wafer of <3 μm. Chemical perfection of these wafers is essential. The largest impurity in these wafers, oxygen, is kept ~20–35 ppma. In this range, oxygen improves the mechanical strength of the wafer and promotes intrinsic gettering, in which oxygen is used to draw fast diffusing metal contaminants into the bulk of the wafer and away from the surface on which active devices are formed. Specific metallic contaminants, particularly heavy metals, e.g., Fe, Ni, Cu, and Au, need to be kept <0.01 ppba because their presence can degrade device performance by reducing minority carrier lifetimes. Perfection is especially necessary on the silicon surface. A {100} of plane silicon contains 6.8×10^{14} atoms/cm^2. Surface defect densities must be <1 part in 10^5–10^6 defects/cm^2 for satisfactory MOSFET operation. Good silicon devices required the discovery that the thermal oxidation of silicon could produce an excellent Si-SiO_2 interface.

The high purity required of silicon and the small size of semiconductor devices place stringent limits on the chemicals used in processing silicon. By far the most important chemical is water, which is used extensively to dilute etchants and clean wafers. Pure water [4] is required to have <0.025 ppba of Na^+ and Cl^-, 0.002 ppba of heavy metals, e.g., Fe, and <10 ppb of total oxidizable (organic) carbon (TOC), e.g., bacteria. In addition, pure water should have <1 particulate/L, >0.5 μm in size. Water this pure is, in fact, an active chemical that absorbs, dissolves, or reacts with all kinds of materials to create contamination. Similar requirements are placed on other process chemicals.

Defects are equally important. Since experience has shown that the density of particles leading to defects is proportional to the reciprocal of the cube of the particle size, smaller device features generally mean a much greater susceptibility of devices to defects. For this defect density, one can show that the yield of a circuit (yield = the fraction of good circuits or chips) remains constant when device features are shrunk to the next technology node. However, this doubles the number of transistors on a chip of the same size. For the high yields (≥0.85) acceptable for manufacturing, chip yield will be squared (~0.72) when the number of transistors doubles. All of these factors mean that maintaining acceptable yields is a continuing challenge for the semiconductor industry.

At the same time, the semiconductor industry is transitioning to 300 mm (12 in.) wafers that can contain ~2.5 × the number of chips as 200-mm wafers. Estimates indicate that the ratio of finished costs for 300–200-mm wafers is only ~1.4. This means that each 300-mm fabrication facility (fab) can produce the output of at least 2.5 200-mm fabs at lower cost and can replace them.

Semiconductor Transport

Charge carriers in a semiconductor are always in random thermal motion with an average thermal speed, $v_{\rm th}$, given by the equipartion relation of classical thermodynamics as $m^* v_{\rm th}^2/2 = 3\,KT/2$. As a result of this random thermal motion, carriers diffuse from regions of higher concentration. Applying an electric field superposes a drift of carriers on this random thermal motion. Carriers are accelerated by the electric field, but lose momentum to collisions with impurities or phonons, ie, quantized lattice vibrations. This results in a drift speed, $v_{\rm d}$, which is proportional to the electric field; $v_{\rm d} = \mu_{\rm e} E$, where E is the electric field in volts per cm (V/cm) and $\mu_{\rm e}$ is the electron's mobility in units of cm^2/Vs.

The electron current density $J_{\rm e}$ has units of amperes per square centimeter (A/cm^2) and in a semiconductor results from drift and diffusion. In the absence of concentration gradients (eq. 1) reduces to Ohm's law, $J_{\rm e} = nq\mu_{\rm e} E = \sigma E$, where σ is the conductivity, q is the magnitude of the charge of an electron, and $D_{\rm e}$ is the electron's diffusion constant. The Einstein relation relates $\mu_{\rm e}$, and $D_{\rm e}$ by $D_{\rm e} = KT\mu_{\rm e}/q$. A similar equation can be written for hole currents, $J_{\rm h}$, if $+qD_{\rm e}$ is replaced by $-qD_{\rm h}$. High mobilities generally lead to high currents. In practice, $\mu_{\rm h} < \mu_{\rm e}$, for most semiconductors.

$$J_{\rm e} = nq\mu_{\rm e} E + qD_{\rm e}\frac{\partial n(x)}{\partial x} = \mu_{\rm e} n\frac{\partial E_{\rm F}}{\partial x} \qquad (1)$$

Ohm's law assumes that the drift speed of electrons in an electric field, $v_d = \mu_e E$, is small compared to their average speed, v_{th}, in a Maxwell-Boltzmann distribution. At high electric fields, E 10 *kV/cm*, v_d no longer increases with electric field and approaches a limiting saturation speed, v_s, determined primarily by optical phonon emission. Figure 1 shows the variation of drift speed with electric field for electrons and holes in various semiconductors.

At still higher fields, carriers can acquire enough energy from motion in an electric field to create electron–hole pairs by impact ionization. For silicon, the electron ionization rate, which is the number of pairs generated per centimeter of electron travel, depends exponentially on electric field. It is $\sim 2 \times 10^3$ cm^{-1} for a 50-kV/cm field at 300 K. The electric field causes electrons and holes so created to travel in opposite directions. They may create other electron–hole pairs causing positive feedback, which leads to avalanche breakdown at sufficiently high fields.

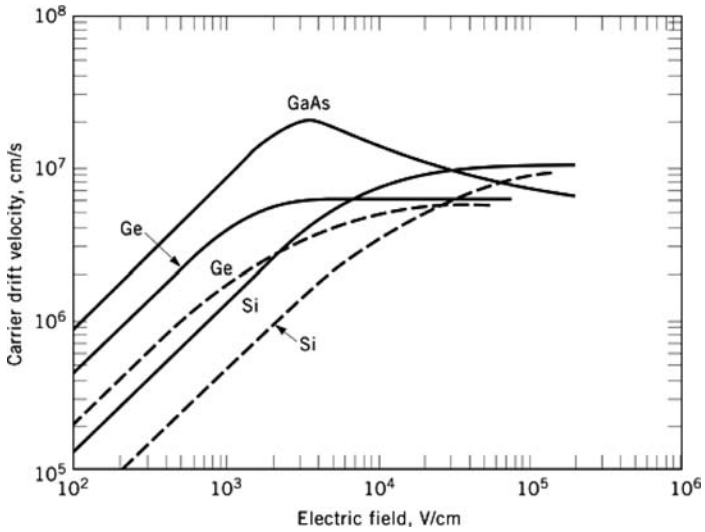

Fig. 1. Electron (_____) and hole (– – –) velocities versus electric field for high purity silicon, Si; germanium, Ge; and gallium arsenide, GaAs, at 300 K.

MOS Capacitance

In practice, the speed of digital (and analog) devices is determined by the time it takes to charge or discharge a capacitor, C, where $\Delta Q = C\Delta V = I\Delta t$. Thus, from this general relationship, low values of Δt require some combination of low C, low ΔV, or large I. Different device technologies and circuit techniques achieve this in different ways, but it can be seen that an understanding of device and circuit capacitance is essential to an assessment of device performance.

This is particularly true for the MOSFET, where conduction is controlled by a metal/oxide/semiconductor (MOS) capacitor. When a voltage is applied to the metal plate of a MOS capacitor most of the voltage drop is across the oxide, but some drop is across the semiconductor. If the semiconductor is p-type, a positive voltage applied to the metal plate induces negative charges in the semiconductor. Initially, this causes holes to move away from the surface of the semiconductor, leaving behind a carrier depletion region containing immobile, ionized acceptors, n_{a-}. As the voltage is increased, mobile electrons are drawn to the surface. Strong inversion is said to occur when the density of electrons at the surface equals the original density of holes. Strong inversion is generally used to define the threshold voltage for conduction in MOSFETs.

The magnitude of the capacitance depends on the voltage approaching the oxide capacitance in accumulation and inversion, and dropping to ~0.4 of the oxide capacitance in depletion, because the negative charge due to ionized acceptors is farther from the metal plate. The rise of capacitance in inversion assumes that electrons can follow the changes in the electric field. This only happens at low frequencies of 5–100 Hz for the M/SiO_2/Si capacitor. At high frequencies, depletion continues and the capacitance continues to drop with increasing voltage reaching a minimum value corresponding to the maximum width of the depletion layer.

The Si–SiO_2 Interface

The simple picture of the MOS capacitor presented in the last section is complicated by two factors, work function differences between the metal and the semiconductor and excess charge in the oxide. The difference in work functions, the energies required to remove an electron from a metal or semiconductor, is $q^{\phi}_{\rm ms} = -25$ meV for an aluminum metal plate over a 50-nm thermally grown oxide on n-type silicon with $n = 10^{16}$ cm^{-3}. This work function difference leads to a misalignment of energy bands in the metal and semiconductor that has to be compensated by a variation of the energy band with distance. When there is no misalignment the flat-band condition results.

Excess charge in the oxide has the effect of charge on the metal plate, but has a larger effect because it is closer to the silicon surface. There are several components of excess charge. Interface trapped charge at the Si–SiO_2 interface actively exchanges with carriers at the semiconductor surface. Fixed interface charges at or near the interface are immobile in an applied electric field. Oxide trapped charges that are also immobile can be created by irradiation or hot-electron injection. They have an important influence on the wear-out and reliability of MOS devices. Mobile ionic charges, eg, Na^+ ions, are notorious because they shift threshold voltages as they move under bias-temperature aging.

Interface states played a key role in the development of transistors. At a semiconductor–vacuum interface, dangling bonds extend from the surface atoms into the vacuum. Surface reconstruction minimizes the electronic energy at a semiconductor surface by forming bonds, but the presence of a large number of surface states can completely overshadow any effects of doping near the surface. Thus, it is important to passivate the surface by removing most of the surface states. Because thermal oxidation could passivate the silicon surface, the first silicon MOSFET could be created in 1960. Electrons are strongly bound in the interfacial Si–O bonds and do not participate in conduction. Thermal oxidation can reduce the number of surface states by four orders of magnitude.

The excellence of a properly formed SiO_2–Si interface and the difficulty of passivating other semiconductors' surfaces has been one of the most important factors in the development of the worldwide market of silicon-based semiconductors. MOSFETs are typically produced on {100} silicon surfaces. Fewer surface states appear at this Si–SiO_2 interface, which has the fewest broken bonds. A widely used model for the thermal oxidation of silicon has been developed.

Applications

As microprocessors and memories move beyond computers to become embedded in communications and consumer products, e.g., cell phones and other wireless devices, other applications are emerging for silicon-based semiconductor technology. Predominant among them are flash memories, flat-panel displays, microelectromechanical systems (MEMS), and power electronics. New materials are beginning to be incorporated in silicon-based IC devices. Some of these, SiGe and SiC, are silicon-based semiconductors that offer advantages for higher performance or higher temperature operation. See also **Semiconductors: Compound Semiconductors**. It is also the case that, as the minimum feature sizes of devices shrink to nanometer dimensions, back-end processing of multilayer interconnects is becoming more important in determining IC performance. Lower temperature operation can improve both CMOS and interconnect performance while reducing the impact of subthreshold leakage currents and exponentially reducing Arrhenius-based degradation mechanisms. Nevertheless, the prospects for cryogenic operation are limited by refrigeration technology, even though IC cooling has become an increasing concern for high performance ICs.

Interestingly, even though silicon is an indirect gap material, the value of integrating light emission with silicon chips has led to several approaches for efficient light emission from silicon. One approach that has achieved an external quantum efficiency of 10% (comparable to standard III–V LEDs) involves implanting rare earths, eg, erbium or cerium, in a layer of silicon-rich oxide, which is silicon dioxide enriched with silicon nanocrystals 1–2 nm in diameter. Another approach uses the Raman effect to produce a continuous laser beam at a new wavelength, when driven by an external laser. The limits imposed by two-photon-generated free carrier absorption on stimulated Raman scattering in silicon waveguides were avoided by designing a PIN diode structure, which has a layer of intrinsic silicon in the middle of a PN junction, along a low loss silicon-on-insulator (SOI) rib waveguide. See also **Molecular and Supermolecular Electronics**.

Nonvolatile and Flash Memories. Volatility, the loss of memory when power is removed has been a concern since MOS SRAM and DRAM memory chips were introduced in the mid-1960s. Two concepts for nonvolatile memory (NVM) were introduced in 1967. Charge can be retained for over ten years when stored at 125 °C (257 °F) on a floating gate of polysilicon surrounded by oxide. Alternatively, charge can be stored in the gate insulator of a metal/nitride/oxide/semiconductor (MNOS) memory transistor. A 1 kb uv-erasable programmable read-only memory (EPROM) chip was introduced in 1971 shortly after 1-kb random access memory (RAM) chips were marketed.

Flash memories are generally fabricated as NOR or NAND arrays of memory cells. In NOR arrays, the drain electrodes of memory transistors are connected in parallel to bit lines, while their source electrodes are connected to a common source line. In NAND arrays, eight or more

memory transistors are arranged in series sandwiched between ordinary NFETs that allow selective connections to a bit line or source line. In both types of array, word lines connect a row of gate electrodes for the memory transistors.

Recently, flash memory has become the Moore's law technology driver, replacing DRAMs and microprocessors. With transistor densities doubling about every year, flash became a $4.8 billion market in 2004. More flash memory, in terms of the number of transistors, is expected to ship in 2005 than has been produced in the entire history of flash production to date. Flash chips are leading in the introduction of new technology. They are already using hafnium-based high gate dielectrics and will likely introduce new transistor structures beyond the 45-nm node. Infineon has built the world's smallest nonvolatile flash memory cell using finFETs with 20-nm gate dimensions. These could be used in 32-Gb flash memory chips.

Displays. Full-color flat-panel displays (FPDs) became a significant market as a necessary component of a growing mobile laptop or notebook computer market. The FPDs consist of an array of closely spaced, separately contacted picture elements or pixels. Thin-film transistor active matrix liquid-crystal displays (AMLCDs) have become the dominant technology for laptop computer displays. The AMLCDs sandwich liquid-crystal material between two plates of glass. One plate contains a matrix of thin-film transistors (TFTs); the other plate contains an array of color filters and polarizers. Assembly involves placing spacers and the injection of LCD material between the plates, followed by sealing the two plates together. In operation, the TFT connects the LCD capacitor, which is formed by the LCD material between electrodes on each plate, to a source line when the TFT is activated by a gate line. Each pixel is driven over a gray-scale range as the TFT MOSFET is driven from threshold to saturation. Amorphous-silicon TFTs have been used, despite their poor mobilities (<1 cm^2/Vs), because the glass plates require low temperature processing ($<500\,^\circ$C). Polysilicon TFTs, with mobilities $50-100\times$ higher, would be preferable, allowing driver inverters to be processed on the same plate, provided a suitable process can be found. Organic TFTs, using materials such as pentacene (≤ 1.7 cm^2/Vs), are being considered as well.

At this time, small AMLCD displays are ubiquitous on cell phones and cameras. Larger AMLCD displays are now common as flat panel computer monitors and televisions. Indeed, the hope of replacing cathode-ray tube (CRT) television displays with FPD displays was an original incentive for developing this technology. There are several competing large-screen FPD technologies. These include plasma FPD, projection FPD, and field emission FPD (FED). Plasma FPDs can be quite large (60 in. diagonal screen size) and emit light by forming a plasma discharge between two glass plates with phosphors deposited on one plate. They are $\sim$50% brighter than AMLCD FPDs. FEDs use an array of field emission microtips as cathodes that emit electrons onto phosphor stripes on a glass plate serving as an anode. The distance between the cathodes and anode is a few millimeters. Projection FPDs may use an array of rotatable micromirrors and are fabricated from silicon wafers using the techniques described in the next section. See also **Flat Panel Display Technology**.

Microelectromechanical Systems (MEMS). Micromechanics uses silicon as a structural material, using microelectronic fabrication techniques to micromachine micromechanical structures and machines. Although single-crystal silicon is brittle and fractures when its elastic limit is exceeded, it has a higher elastic limit than steel and remains strong under repeated cycles of tension and compression. Chemical etching techniques have been developed that allow formation of basic 3D elements, eg, pits, trenches, holes, diaphragms, and cantilevers. Anisotropic etchants, eg, potassium hydroxide (KOH), are particularly useful for *bulk micromachining* of silicon because the etch rate depends dramatically on crystal plane. For silicon, the KOH etch rate is $\sim$400:1 for {100}/{111} crystal planes. More recently, surface micromachining has become popular. *Surface micromachining* is based on the patterning of a thin sensor film, typically polysilicon, which has been deposited on a sacrificial spacer material, typically SiO_2, which is subsequently removed. Since deposited films for surface micromachining exhibit built-in stress, sensor and spacer thicknesses were limited to ~ 1 μm to facilitate integration.

Micromechanical applications include the fabrication of ink-jet nozzle arrays, gas chromatographs, and microgrooved heat exchangers for cooling semiconductor chips. Techniques have been developed for fabricating rotating gears and miniature motors.

Power Semiconductors. Power semiconductor devices cover a diverse range of applications from 100 W at microwave frequencies (microwave ovens) to 100 MW at low frequencies (motor drives or power supplies). Automotive electronics and switching power supplies require relatively low voltages (<100 V), but high current construction.

Avalanche breakdown sets a fundamental limit on the maximum operating voltage for power devices. Because depletion layer curvature increases the crowding of electric field lines and reduces the breakdown voltage, multiple-junction field rings or other termination techniques are used to reduce the depletion layer curvature and increase the breakdown voltage. Large device areas are required to handle large current flows. For example, a single power thyristor may require >400 cm^2. Large chip areas for a single device require careful attention to chip yields, which tend to decrease exponentially with chip area. More vertical channel structures, eg, VMOS, DMOS, or UMOS, offer higher performance than the surface channels of conventional MOSFETs. The surface of the chip is covered with an array of parallel MOSFET cell structures.

Silicon carbide, SiC, is a compound semiconductor composed entirely of Group 14 (IV) elements and is expected to have properties intermediate between those of silicon and diamond. Several polytypes of SiC exist, but homoepitaxial growth on 6H−SiC substrates has been preferred. Its high band gap leads to spectacular decreases in intrinsic carrier concentration which means that SiC devices should have excellent performance at high temperatures. Early application for SiC devices were as blue light-emitting diodes (LEDs) and UV photodiode detectors. This means that SiC is a desirable material for power devices, since higher current and voltage ratings can be achieved with higher temperature operation. However, much lower defect densities will be required to achieve the large device areas that power devices need.

SEMIDIAMETER CORRECTION (Sextant). When the altitude of a celestial object that is close enough to the earth to present a finite disk (e.g., moon, sun, planet) is measured with reference to the visible sea horizon or to an artificial horizon, other than that contained in the bubble sextant, it is more convenient to use the upper or lower limb (edge) of the disk than to estimate the center of the object. When solving the astronomical triangle using this measured altitude, as in determining position at sea, the position of the object given in the almanac is that of the center. Hence, to obtain the observed altitude of the center, a correction must be applied known as the correction for semidiameter. The correction is to be added or subtracted from that obtained with the sextant, depending upon whether the lower or upper limb of the object is observed. The value of the semidiameter is given in the almanac for the given date of observation. In using the moon for accurate determination of position, an additional factor, known as augmentation, must be considered due to the fact that the distance of the object from the observer varies with the altitude of the object. See also **Sextant**.

SEMIPERMEABLE MEMBRANE (or Semipermeable Diaphragm). A membrane or septum through which one (or more) of the substances composing a mixture or solution may pass, but not all.

In osmotic pressure determinations, semipermeable membranes permit the passage of a solvent but not of certain colloidal or dissolved substances. Many natural membranes are semipermeable, e.g., cell walls; other membranes may be made artificially, e.g., by precipitating copper cyanoferrate(II) in the interstices of a porous cup, the cup serving as a frame to give the membrane stability.

Semipermeable membranes are also used in the separation of gases. See Fig. 1. When a semipermeable membrane is placed in a gas mixture, being impermeable to gas 2 and allowing gas 1 to pass, the force exerted on it will equal the area times the partial pressure of gas 2 only. While there are no ideal semipermeable membranes for gases, there exist in practice reasonable approximations to them, such as incandescent platinum or palladium sheets, which can be penetrated by hydrogen but not by other gases. A film of water also acts as a semipermeable membrane for gases, since it is previous to NH_3 or SO_2 because of their solubility in water, but gases which are not easily soluble are held back.

See also **Desalination**.

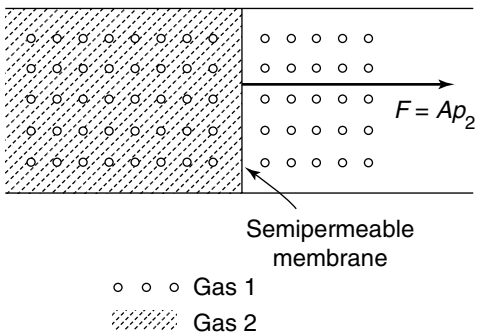

Fig. 1. Separation of gases by semipermeable membrane.

SEMISYNTHETIC HYDROCOLLOIDS. See **Food Additives**.

SEMITONE (Half-Step). The interval between two sounds whose basic frequency ratio is approximately equal to the twelfth root of two. The interval, in equally tempered semitones, between any two frequencies, is 12 times the logarithm to the base 2 (or 39.86 times the logarithm to the base 10) of the frequency ratio.

SENSIBLE TEMPERATURE. The temperature at which average indoor air of moderate humidity would induce, in a lightly clothed person, the same sensation of comfort as that induced by the actual environment. Sensible temperature depends on the air temperature; radiation from the sun, sky, and surrounding objects; relative humidity; and air motion. The wet-bulb temperature is often taken as an approximate measure.

SENSILLAE. The sense organs of insects. The term is usually applied to the integumentary sense organs of the group but it is also extended to include the scolophores on which organs of hearing and chordotonal organs are based, and the ommatidia and retinulae of the eyes.

The sensillae of other kinds include some form of cuticular structure, often a projection, associated with a nerve ending and in some cases with gland cells. These organs include some of tactile function and chemoreceptors, both of taste and of smell. In form, their external parts are classed as six types. (1) Placoid sensillae end in a thin porous plate or membrane covering a canal. (2) Trichoid sensillae end with a slender seta. (3) Basiconic sensillae have a conical protuberance. (4) Styloconic sensillae have a fixed conical base bearing subordinate projections. (5) Coeloconic sensillae end with a depression containing a conical projection. (6) Ampulliform sensillae end with a slender projection in an expanded chamber at the inner end of a long tubule.

Tactile sensillae are distributed over the entire body but are often much more abundant on the legs and sensory appendages such as antennae and palpi. Organs of smell are often abundant on the antennae and in some species appear to be limited to these appendages. There is some possibility that they may occur on other parts of the body. Organs of taste are undoubtedly associated with the mouth parts, but they are supposed to be present in aquatic insects on the outer surface of the body as well.

SENSITIVITY (Instrument). With reference to industrial and scientific instruments, the Instrument Society of America defines *sensitivity* as the ratio of a change in output magnitude to the change of input which causes it after the steady-state has been reached. Sensitivity is expressed as a ratio with the units of measurement of the two quantities stated. The ratio is constant over the range of a linear device. For a nonlinear device, the applicable input level must be stated.

Sensitivity has been used frequently to denote the *dead band*. However, its usage in this sense is deprecated since it is not in accord with accepted standard definitions of the term. See also **Dead Band (Instrument)**.

SENSITOMETRY. The measurement of the light response characteristics of photographic film under specified conditions of exposure and development.

SENSOR (Measurement). A device that detects or senses the value or change of value of a variable being measured. The first link in the measurement-system chain. In some cases, the sensor essentially comprises the total measurement system, as in the case of a liquid-in-glass thermometer where complete measurement is accomplished by calibrating a capillary column connected directly to the temperature-sensitive thermometer bulb. In other instances, the output of the sensor may be converted from one form of energy to another (for example, mechanical motion transduced to an electrical voltage or current) and amplified and conditioned one or more times before a useful output signal for display, recording, or control is obtained. There are hundreds of different kinds of sensors to detect changes, ranging over dozens of major variables. The term *sensor* is essentially synonymous with detector or primary element.

SENSORS. Sensor technology is being revolutionized by advances in microelectronics and optoelectronics. The newer sensors are demonstrating improvements in the operation, reliability, safety, and efficiency of many engineering systems. Perhaps the most familiar consumer example of this technology is found in automobiles, where silicon-micromachined pressure sensors, coupled to an electrochemical oxygen sensor, allow the engine management computer to provide the correct fuel and spark parameters for smooth, low pollution operation. Some automobiles include rotation rate sensors for antilock brakes, fluid flow sensors for gas mileage computation, accelerometers for air bag deployment and antiskid operation, proximity sensors for anticollision and temperature sensors for closed-loop temperature control of the passenger area. Development of other sensors for safety, comfort, and pollution control are underway.

Increasingly, the word sensor is used interchangeably with, or in place of, the word transducer to represent the conversion of one type of energy into another. The word actuator, however, refers to a distinctly different set of devices capable of activating a device upon receiving an appropriate signal. Sensors and actuators may be found as part of a system on a single piece of silicon.

Sensor systems of the new century almost always include data acquisition capabilities. Because of the low cost of computers, microprocessors, analogue–digital converting circuit boards, and other peripherals, the concept of large arrays of distributed sensors has become commonplace. The sensor itself is often the weak link in such a system, partly because the investment in sensor technology has been dwarfed by the development of microelectronics technology, but also because of fundamental differences in the nature of the problem. Personal computers deal with a relatively limited set of physical variables, i.e., principally the flow of electrons through semiconductors and metals. With the exception of some impressively precise and sophisticated electromechanical engineering for disk drives and printers, the means of computer input and output are relatively minor extensions of extremely well-developed technologies: the typewriter keyboard, the cathode ray tube, and sometimes audio speakers.

In contrast, various sensors are expected to respond in a predictable and controlled manner to such diverse parameters as temperature, pressure, velocity or acceleration of an object, intensity or wavelength of light or sound, rate of flow, density, viscosity, elasticity, and, perhaps most problematic, the concentration of any of millions of different chemical species. Furthermore, a sensor that responds selectively to only a single one of these parameters is often the goal, but the first attempt typically produces a device that responds to several of the other parameters as well. Interferences are the bane of sensors, which are often expected to function under, and be immune to, extremely difficult environmental conditions.

Although it is possible to obtain, manipulate, display, and act on huge amounts of data, the degree to which such data are meaningful often hinges on the reliability of the sensor itself. The pervasiveness of inexpensive microprocessors has also freed sensor technology to exploit phenomena that give logarithmic and other nonlinear responses to measurands. In some commercial sensors, the calibration curves for the individual sensors are stored in an embedded memory chip so that when the sensor is plugged into a system the correct sensor values are transmitted automatically. This standard is now called TEDS (Transducer Electronic Data Sheet) following the IEEE P1451.4 standard. One problem not solved as of 2005 by computer technology is a sensor output that is not repeatable or predictable (eg, due to baseline drift or change in sensitivity). Automated or automatic calibration is a partial solution to this problem, however, manual recalibration against standards is commonly used to correct this problem.

In the field of chemical sensors, the revolution in software and inexpensive hardware means that not only nonlinear chemical responses can be tolerated, but incomplete selectivity to a variety of chemical species can also be handled. Arrays of imperfectly selective sensors can be used in conjunction with pattern recognition algorithms to sort out classes of chemical compounds and their concentrations when the latter are mixed together. These arrays are sometimes called “electronic noses” and there has been considerable recent research interest in them. Since Sept. 11, 2001 there has been a new urgency in the development of sensor technology, particularly chemical sensors, driven by homeland security concerns. The inadequacy of portable anthrax detection technology was demonstrated by the mail anthrax attacks. The detection of explosive devices, particularly at a distance, is being emphasized, as is the detection of chemical weapons in R&D programs. Although progress in improved technologies for these areas is promising in 2004, much remains to be done to protect us from these kinds of attacks.

Decision-Making Tool for Sensor Technology

The rapid advances in sensor technology have increased the difficulty of the task of finding the best sensor system for a given application. The sensor customer or engineer needs to be specific about defining the sensor problem to be solved, using language and descriptors that are commonly shared between the customer and a sensor technologist.

Many physical principles can be employed by different sensor vendors to obtain the same measurement. Represented among the sensor systems are mass spectrometers, gas chromatographs, electrochemical cells, thermal conductivity cells, Raman scattering instruments, metal-oxide semiconductors, and pellistor (catalytic material-coated wire) sensors. To the process of sensor selection, the engineer brings specifications such as cost, size, weight, sensitivity, selectivity, and lifetime. The engineer must also specify the environmental conditions to which the sensor system is to be subjected: high or low temperature, vacuum, corrosive chemicals, vibration, etc. The specifications can be cast in the form of descriptors and matched against each vendor’s performance specifications. No common database for performance specifications is available as of this writing (~2006), and often the literature for each vendor must be compiled at a cost of much time and effort. Performance under hostile conditions is often not available, forcing the sensor engineer into a test program to verify the commercial sensor’s performance. In many cases, all the commercially available sensor systems fail to meet the specifications, leaving the engineer with the choice of redefining the specifications or launching a development project to fabricate a sensor system that solves the problem.

Developing a new solution may take the form of a modification of sensors already available or using the sensor principles of an available sensor, but modifying it to meet the specifications. On the other hand, new principles and manufacturing techniques may be explored in a long-range project to yield improved sensor performance. There is a large and growing research and development (R&D) effort in sensor technology because many engineers see that the advances in microelectronics, optoelectronics, and biotechnology are pointing the way to sensor performance unobtainable with commercially available sensor systems.

An important part of the decision-making tool flow chart is the redefinition of the specifications by the sensor customer after the surveying and testing of commercial sensor systems. This process almost always involves a downgrading of the expectations of the sensor customer, but it can also force a realistic evaluation of what sensor information really needs to be made available and at what cost.

In an era of inexpensive, batch-processed sensors, the concept of throwing away the sensor element, i.e., the transducer, actually becomes cost effective. An example would be the miniature electrochemical cells on a paper test strip for monitoring blood glucose. The instrument for measuring the electrochemical current may be relatively expensive, but each test strip costs only pennies, in spite of the apparent complexity of having screen-printed electrodes with a membrane containing dry glucose oxidase. Under long-time exposure to blood, this sensor no longer gives the calibrated electrochemical current level for values stored in the reader memory. Thus the sensor, not adequate for closed-loop control of an implanted insulin pump, is adequate for a quick, one-time reading of glucose in a fresh drop of blood.

Another important path is the short-term implementation of proven concepts. Often it is the packaging, not the sensor itself that fails in the test environment. An old sensor may be improved by application of more rugged packaging, encapsulation, wiring, etc. When all else fails, however, the customer may have to fund longer-term directed research and development on unproven sensor concepts. The strategy for this kind of R&D involves a strongly interdisciplinary activity, combining materials science, electrical engineering, chemistry, packaging science, etc.

Sensors Based on Silicon Processing Technology

The art of batch processing has brought the silicon-based integrated circuit (IC) and related electronic components to an almost unbelievably low cost. See also **Integrated Circuit (IC)**. A digital watch, which could not be purchased at any price in 1970, could be had for <$10 retail in 2004. The watch contains integrated circuits, a quartz crystal oscillator, a liquid crystal (LC) display, a battery, and the case. For a somewhat higher price, watches having sensors for temperature, barometric pressure, altitude, compass direction and global positioning data were available.

The tools for the revolution in new sensors include micromachining, batch processing, integrated sensors, readout and networking electronics, light-emitting and detecting structures, fiber optics, etc. This revolution has led and is leading to new applications of old fields of science from mechanics to physical chemistry, fluid mechanics, electrokinetics, capillary action, etc. These principles are being applied in a micro/nano-scale world, where batch processing means inexpensive, rugged systems. Nanomaterials are under intense development and may provide sensor materials with unprecedented sensitivity and stability. See also **Nanotechnology**.

The most commercially successful silicon-based sensors are the photodetectors. See also **Photodetectors**. These are found in video cameras, security systems, ionizing radiation detectors, and many other applications. Photodetectors, closely related to solar cells in the principles of operation, all depend on light and ionizing radiation creating electron–hole pairs in the semiconducting material. There are many ways that the presence of the excess number of electron–hole pairs can be monitored. The simplest is the observation of a change in electrical conductivity, ie, photoconductivity. Ingenious schemes involving the storage of photoelectrons or holes are used to make the very sensitive charge-coupled device (CCD) arrays.

There are also a large number of photodetectors made from semiconductors other than silicon. Gallium arsenide, GaAs, and its alloys are the most common because the wavelengths to which they are sensitive can be widely varied, and light-emitting sources such as light-emitting diodes (LEDs) and lasers can be made from the same materials. The compact-disk player is a good example of the common use of both a semiconductor photoemitter and detector.

One of the fastest growing areas of sensors based on silicon involves the use of micromachining to fabricate the sensor. The largest commercial markets are for micromachined pressure sensors and accelerometers. See also **Accelerometer**. Chemical etching of the silicon is the key technology for the fabrication of these sensors. Isotropic etching refers to a process in which the etch rate of the materials is uniform in all directions. Anisotropic etching refers to etch rates that depend on the crystallographic orientation of the silicon wafer. Anisotropy ratios of 400:1 are possible for special directions. Doping of the silicon can have a large effect on the etch rate, and layers of different materials, such as SiO_2 and Si_3N_4 can have different etch rates. For pressure sensors, thin diaphragms of Si or related materials are etched into the wafer. See also **Pressure**.

Many of the variations developed to make pressure sensors and accelerometers for a wide variety of applications have been reviewed. These sensors can be made in very large batches using photolithographic techniques that keep unit manufacturing costs low and ensure part-to-part uniformity. A pressure differential across these thin diaphragms causes mechanical deformation that can be monitored in several ways: piezoresistors implanted on the diaphragm are one way; changes in electrical capacitance are another.

A smart sensor is loosely defined as a sensing device with built-in intelligence that usually involves some kind of digital signal processing. Because the sensor is already being batch-fabricated on a silicon wafer, it seems natural to create the signal-processing electronics on the same chip as the sensor itself. Some devices based on this technology are commercially available.

Pressure sensors that give temperature-corrected, linear, analogue voltage output are available from Motorola and other manufacturers. In such sensors, the on-chip electronics correct any temperature effects and nonlinearities in the output of the piezoresistors. The on-chip electronics replace a shoebox-size collection of printed circuit boards. The price of this kind of smart sensor is considerably <$100. The integration of a large amount of circuitry on the chip allows functions like amplification, offset correction, self-testing, autocalibration, interference reduction, and compensation of cross-sensitivities.

The integration of standard integrated circuitry and a sensor is not always a trivial extension of the IC process, because the processing steps involved in fabricating the sensor may be incompatible with the correct functioning of the IC. An alternative is the hybrid package where the sensor chip and the signal-processing chip are fabricated separately and then glued together in the same package. There are a number of methods for connecting the leads from the sensor chip to the signal-processing IC. The hybrid method may be more expensive to package, but the integrated smart sensor may entail expensive and time-consuming process development to implement the ultimately less expensive final chip.

Even the tight controls in silicon integrated circuit manufacturing are not yet sufficient to produce absolutely identical sensors on a single wafer. Calibration of the final product is usually necessary, often by adjusting the value of a circuit element on the IC such as a resistor. The calibration process can be automated, but it still adds to the cost of batch-fabricated sensors. Clever means of self-calibration, particularly in field use, are constantly being sought.

Silicon microelectronics are often touted as giving the most sensitive and stable measurements of physical phenomena, e.g., charged particle detectors that can record a single X-ray photon or beta particle. In the realm of chemical detection, biological systems unequivocally outperform all of the microelectronically based chemical sensors in terms of sensitivity and selectivity. One of the best studied examples of biological chemical detection is the sex attractant receptor of moths.

A silicon-based sensor that operates on a similar principle is the chemically sensitive field-effect transistor (ChemFET) http://microfab.utah.edu/TechnologyLibrary/ChemFETs/Technology_Description.html. The channel through which the electrical current flows is a very thin (~10-nm) layer in the silicon crystal near a planar interface with an oxide of silicon that is thermally grown on the crystal. This interface has received an enormous amount of interest because it forms the basis for most active devices in integrated circuits. The very high sensitivity of the ChemFET is in part a result of it acting as a chemical amplifier. In these small devices, as few as 10^6 hydrogen atoms occupying interfacial sites can cause an order of magnitude increase in conductivity.

ChemFETs have been fabricated for the detection of a wide variety of chemical species. In the gas phase, catalytic metal gates (field plates) have been used to sense hydrogen, ammonia, ethanol, formic acid, ethylene, carbon monoxide, and many other molecules. Ion-conductive liquids, usually water, can also form the field plate, and pH-sensitive dielectric layers have led to commercially available pH sensors. Other ions can also be detected by placing various kinds of ion-sensitive membranes on the dielectric. Detectors known as biosensors have been fabricated by placing

membranes containing immobilized enzymes on the dielectric. See also **Biosensors**.

Technologies Other than Silicon

Another emerging physical transduction technique involves the use of acoustic waves to detect the accumulation of species in or on a chemically sensitive film. This technique originated with the use of quartz resonators excited into thickness-shear resonance to monitor vacuum deposition of metals. The device is operated in an oscillator configuration. Changes in resonant frequency are simply related to the areal mass density accumulated on the crystal face. These sensors, often referred to as quartz crystal microbalances (QCMs), have been coated with chemically sensitive films to produce gas and vapor detectors, and have been operated in solution as liquid-phase microbalances. A dual QCM that has one smooth surface and one textured surface can be used to measure both the density and viscosity of many liquids in real time.

Another class of acoustic wave sensors uses surface acoustic waves (SAWs) to probe the accumulation of species in a surface film. These devices use interdigital electrodes that are photolithographically formed on the surface of a piezoelectric crystal to excite and detect the surface wave.

The acoustic wave gravimetric technique can be extended to liquid-phase sensing in one of two ways. Because the SAWs surface-normal displacement component generates compressional waves in a contacting liquid, excessive attenuation of the SAW occurs, rendering it unsuitable for liquid-phase measurements. A mode having exclusively in-plane surface displacement, such as the shear-horizontal acoustic plate mode, can, however, be used successfully. Shear waves propagate poorly in liquids, so attenuation is minor. The quartz thickness-shear resonators described also have no surface-normal displacement and thus function in contact with liquids. A second alternative is to use an acoustic mode of velocity slower than that of sound in the contacting liquid, such as the Lamb wave, which is described in detail in the literature.

A number of gas and vapor sensors have been realized by placing chemically sensitive films on SAW devices and relying on their extreme mass sensitivity. The first such sensor, reported in 1979, detected a range of organic vapors utilizing thin films of vacuum grease, oils, and waxes commonly used in gas chromatography. See also **Chromatography**.

Optical fibers offer a number of advantages for chemical and physical sensing. This technology offers long-distance telemetry, freedom from electromagnetic interference, and small size, ie, approximately that of a human hair. Furthermore, the basic components necessary for sensor applications are being developed by the optical communications industry. Indeed, optical communications systems and optical sensors have the same functional design. Both need a light source, a detector, and a method of transmitting the light from the source and to the detector, namely, the optical fiber. For optical communications, a modulator is used to impose the information to be transmitted on the light beam. For optical sensing, the sensing element replaces the modulator and again imposes information on the light beam.

A successful chemical microsensor in use is the oxygen sensor found in the exhaust system of almost all modern automobiles. It is an electrochemical sensor that uses a solid electrolyte, often doped ZrO_2, as an oxygen ion conductor. The sensor exemplifies many of the properties considered desirable for all chemical microsensors. It works in a process-control situation and has very fast ($\sim$100 ms) response time for feedback control. It is relatively inexpensive because it is designed specifically for one task and is mass produced. It is relatively immune to other chemical species found in exhaust that could act as interferants. It performs in a very hostile environment and is reliable over a long period of time.

The success of the O_2 sensor has made the auto manufacturers, regulators, and environmentalists anxious to extend chemical sensing to a variety of tailpipe gases, notably CO, NO_x, and short-chain hydrocarbons. Considerable research and development is needed for these molecules to be monitored in the hostile exhaust system environment.

Ion-selective electrodes and amperometric cells have had a long history of success in a wide variety of applications. A microelectronics-inspired revolution is also occurring in these devices, brought about by the advent of photolithographically defined arrays of microelectrodes on planar substrates.

Another kind of conductometric sensor that is commercially available and has growing sales is formed from ceramic semiconducting metal oxides. The most common type of sensor consists of a thin porous film of tin oxide, SnO_2, deposited with a heater and electrodes to monitor the metal oxide conductivity. These sensors are often called Taguchi gas sensors, after the inventor. They are primarily used in small stand-alone sensor packages for detecting hazardous gases such as carbon monoxide and natural gas, i.e., methane and butane, leaks.

SENSORY ORGANS. Structures in the animal body that are influenced by certain factors in the environment. Also known as receptors. The action of the environmental factor on the living substance is known as a stimulus. It results in the transmission of a nerve impulse to some nerve center and from this point may influence appropriate reactions of the animal or may be stored in memory. Special sense organs are found only in animals with nervous systems. Their development involves high specialization in some phase of the general property of living matter called irritability, and to some extent this property persists in all living tissue, whether nervous or sensory or not.

Stimuli arise from contacts with solid objects, from chemical compounds, either dissolved or in the gaseous state, from the incidence of light rays, and from factors which damage the body. It is known from various evidences that some animals perceive factors to which human organs are not sensitive, but as far as is known, the only stimulating factors are in the following groups.

Contact results in variable pressures to which organs of several kinds are sensitive. In vertebrates tactile corpuscles and other similar structures located in surface tissues may be classed as organs of touch. They are sensitive to simple pressure and give rise to images of form through the varying pressures due to uneven surfaces and gross contours. Since sound waves are due to rhythmic compression of the air, the ears and other auditory organs such as those of insects are also sensitive to pressures,

but only to fluctuations of relatively high frequency (in man 30–30,000 per second). Between auditory organs and simple organs of touch are the lateral line organs of fishes and the chordotonal organs of insects, both related in some anatomical details to the auditory organs of the groups to which they belong. These organs are supposed to be sensitive to fluctuating pressures of lower than auditory frequency.

Tactile organs are also closely allied to sensory organs of insects, which apparently enable them to avoid obstacles when flying. Supposedly, these organs are sensitive to the changes of air pressure, often extremely delicate, resulting from approach to objects. They are located in the wings.

Dissolved substances stimulate organs of taste and gases or vapors act on organs of smell (olfactory organs). In the vertebrates the olfactory organs are associated with the nasal passages or occupy a similar position; nasal structures of fishes are limited to the olfactory function. Vertebrate organs of taste are known as taste buds and are located in the oral cavity principally, although aquatic forms may have them also in the skin. Sensory organs of this class in the invertebrates are extremely varied. Some are known as sensillae. In addition to organs of taste and smell, a general chemical sense is recognized. It is resident in various surface layers and is the least sensitive of the group. These sense organs are known collectively as chemoreceptors.

The varied integumentary sense organs of the human body are known to include some sensitive only to heat, cold, or pain. These organs may be the free nerve endings found in the skin. It has been suggested that pain may also result from overstimulation of other types of sense organs.

Sense organs that are stimulated by light are familiar to us in our own eyes. From this stage of complexity they range downward to simple light-sensitive cells. The transition includes organs capable of perceiving fluctuations of light, the direction from which it comes, and movements, as well as organs which form images in varying degrees of precision.

In contrast with sense organs of the kinds mentioned, which are classed as exteroreceptors, the body contains others called interoceptors. They are the source of sensations of hunger, thirst, nausea, and pain. Other interoceptors in the muscles, joints, and tendons are associated with the maintenance of equilibrium and are classed as proprioceptors. They are probably subject to varying pressure due to tension of muscles and shifting of the weight of the body. The semicircular canals of the inner ear of vertebrates are also organs of equilibration.

Organs of many invertebrates, such as the tentaculocysts of jellyfishes, can be interpreted only by experimental evidence. By testing the animal with different stimuli definite conclusions can often be drawn from its reactions. In most cases there is evidence of functions like those of our own sense organs.

All sense organs consist of nerve endings associated with various specialized cells or tissues. The nerves are not limited to one type of stimulation but their response may be identical under various stimuli. Thus a mechanical shock to the eye produces a sensation of light. The nerve fibers leading from the sense organ toward the central system are sensory or afferent.

SENSORY RECEPTOR. Specialized dendrites of certain neurons (sensory neurons; see also **Central and Peripheral Nervous Systems**), which are sensitive to some physical state such as stretch, temperature, or chemical environment, e.g., stretch receptor, cold receptor, etc. In the case of the visual, auditory, and olfactory systems the dendrites of the sensory nerve fiber form a synapse with a specialized sensory cell which is highly sensitive to the given physical agent, e.g., rods and cones of the retina are specifically sensitive to light.

Some receptors lie within the body (*interoceptors*) and some are on the surface (*exteroceptors*). It is the function of receptors to initiate sensory impulses.

SEPALS. Sepals are the outermost organs of a flower. They are sterile and leaf-like and protect the flower in bud.

Evolution, Structure, and Diversity

The outer whorl of the perianth in flowers called the calyx is made up of segments called *sepals*. The calyx is usually green and leaf-like in texture — emphasizing the homology of sepals to leaves. Bracteate sepals like those found in roses are particularly leaf-like. Their homology to leaves is emphasized by the presence of an extra appendage, a stipule like that possessed by many leaves. The epicalyx is a whorled fringe around the calyx. The epicalyx is stipular in origin formed by the fusion of a stipule on each side of the sepals or by the stipules of the outer sepals. See also **Flower**; and **Plant Anatomy**.

The Difference between Sepals and Petals. One distinction that can sometimes be applied is that petals have a single main vein but sepals have several. Petals are often clearly derived from sterile stamens but alternatively they may be derived from sepals. In practice it may be difficult to determine what is a sepal and what is a petal. In peony, *Paeonia*, for example, the sepals and petals are produced in a single continuous spiral and the petals have as many veins as the sepals. See also **Petals**.

Another distinction between sepals and petals is that sepals are green and petals are brightly colored. However, showy sepals are quite common, especially in some families like the Verbenaceae. In *Clerodendron* (tropical or sub-tropical trees or shrubs) a white inflated calyx provides a contrasting background to the smaller bright red corolla. In *Petraea* the corolla soon falls but the beautiful hanging tresses of mauve or white star-shaped calyces are long-lasting. In *Hydrangea* the outer flowers of the inflorescence consist of only a much expanded showy calyx. Double flowered garden cultivars have the majority of flowers like this. In some species, like *Alchemilla*, the lady's mantle, there are two whorls, the inner showy and the outer protective as if they are a normal corolla and calyx, but in fact the outer ones are an epicalyx, and the inner are sepals. In the currant *Ribes* the calyx is large and showy and the small petals alternate with the sepal lobes.

In many flowers, including most monocots and many paleoherbs and basal eudicots, a traditional distinction between the corolla of petals and calyx of sepals is arbitrary. In these circumstances it is more practical not to make a distinction but simply to describe one or more whorls of perianth made up of segments which are sometimes called *tepals*.

Function

The calyx has a protective function. This protection is maximized by the overlap of the sepals or by their hairiness. Sepals confer greater protection by greater breadth and overlap. In contrast to the showy petals, sepals are relatively thick, have cells with thicker cell walls and have fewer intercellular spaces. The sepals frequently have collenchymatous (collenchyma) or sclerenchymatous (sclerenchyma) cells present. They may be rich in chemical compounds that discourage predation like tannins or have crystals or sclereids. The calyx may secrete a mucilaginous liquid that protects the developing bud. See also **Collenchyma**; **Sclerenchyma**; and **Shoots and Buds**.

The fusion of the calyx into a single protective layer makes protection more efficient. An extreme kind is the woody calyptra, which is a kind of hood formed by the sepals. It is found in *Eucalyptus*. It splits off around its equator for the flower to open. Hairiness or a glandular surface also offers protection. Sepal nectaries encourage ants to guard the flower.

Often the protection sepals confer is transitory. In some flowers, which are called *caducous*, the sepals fall off as the bud opens. Poppies in the family Papaveraceae are one example. In the Fumariaceae the paired bract-like sepals are small and do not enclose the flower in bud. However, usually sepals are persistent in the flower and then they may give rigidity to the flower or protect the basal part of the flower. In some species the sepals remain green and photosynthetic even into the period of fruit formation. See also **Photosynthesis**.

In some species the sepals are colorful and showy. They replace functionally the petals that may be absent or provide an extra showy whorl as in the passion flower *Passiflora*. Sometimes the sepals are associated with nectaries. In some species these sepal nectaries are not associated with pollination but encourage the presence of ants, thereby protecting the flower.

The calyx may be persistent in the fruit, forming part of the structures that aid dispersal. It is a persistent coloured calyx that provides the showiness of the dried flower statice (*Limonium*). The fruit is dispersed by the wind inside the tubular papery calyx. In the daisy family, Asteraceae, the calyx is reduced to a ring of hair that provides the pappus, the plume that aids dispersal of the fruit in the wind. Persistent calyces often enlarge in fruit. The bladder of the Chinese lantern (*Physalis*) is a familiar

example. In the Dipterocarpaceae the sepals become large wings on the nuts. In some Dilleniaceae they become fleshy in fruit. See also **Fruit**; and **Seed**.

Genetic Control of Development. In development a gene called LEAFY switches meristems from producing leaf primordia to flower primordia. A mutant in this gene produces leaves instead of floral organs. LEAFY appears to switch on the expression of flower organ genes. There are three genes expressed in sequence. When gene A is expressed sterile leafy perianth segments are produced. When gene A ceases expression and gene C is expressed fertile floral organs are produced. If gene B is expressed at the same time as gene A petals and not sepals are produced.

Sepals are normally formed by a spiral phyllotaxy with the margins of adjacent sepals strongly overlapping. In contrast, petals are normally initiated simultaneously in a whorl. A consequence of spiral initiation is that the margins of the sepals overlap. The pattern of overlapping is called *imbricate* aestivation. A very common type of imbricate aestivation is called *quincuncial*: two outer sepals have both margins exposed, two innermost sepals have both margins tucked out of sight and one intermediate sepal has one margin exposed and one tucked away. An alternative imbricate aestivation is contort or convolute, with each sepal having one margin exposed and one tucked away. This pattern is more commonly found in the corolla. An alternative to imbricate aestivation is valvate where the margins of sepals meet without overlapping, but this is relatively rare in sepals though common in petals. See also **Flower**.

SEPARATION: MAGNETIC SEPARATION. The application of magnetic separators relies on the behavior of individual particles under the influence of magnetic forces. When exposed to a magnetic field, all materials are affected in some way. Those that are attracted to the magnetic field are designated ferromagnetic; those that are repelled by it are called diamagnetic. Ferromagnetic materials are attracted along lines of magnetic force from points of lower magnetic field intensity to points of higher magnetic field intensity. The particles frequently retain magnetic properties after the applied magnetic field is removed. Diamagnetic materials are repelled along the lines of magnetic force from points of high magnetic intensity to points of lower field intensity.

For practical applications, ferromagnetic materials are described as strongly magnetic (ferromagnetic), magnetic, weakly magnetic, or nonmagnetic. The limits of these groupings are not well defined and can vary in some mineral species. Only a few minerals are ferromagnetic, e.g., magnetite. The dividing line between high and low intensity magnetic fields has been selected by some investigators to be one Tesla (10 kG).

Magnetic separation methods are used either to separate valuable minerals from nonmagnetic waste, or magnetic impurities or other valuable magnetic minerals from bulk nonmagnetic values. Magnetically susceptible mineral particles occur as individually discrete particles; as partially liberated particles consisting of two or more minerals, one of which is magnetically susceptible; or as particles stained or coated by a magnetically susceptible mineral such as geothite staining quartz or kaolin.

Minerals normally considered nonmagnetic may be rendered magnetic by elemental substitution of a small amount of a magnetic element in the crystal lattice. Magnetic properties may also be affected by partial alteration in weathering effects.

Terms used in magnet evaluation are distinct from those in other processes and are defined as follows. Magnetic flux density refers to the number of magnetic lines of force passing through a unit area and is measured in Tesla (Gauss). One Tesla equals 10,000 Gauss. Magnetic field intensity, i.e., the magnetizing force that induces the lines of force in the specific area under consideration, is also measured in Tesla. In addition, the term magnetic field gradient is used and refers to the rate of change of magnetic flux density from areas of low intensity to points of high intensity. This term is measured in Tesla per meter (Gauss per centimeter). Ferrous particles placed in a magnetic field can serve to focus magnetic lines of force. Thus the particles can become sites of high intensity.

From the applications standpoint, magnetic equipment falls into one of four broad categories: tramp iron removal, magnetic particle separation and concentration, product cleaning, or eddy current separation on nonmagnetic metallics.

Tramp iron removal equipment is usually related to the material handling system involved. The most commonly applied magnetic separators include pulleys of the permanent magnetic and electromagnetic types applied in belt conveyor systems as head pulleys, suspended magnets applied over belt conveyor chutes or feeders, magnetic drums usually applied as a separately installed unit, plate magnets applied in or above chutes, and grate magnets applied in free-flowing product streams.

For magnetic particle separation and product purification, a selected plant area is determined and the feed is usually brought to that area for treatment. Magnetic separators applied include magnetic pulley separators, magnetic drums of several types, high intensity induced-roll magnetic separators, high intensity cross-belt magnetic separators, magnetic filters, wet high intensity magnetic separators (WHIMS), and special magnet types.

Eddy-current separation is usually applied to the removal of nonferrous metallics from product streams containing nonmetallic or nonmagnetic materials. These include applications such as material recovery facilities (MRF), e.g., aluminum can recovery from commingled containers; both preburned and ash municipal solid waste plants; and nonferrous recovery from scrap fragmentizing operations.

Trap Iron Magnetic Separation. Tramp iron magnetic separators are used to protect handling and processing equipment such as crushers, pulverizers, and material handling equipment. Separators are usually applied to dry material or material that contains only surface moisture. Iron coarser than 13 mm ($\frac{1}{2}$ in) is usually defined as tramp iron. The size and shape of the tramp iron, together with the material handling system in place or proposed, must be considered when selecting the protective magnet. Magnetic equipment developed for tramp iron removal may involve magnetic head pulleys, suspended magnets, magnetic drums, plate, or grate magnets.

Magnetic Concentration and Purification. The magnetic responsiveness of mineral particles provides a positive means of concentrating and/or purifying ores. The type of magnetic separator used is influenced by feed condition, i.e., wet or dry; the mineral to be concentrated or purified; the relative magnetic responsiveness of the mineral; the feed size; the purity to be obtained, in either the magnetic concentrate or the nonmagnetic product; the capacity to be handled; equipment operating and maintenance costs; and temperature of magnet applications.

Eddy-Current Separation of Nonferrous Metallics. The advent of material recovery facilities (MRFs) has increased the need for automatic removal of metallic values tenfold. Although many small facilities rely on hand sorting of commingled refuse, ie, glass, aluminum, tin, and plastic, as these plants grow in size, ways of reducing labor costs become more important. Suspended magnets are used to remove ferrous material. The removal of aluminum is relegated to a form of eddy-current separation.

SEPARATION PROCESSES. Separation processes are widely used for the recovery and purification of desired products in manufacturing operations in various industrial sectors including the chemical, petrochemical, petroleum, pharmaceutical, medical, food, dairy, beverage, paper, textile, metallurgical, and electronic industries, as well as for the removal of pollutants in pollution control and environmental protection.

See also **Absorption (Process)**; **Adsorption (Process)**; **Crystallization**; **Distillation**; **Extraction (Liquid-Liquid)**; **Extraction (Liquid-Solid)**; **Filtration**; **Ion Exchange**; **Ion-Exchange Resins**; **Membrane Separations Technology**; **Sedimentation**; and **Separation: Magnetic Separation**.

SEPARATION: SIZE SEPARATION. Size separation, the parceling of particulate material on the basis of size, is an important industrial unit operation that produces, on a continuous basis, coarser and finer streams from a feed stream in a single stage or multiple stages. Multiple stages of size-separation devices can be arranged to produce multiple streams of differing degrees of fineness, such as various grades of aggregates or coals. Multiple staging, i.e., multiple stages combined with blending, is also practiced to produce two streams, in the same manner as a single-stage separation, except more efficiently. Examples are the degritting of starch or paper pulp. Size separation devices are also used in conjunction with other unit operations, such as closed-circuit crushing and grinding. See also **Starch**; **Paper**; and **Papermaking and Finishing**.

Devices for size separation fall into two general categories: those basically involving the probability of passing through an aperture and those that separate by forces of fluid dynamics. The former, probability size separation, is based on the repeated presentations of particles to uniformly sized apertures in screen decks. The latter, fluid-dynamic size separation, takes advantage of the interplay between gravity and drag forces. If the particles are conveyed in a liquid, the separation is termed wet sizing; if conveyed in a gas, the separation is termed dry sizing.

A method of presenting particle size data is as the cumulative fraction (or percentage) finer than (or coarser than) some size, termed a particle size distribution (PSD). The precise definition of particle size is, however, very difficult. It is usually defined on the basis of the size analysis method. Fluid-dynamic partitioning is also influenced by other particle properties such as relative density or shape, as is probability partitioning, though to a much lesser degree. Size separation implies that these properties are relatively constant among the particles, and that the size is the basis of the partitioning. If, on the other hand, there are several properties that influence the separation, then this is sorting and interpretation of the separation is not possible. In order to interpret the size separation, the particles must be grouped into subpopulations of common properties.

Screening devices are used to make coarser separations; that is, fine products having 95% passing ca 100-mm–50-μm size. Dry-screening devices have a lower recommended size of ca 500 μm. Wet-screening devices that produce 95% passing ca 500–50-μm size are continually being improved.

Fluid-dynamic separating devices, called classifiers, are used to make finer separations; that is, fine products having 95% passing ca 1000–5-μm size. However, different devices have different separating ranges. For example, hydraulic-settling classifiers based on gravity sedimentation principles produce fine streams in the range of 95% passing ca 1000–100-μm size. Hydraulic-centrifugal classifiers (hydrocyclones) based on multiple *g*-force sedimentation principles, produce fine streams in the range of 95% passing ca 500–5-μm size.

Generally, as the product size becomes finer, the capacity of the separating device decreases. Thus, there are devices that can be fed hundreds of metric tons per hour (MTPH) and produce a 95% passing 50-μm product; but a device that produces 95% passing 5 μm may have a capacity of ca 1 MTPH or less.

Screening. Screening is a process whereby particles are presented in an appropriate manner to a series of apertures of fixed dimensions that allow finer particles to pass through into the undersize, and coarser particles to be retained in the oversize. In addition to sizing, screens are used for desliming, i.e., the removal of very small particles from much larger ones by draining or rinsing; dewatering, ie, the removal of water from particles by draining; and prewetting, i.e., the addition of water to the particles by spraying. See also **Water**.

Wet Classification. The settling-pool group of fluid-dynamic separating devices (classifiers) consists of a rectangular tank having an inclined floor that creates a pool. Feed slurry is introduced at the side of the tank and the overflow of fine particles and water exits through an overflow weir and box arrangement. The coarse particles settle to the bottom and are discharged over the upper edge of the tank after being dragged up the inclined floor by some mechanism, such as intermittently operating rakes, continuously operating drag conveyors, or continuously operating spirals.

The length of time the particles stay in the pool determines the distance the particles settle in the pool. Thus, the feed entrance must be located so that the velocity of the pulp toward the weir, together with the distance, allows sufficient time for the fine particles to be carried out over the weir as the coarse particles settle out below. It is assumed that if a particle settles more than twice the overflow weir crest, it settles out as a coarse particle. The coarse particles are agitated and washed as they are conveyed up the inclined floor, thus reducing the amount of undersize particles carried out in the coarse stream. The pulp velocity, and hence time in the pool, can be varied by altering the weir geometry, the total volume flow, or the solids' concentration. All basically change the mean residence time, i.e., the ratio of the mass of holdup material to the feed rate, by varying the mass of holdup material or the feed rate. However, some changes may force the pseudo-free settling conditions more toward hindered settling conditions, thus giving an unexpected result. See also **Sedimentation**.

As the settling type of classifiers are used to produce finer size separations, the pool volume is increased. A settling-type classifier can be operated to produce cut sizes between 150 and 25 μm but having a corresponding decrease in the sharpness index from 0.5 to 0.2, apparently caused by the increased influence of turbulence. Also, the percentage of solids in the fine stream is reduced from 25 to 7% and the coarse stream percentage of water increases from 15 to 25%. This increases the apparent bypass percentage or void-filling material. In addition, because the maximum flow rate of the coarse stream is fixed for each device, the feed rate must be reduced, thereby reducing device capacity.

Hydrocyclones. Increasing the gravitational force by developing centrifugal force decreases the settling time of smaller particles. A centrifugal force can be imposed on particles by rotating the slurry of particles. The classifying hydrocyclone is designed to rotate the slurry of particles by introducing it tangentially into a cylinder, thereby achieving essentially free vortex motion. A second, smaller-diameter (20–40% of the cylinder diameter) pipe, called the vortex finder, is placed through the exact center of the solid top of the cylinder, extending substantially below the feed inlet but above the bottom of the cylinder. The slurry that exits through the vortex finder is termed the overflow and contains the finer particles. Attached to the bottom of the cylinder is an inverted truncated cone section, the included angle of which ranges from 10–30° and is typically 15–17°. The slurry that exits through the cone section (apex) is termed the underflow and contains the coarser particles. The hydrocyclone is the most popular industrial wet classifier.

Dry Classification. Pneumatic classification can be partitioned conveniently into coarse, i.e., fine products above 95% <100 μm; intermediate, ie, fine products ranging between 95% <100 and 30 μm; and fine, i.e., fine products below. Pneumatic classification, like hydraulic classification, balances the force of gravity with drag forces (counter flow) in order to bring about a separation.

The vane classifier is an example of a free-vortex counterflow classifier. The solids to be classified enter the outer cone dispersed and entrained in a gas stream. A cyclone flow pattern is imparted on the feed stream before it passes through the adjustable vanes into the inner cone. As the vanes are closed down, an increase in the centrifugal motion causes more of the larger particles to strike the inner wall of the inner cone and drop out. The finer particles remain in the gas stream, exiting through the centrally located exit conduit. For a pilot-scale twin-cone classifier, the sharpness index was constant for a set vane position.

SEPIOLITE. The mineral sepiolite or meerschaum is soft, white, light in weight, and occurs in clay-like nodular masses. It is a complex, hydrous magnesium silicate corresponding to the formula $Mg_4Si_6\ O_{15}(OH)_2{\cdot}6H_2O$. It crystallizes in the orthorhombic system; hardness, 2–2.5; specific gravity, 2; color, white, grayish white, sometimes a yellowish- or bluish-green; opaque. It is capable of floating on water, hence the name meerschaum or sea foam. It occurs in Asia Minor associated with serpentine and magnesite, and may be derived from the latter. Other deposits are in the Czech Republic and Slovakia, Morocco, and Spain; and in the United States in Pennsylvania and New Mexico. The name meerschaum is from the German. Sepiolite is from the Greek, meaning cuttlefish, referring to the similarity of the bone of that animal to the light, porous sepiolite. The material is used in the manufacture of smoking pipes.

SEPSIS. A toxic condition of the human body as caused by the spread of bacteria from a focal infection to other portions of the body. See also **Septicemia**. *Sepsis neonatorum* is an invasive bacterial infection that occurs in the first week of life, accounting for 10–20% of neonatal deaths, particularly in premature, low-birth-weight infants.

SEPTARIAN STRUCTURE. Mineralized irregular polyground joints or cracks in certain concretions. The structure resembles the pattern of cracks developed by desiccation of mud, and probably resulted from a similar cause — contraction due to desiccation of colloidal material.

SEPTICEMIA. A condition wherein pathogenic organisms circulate in the blood, causing fever and other symptoms of their presence. A number of years ago, this condition was rather aptly called "blood poisoning," a term which purveyed the grave significance of septicemia prior to the appearance of antibiotics and other effectual therapies. Septicemia persists as a serious complication of numerous acute infections, as caused by hemolytic streptococci, staphylococci, pneumococci, meningococci, color bacilli, and other pathogens. Portals of entry of these pathogens into the blood include the lungs, middle ear, the mastoid process, the skin, and the genitourinary tract. Although there are no consistent signs of septicemia, the condition is suspected when, during the course of an infection, a patient develops unusual fever, hemorrhages into the skin (purpura) or joints, symptoms of endocarditis, jaundice, and widespread abscesses. In pneumonia, meningococcus meningitis, osteomyelitis, and puerperal or post-abortion infections, the physician is on the alert for the development of the signs of septicemia. Whenever the complication is suspected, a blood culture is made immediately.

Acute septicemia is a major manifestation of meningococcal disease caused by *Neisseria meningitidis*. In nongonococcal infection of the female genital tract, anaerobic bacteria of a type found in the intestinal tract are frequently the causative agents of septicemia. These infections may involve vulvovaginal abscesses, tubo-ovarian abscesses, and pelvic peritonitis. Similar microorganisms are present following gynecologic surgery, parturition, and abortion. A dreaded complication of septic abortion is clostridial myometritis with septicemia. Septicemia is sometimes a complication which may occur in patients on hemodialysis. See also **Kidney and Urinary Tract**.

Since the availability of antibiotics and other drugs, the former high mortality from septicemia has been markedly reduced.

SEPTUM. A thin wall or partition. The term is applied to the radiating plates on the foot of the coral polyp, to the transverse partitions which subdivide the body cavity of the annelid worms into chambers, and to the partitions between chambers of the shell of Nautilus, among the invertebrates. Its most familiar use among the vertebrates is to designate the nasal septum which separates the right and left nasal passages, although it applies also to the partition between the right and left chambers of the heart and to numerous other structures.

SEQUENCE. A set of quantities $s_1, s_2, \ldots, s_n, \ldots$, called elements, which can be arranged in an order so that when n is given, the nth member of the sequence s_n is completely specified. A relatively simple type of sequence is a progression. The elements are usually arranged by matching them up, one by one, with the positive integers $1, 2, 3, \ldots, n, \ldots$. A common symbol for a sequence is $\{S_n\}$. Let N be an arbitrary positive number. If it can be chosen so that $N \geq |s_n|$ for all absolute values of the members of a sequence, then the sequence is bounded. If there is at least one $|s_n| \geq N$ it is unbounded. This definition applies to an upper bound but a lower bound can be described in a similar way. A sequence is convergent if it has a limit; divergent otherwise. For example, the sequence of integers $1, 2, 3, \ldots, n, \ldots$ is divergent.

Examples of other sequences are series, finite or infinite; infinite products; continued fractions.

See also **Progression**.

SEQUENTIAL ANALYSIS. The analysis of material derived by a sequential method of sampling, that is to say, it is the data, not the analysis, which are sequential.

In sequential sampling the members are drawn one by one (or in groups) in order, and the results of the drawing at any stage decide whether sampling is to continue. The sample size is thus not fixed in advance but depends on the actual results and varies from one sample to another. The sampling terminates according to predetermined rules which are decided by the degree of precision required. See also **Sampling (Statistics)**.

SEQUESTERING AGENTS. See **Chelates and Chelation**.

SEQUESTERING AGENTS (FOODS). See **Food Additives**.

SEQUOIA. See **Giant Sequoia**; and **Redwood (Coast)**.

SERANDITE. The mineral serandite is a hydrated manganese-sodium silicate corresponding to the formula $Mn_2NaSi_3O_8(OH)$, crystallizing in the triclinic system, of pseudo-monoclinic character. Color, rose-red, pink; transparent; brittle, and uneven fracture. Prominent basal and prismatic cleavage; vitreous to pearly luster. Crystals thick tabular or prismatic, and as intergrown aggregates. Occurs as superb crystals in a carbonatite zone in a host body of nepheline-syenite in association with analcime, aegerine, and other rare minerals at Mt. St. Hilaire, Quebec, Canada. Its only other known world occurrence is on the Island of Rouma, Los Islands, Guinea.

SERIAL LINE INTERNET PROTOCOL (SLIP). See **Transmission Control Protocol (TCP) / Internet Protocol (IP) Suite**.

SERIATE FABRIC. A geological term proposed in 1906 by Cross, Iddings, Pirsson, and Washington, for the texture of an igneous rock whose granular crystals form a complete gradation in size.

SERIES. An expression of the form $a_1 + a_2 + a_3 + \cdots + a_n + \cdots$ which may have a finite or an infinite number of terms. Its partial sums constitute a sequence $\{S_n\}$, where $s_1 = a_1, s_2 = a_1 + a_2, \ldots, s_n = \sum_{k=1}^{n} a_k$. If the number of terms in its partial sums is allowed to increase without limit, either: (a) S_n approaches a limit; (b) it does not approach a limit. In the first case, if $\lim_{n\to\infty} s_n = s$, then s is the sum of the convergent infinite series and one writes $\sum_{k=1}^{\infty} a_k = s$. If $\lim_{n\to\infty} s_n = \pm\infty$, the series is said to be definitely divergent to $\pm\infty$. It can also be indefinitely divergent, where M and m are upper and lower limits of the sequence and the series oscillates. A simple example is the alternating series, $S_n = 1 - 1 + 1 - 1 \pm \cdots + (-1)^{n-1}$, for its sum is either unity or zero, depending on whether n is even or odd.

Convergent series are generally the most useful type for practical applications (but see also **Asymptotic Series**), hence it is of great importance to test them for this property (see also **Convergence**).

Algebraic combination of series should not be made carelessly for it does not follow that the usual associative, distributive, and commutative laws of algebra will always hold. One important case is the Cauchy product. If

$$S_1 = \sum_{n=0}^{\infty} a_n \quad \text{and} \quad S_2 = \sum_{n=0}^{\infty} b_n$$

are absolutely convergent to the sums A and B, respectively, then the Cauchy product,

$$S_1 S_2 = \sum_{n=0}^{\infty} \sum_{i=0}^{\infty} a_i b_{n-1}$$

is absolutely convergent to the sum AB. This procedure is especially useful for power series, for if

$$y_1 = \sum_{n=0}^{\infty} a_n (x - x_0)^n \quad \text{and} \quad y_2 = \sum_{n=0}^{\infty} b_n (x - x_0)^n$$

then

$$z = y_1 y_2 = \sum_{n=0}^{\infty} \sum_{i=0}^{\infty} a_i b_{n-1} (x - x_0)^n$$

Similarly, a uniformly convergent series may be either differentiated or integrated, term by term. See also **Reversion of Series**.

SERIES MOTOR. See **Motor (Electric)**.

SEROUS GLAND. A gland that produces a watery secretion, in contrast with mucous glands, whose secretions are composed of or contain mucus. The term is used in connection with the salivary glands of vertebrates, which are partly serous and partly mixed. The serous gland cells are distinguished in part by their more granular cytoplasm and rounded nucleus, located near the middle of the cell.

SEROUS OTITIS MEDIA. See **Hearing and the Ear**.

SEROWS. See **Goats and Sheep**.

SERPENTINE. This is a group name for minerals encompassing two principal polymorphic forms: *chrysotile* and *antigorite*. This monoclinic mineral of hydrous magnesium silicate composition $Mg_3Si_2O_5(OH)_4$ is essentially a product of metamorphic alteration of ultrabasic rocks rich in olivine, pyroxene, and amphibole. Serpentine crystals are unknown except as pseudomorphic replacements of other minerals, e.g., after clinochlore crystals at the Tilly Foster Mine, Brewster, New York, Antigorite occurs as platy masses; *chrysotile* as silky fibers. Most massive serpentine rocks are composed essentially of antigorite. The hardness is 2–5, specific gravity ranges from 2.2 (fibrous varieties) to 2.65 (massive varieties). Color usually mottled green. The name *serpentine* stems from the mottled character, somewhat resembling the skin of a serpent. There is a greasy to waxlike luster in massive material; silky in fibrous material. The minerals are translucent.

Chrysotile fibers are the source of commercial asbestos, although fibrous amphiboles also contribute to similar usage. Asbestos is economically valuable for its incombustibility and low conductivity of heat, thus as fireproofing and insulating material. See also **Asbestos**.

Chrysotile deposits of economic value are found in Quebec, Canada, in the former U.S.S.R., and in South Africa. Minor occurrences are found in the United States in Vermont, New York, New Jersey, and Arizona. *Verd antique* marble (serpentine marble) is quarried extensively near West Rutland, Vermont.

ELMER B. ROWLEY, F.M.S.A. Union College, Schenectady, NY

SERTÜRNER, FRIEDRICH WILHELM (1783–1841). Friedrich Wilhelm Sertürner qualified as an apothecary in Paderborn, Westphalia, in 1803. He remained there and extracted meconic acid from opium. It was inactive, but ammonia treatment of the liquor from which it had been obtained precipitated a solid which Sertürner was able to crystallize from alcohol. This put a dog to sleep and was reported in 1805 in the first of several publications on morphium. The description of its "almost alkali-like character" surprisingly failed to capture attention. Further studies were carried out in Einbeck, where Sertürner had established his own pharmacy, resulting in 1817 in the publication of a method for preparing pure salts of morphium with a variety of acids. Sertürner and three companions, it was noted, nearly died after swallowing 100 mg of the drug. The paper caught the attention of the eminent chemist Joseph-Louis Gay-Lussac, who republished it in the renowned *Annales de Chimie*. In an editorial, Gay-Lussac emphasized the significance of the isolation of a product that could form salts with acids in an analogous manner to the plant acids that formed salts with alkalis. He astutely predicted the finding of more such compounds and suggested their names should end with the suffix "-ine." Morphium was renamed morphine and in 1818, Wilhelm Meissner proposed that plant alkalis be called *alkaloids*. By 1820 morphine, emetine, quinine, colchicine, and several other alkaloids were being used medicinally. Their introduction revolutionized therapeutics since physicians were at last able to rely on pure plant products of fixed composition.

SERVOMECHANISM. A closed-loop system which depends upon the feedback concept for operation. The terms *control system, regulator*, and *servomechanism* are often used interchangeably. There are some historical differences, but the distinctions frequently are fine. In terms of current usage, the terms servomechanism and regulator are gradually phasing out of the literature in deference to control system or controller.

Conventionally, for the servomechanism, it is assumed that the output or controlled variable is forced to be a preassigned function of the reference input, where the reference input is, in general, an arbitrary function of time. A typical example is a gun fire control system. Since the target is moving, the reference input (which could be a radar output signal of target position) must be variable. If the target is to be hit, gun position (controlled variable) must be forced to a preassigned function of the reference input. This characteristic of a servomechanism is contrasted with regulator operation in which the controlled variable is maintained substantially constant. Control of gas line pressure is an example of a regulator system. The reference input (desired value of line pressure) is a constant quantity. The system works to maintain the controlled variable (line pressure) at the desired

value regardless of user load requirements. From an analytical standpoint, there is very little difference between the two systems.

A servomechanism also has been defined as a feedback control system in which one or more of the system signals represent mechanical motion. Thus, a servomechanism usually is used to control an output position mechanically in response to input signal changes.

Similarly, a regulator has been defined as a device that maintains a desired quantity at a predetermined value or varies it in accordance with a predetermined plan. A controller is aptly termed a regulator when it is relatively simple in design, easy to apply, relatively inexpensive, and has comparatively coarse performance characteristics. There are exceptions, of course, where manufacturers of sophisticated equipment elect to term their products regulators rather than controllers. Normally, a regulator does not incorporate means for transmitting or receiving signals from remote locations, indication, or recording. Usually a regulator is close-coupled to the equipment that it is controlling. Often, regulators are self-contained, self-actuating without requiring external energy sources. They depend upon energy derived from the equipment or system that they are regulating. A regulator in this category is logically termed a self-actuated regulator, or self-operated controller. See also **Self-Operated Controller**.

SERVOMOTORS. Electric motors are widely used in industry for effecting desired speeds and motions of machines, the positioning of parts or machines, and indirectly to control draw, thickness, stretch, and a number of other variables that must be controlled. Thus, servomotors are integral parts of automatic control and automation systems.

Servomotor and Servosystem Design Trends[1]

Whether it be *X-Y* or point-to-point positioning, or a constant or variable speed requirement, an electric motor provides precise motion control in a diverse group of products, ranging from simple conveyors to more complex machine tools and computer peripherals. The more complex systems utilize a 4-quadrant servo drive system in conjunction with the servomotor. With emphasis on increased industrial productivity and reliability, numerous advances in servotechnology have been made in the comparatively recent past. Advancements are leading to more effective use of the microprocessor in servo loop control. This article explores trends in both servomotors and servosystems, and how these trends relate to applications when a manufacturing firm upgrades its facilities to reflect the philosophy of modern control and automation technology.

Industrial Motors — A Perspective

The direct current (D.C.) motor was one of the first machines devised to convert electrical energy to mechanical power. Origin of the D.C. motor can be traced to machines conceived and tested by Michael Faraday.

Since D.C. motor speeds can easily be varied, they are utilized for applications where speed control, servo control, and/or positioning tasks exist. Most small motors used in industry are alternating current (A.C.) motors. These motors are relatively constant-speed devices and are applied where speed *control* is not required. The speed of an A.C. motor is determined by the frequency of the voltage applied (and the number of magnetic poles). See also **Motor (Electric)**.

Alternating Current (A.C.) Motors

There are basically two types of A.C. motors: (1) induction, and (2) synchronous. If the *induction motor* is viewed as a type of transformer, with the stator as the primary and the rotor as the secondary, it becomes easier to understand its operation. The currents that flow in the stator induce currents in the rotor, and two magnetic fields are set up. These two magnetic fields *interact* to produce *motion*. The speed of the magnetic field going around the stator will determine the speed of the rotor. The rotor will attempt to follow the stator's magnetic field, but will "slip" when a load is attached. Therefore, induction motors always rotate slower than the stator's rotating field. The *synchronous motor* is basically the same as the induction motor, but with slightly different rotor construction. The rotor is either (1) self-excited (same as induction), or (2) directly excited to set up the rotor field. The salient poles (or teeth) construction prevents slippage of the rotor field with respect to the stator field. Thus, this type of motor always rotates at the same speed (in synchronization) as the stator field. A single-phase A.C. motor is not self-starting. They employ a starting mechanism in order to start rotation — in the form of a start winding or a capacitor in a winding. Thus both motor types, induction and synchronous, utilize stators with rotating magnetic fields. They suffer from low starting torque, slow acceleration, and torque breakdown at overload.

Direct Current (D.C.) Motors

In a D.C. motor, the stator field can be set up by either permanent magnetics or a field winding. Thus, in contrast with the A.C. stator field which is rotating, the stator field is stationary. The second field, the rotor field, is set up by passing current through a commutator and into the rotor assembly. The rotor field rotates in an effort to align itself with the stator field, but at the appropriate time (due to the commutator) the rotor field is switched. Thus, by this method the rotor field never catches up to the stator field. Rotational speed depends on the strength of the rotor field, i.e., the more voltage on the rotor, the faster the rotor will turn. Thus, the D.C. motor is straightforward — it has predictable speed-torque characteristics, and suffers none of the speed control problems associated with A.C. motors.

Brushless Motors

In recent years, there has been a trend to favor *brushless* motors. The brushless motor technology emerged in the 1930s, along with vacuum tube power technology, more sophisticated control systems, and the industrial needs for velocity control and position control of basic motors. The transistor became an efficient power-handling device in the 1950s when PWM (pulse width modulation) and PFM (pulse frequency modulation) techniques became practical. With subsequent developments of transistor circuits, analog operational amplifiers, low-cost logic components, memory arrays, and microprocessor chips, control systems became oriented toward the retention and processing of information and thus able to handle more complex calculations. In the 1970s, the development of new magnetic materials provided the opportunity to explore and to design innovation in terms of pulse-modulated D.C. motors. It was not until this rapid expansion of modern semiconductors and new magnetic materials, along with the requirements for upgrading existing products for the automation of industry, that brushless motor development and use began in earnest.

Motivations for considering the brushless motor include the desire for improved productivity, improved product requirements in terms of higher speed, greater acceleration/deceleration, reduced maintenance, reduced size, improved power-to-weight ratio, and increased reliability.

Operating Principle of Brushless Motors

A cross-sectional view of a brushless motor is shown in Fig. 1. Brushless motors are similar to A.C. motors in that a moving magnet field causes rotor movement or rotation. Both motor types use stator windings and have no brushes. Brushless motors are also similar to permanent magnet (PM) D.C. motors since they have linear characteristics. Also, both motor types use permanent magnets to generate one field. The brushless motor is, in essence, a *hybrid*, which combines the best attributes of both the A.C. and D.C. motors.

The configuration of the brushless motor most commonly used in contemporary systems is shown in Fig. 2(**a**). In this motor the rotor consists of permanent magnets and the stator consists of windings. These windings are termed "commutation" windings. By passing a current through a winding, a magnetic field is set up with which permanent magnets on the rotor interact. This results in rotation of the rotor. A representative family of modern brushless motors is shown in Fig. 2(**b**). Examples of brushless rotor assemblies are illustrated in Fig. 2(**c**).

Figure 3 illustrates, in simplified form, how rotation occurs. With a current passing through *winding 1* (Fig. 3(**a**)), a south pole is set up with which the permanent magnet will react and movement will begin. If, at the appropriate time, current is shut off in *winding 1* and turned on in *winding 2* (Fig. 3(**b**)), then the rotor will continue to move. By continuation of this timing sequence, complete rotation will occur as the rotor repeatedly tries to catch up to the stator magnetic field. In this example, the operation

[1] By John Mazurkiewicz, Manager, Application Engineering, Pacific Scientific, Rockford, Illinois.

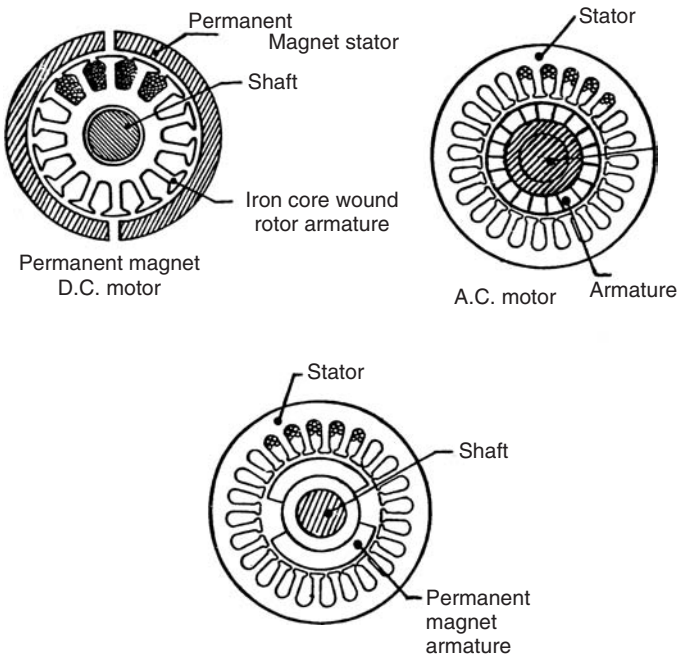

Fig. 1. Cross section of various types of electric motors used in servosystems.

is simplified for explanation by exciting only one winding at a time. In practical situations, two and sometimes three windings are energized at a time. This procedure permits the development of higher torques.

As indicated, if current is properly switched from winding to winding, the rotor will continue to rotate. Switching is accomplished in conjunction with a position sensor. Frequently, solid-state Hall-effect sensors are located on the shaft assembly. These extremely rapid sensors note the position of the shaft and provide an output signal. This output signal informs the motor's electronics when to switch current from winding to winding.

In comparing two motors that develop the same torque, the brushless type has advantages. Figure 4 illustrates this point by showing a locus of safe operating areas. The maximum speed is the maximum recommended top speed of the motor, determined by (1) commutator bar-to-bar breakdown voltage in a brush type motor, and (2) by mechanical centrifuge conditions in a brushless motor. The maximum temperature limit is determined by the motor's hot armature temperature. These are quite close inasmuch as the motors develop the same approximate stall torque. Operation above this line will result in the motor's armature temperature exceeding the recommended manufacturer's maximum limit.

Control of Brushless Motors

Control of the brushless motor is accomplished by incorporating two additional output stages over the conventional servo control design. Figure 5 illustrates a simplified block diagram. *Basic operation*: Once the "run" command is given, the binary decoder compares outputs from the Hall sensors (which Halls are *on*). For example, if the shaft is sitting at "zero", input to the logic circuit (Hall sensor output) informs the logic that Hall sensors #1 and #3 are *on*. The binary decoder interprets these data and outputs a binary code. In this example, the output code from the switch logic is a "5." This code will turn on appropriate OR gates, which turn on switches 3 and 2. The switches apply power from the voltage supply to motor windings (active legs T and R). As the motor rotates through 60°, the logic input will change state, as Hall #3 shuts off. The binary decoder output changes to a "1." This code will turn on appropriate OR gates, which turn on switches 2 and 5. (Note that during this transition, switch 2 has remained on, whereas switch 3 shuts off and switch 5 is turned on.) Again, the switches apply power to legs R and S. As the motor continues to rotate, the sequence continually progresses, changing current flow through the motor windings until complete rotation through 360° is attained, after which the sequence repeats. As current flow changes from winding to winding, the magnetic field also changes. In effect, the magnetic field is sequencing around the stator. The permanent magnet rotor will try to catch up to the field created, but never will — due to switching of the magnetic fields as a result of the Hall-effect sensor signals.

Thus, brushless rotation depends upon the stator field rotating (similar to A.C. motors). The significant difference is the presence of internal shaft position feedback in the brushless design. This element gives brushless motors their linear and predictable speed-torque characteristics (similar to D.C. motors).

Microprocessors in Servo Control Systems

Several types of controls have been developed over the years for D.C. motors, including SCR (silicon-controller rectifier), linear, pulse-width

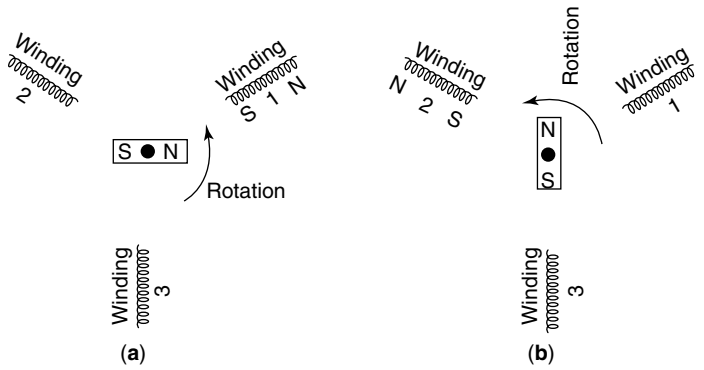

Fig. 3. Basic rotation of a brushless motor.

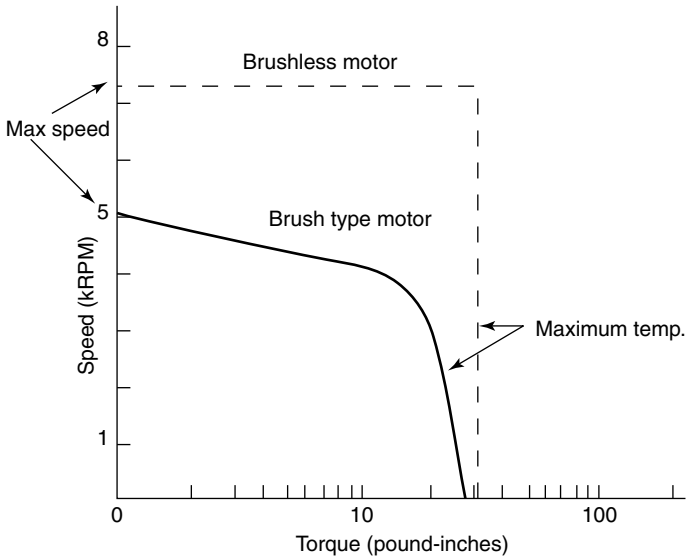

Fig. 4. Safe operating areas of two equivalent motors.

modulation, among others. These controls have served the needs of a diverse group of applications and generally they are basic and simple. The D.C. approach was chosen because no economically equivalent A.C. package existed. The A.C. motor manufacturers traditionally ignored this market. However, after the rapid escalation of energy costs in the 1970s, the motor industry perspective changed. Controls for A.C. motors quickly assumed a new level of sophistication. Two basic types of control emerged and are currently available: (1) the six step, and (2) pulse-width modulation. In development are more sophisticated controllers that employ SCR microprocessors and large scale integrated (LSI) dedicated electronics. In these cases, the control converts 60 Hz to direct current and then synthesizes a sine wave at a frequency to produce the desired speed.

The traditional cumbersome approach with discrete components would be unacceptable when using higher technology involving brushless designs. A search for a new approach began and, in light of the microprocessor, with its power and flexibility and its increased use in numerous applications, the concept of servosystem design was revolutionized. This approach has succeeded in providing greater flexibility in design of new systems and has potential to enhance the capabilities of existing systems. This could be termed the "intelligent" approach that utilizes microprocessor technology — an approach that impacts very favorably on design time, setup time, and implementation time.

Adjustable-Speed Brushless Control. A control of this type is self-contained, including power supply and heat sink, with the objective of driving a permanent-magnet brushless motor with Hall sensor feedback. The microprocessor-based control operates by energizing two of the motor's three windings, and switches power from winding to winding according to the feedback from the Hall sensors as previously described.

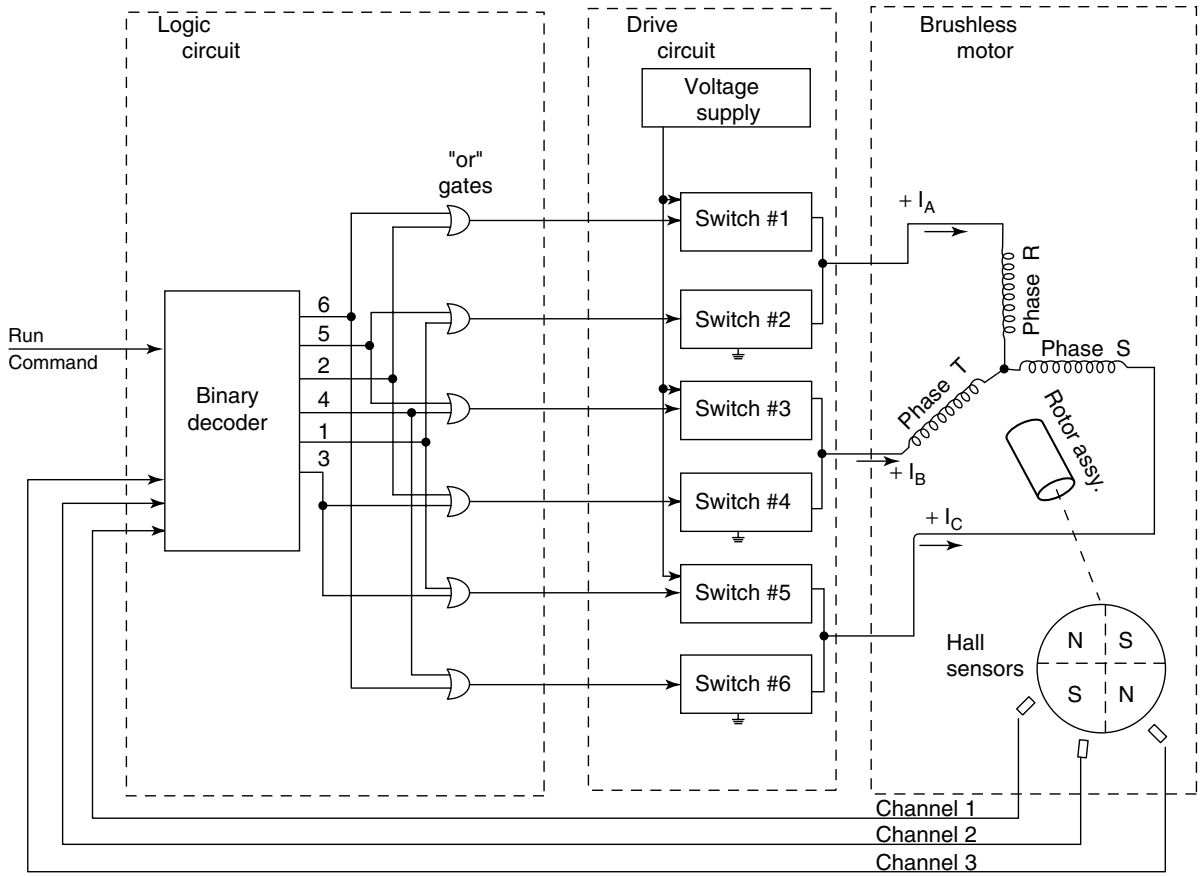

Fig. 5. Simplified block diagram of control system for brushless motor.

This is coupled with pulse-width modulation drive techniques to make effective use of the output power transistors.

A user-friendly operating panel activates the control, while status lights provide easy readout. Also on the front panel is a speed adjustment pot, and a digital speed readout indicator. The tight speed regulation offered by the microprocessor approach improves system accuracy. Accuracy of ±5 RPM over speed ranges of 100 to 10,000 RPM is possible even with dynamic load variations of 50%. The digital readout also serves as a diagnostic indicator should any of the system's protection require activation to shut down the system. This provides simple, easy-to-use user interfacing.

The Servosystem (Servocontroller) Approach. This is used with brushless technology in the same basic manner as it is employed with other prime mover (motor) technologies. Traditionally, these closed-loop servosystem designs will involve determination of load conditions and velocity profile, then prime mover (motor) selection, and determination of amplifier requirements. Following is the tedious task of compensation for gain and bandwidth adjustments for accuracy and response. The latter may involve a paperwork analysis prior to breadboarding a prototype. Or, if the individual components are purchased from independent suppliers, the "tweeking" of potentiometers would begin — in an effort to set up and adjust the compensation values. This approach can be difficult. As an example, in some servo amplifiers, there are ten potentiometers for a variety of adjustments. Throughout the compensation process, the main consideration is to set up the compensation for a given load condition. If the load changes, then the entire process must be repeated. To alleviate this problem, the system is designed to accommodate worst case conditions. This results in a system design that will be overdamped for all conditions (except the worst case), thus severely compromising system performance (speed and accuracy).

A much less cumbersome and effective approach is to utilize microprocessor techniques — an approach that uses digital control and digital filtering. The "intelligent" system compensates by simply inputting or programming the controller with parameters that describe the servo loop parameters. The algorithms precisely control servo loop velocity. Execution is under microprocessor control and all servo loop compensation (motor, load, or environmental conditions) is monitored and controlled should changes occur. This simplifies design and gains flexibility for the system.

One approach is the use of a general-purpose microprocessor-based control as shown in Fig. 6. The advantages of this approach include fewer components needed, which in turn lowers cost, reduces circuitry, and improves reliability. Components must be added to complete the system design, such as a drive amplifier. However, there are microprocessor-based controls, which include an internal drive amplifier, available today in production quantities to drive a brushless motor. These devices are termed "intelligent servo drives" as shown in the block diagram of Fig. 7.

These brushless servocontrols are software compensated, thus eliminating the need for pot adjustments. The microprocessor-based control can accept a variety of inputs — either analog or digital (serial or parallel) velocity commands. Parameters are factory-loaded in nonvolatile EEPROM (electrically erasable/programmable read-only memory) so the engineer receives a stable system, thus reducing design, implementation, and setup time. Although most applications do not require further adjustments, the engineer may fine tune the system by way of a hand-held pendant, or any RS232C interface. The versatility of the microprocessor allows incorporation of self-protection, which makes the overall system virtually indestructible. Protection features include peak, RMS, and short-circuit protection, as well as thermal protection, hardware and software protection, loss of feedback and velocity error. A brushless resolver serves as the feedback device and replaces the Hall sensor feedback. This assures operation at the optimum phase angle. The entire unit controls the brushless motor by way of PWM sinusoidal driving function, thus allowing smoother operation even at very low speeds.

The "intelligent control" closes the velocity loop and directly interfaces with most readily available programmable motion controllers for position control. Basic system operation is shown in Fig. 8. The first function is to receive instruction from the motion controller and generate the speed command for the velocity loop. The algorithm looks at the *present command* of the motor, the *previous command*, and the *next instantaneous position*. This is a periodic *sample* and *compare* to a desired reference

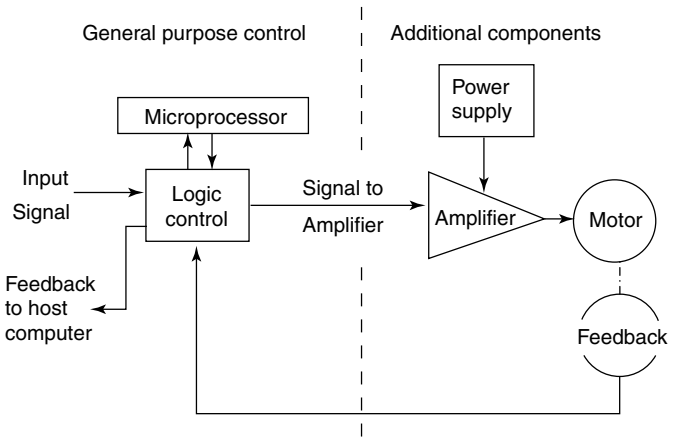

Fig. 6. A general-purpose microprocessor-based control system.

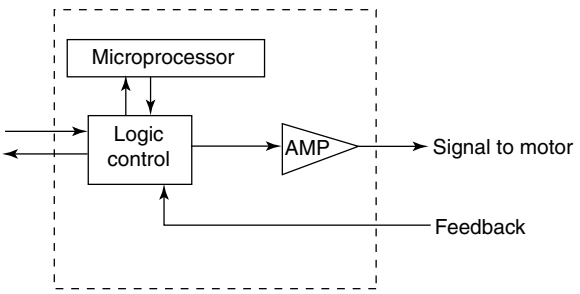

Fig. 7. Example of intelligent servo drive.

value. The difference between the speeds at two time periods serves as an indication for velocity errors and is used for velocity corrections. The feedback signals from the brushless resolver are conditioned and routed to the CPU (central processing unit) through the interrupt control. All real-time inputs have interrupt-driven software. A control manipulation is calculated and subsequently used to command the drive system. The algorithm generates a command that is the difference of a term proportional to the velocity error and a term that is proportional to the integral of the velocity error. This velocity feedforward technique, included in the microprocessor servo reference generation circuitry and applied directly to the velocity loop, allows the controller system to operate with minimal error, even during hard acceleration and deceleration. Velocity feedforwarding is valuable for maintaining wide dynamic system response. This technique stabilizes the loop and allows the system to drive the brushless motor in a smooth manner regardless of the trajectory.

The microprocessor must also determine the sign and magnitude of the current/voltage for each of the brushless motor's three phases in order to drive the motor at the appropriate torque/speed. The function of the waveform is described by a sine wave. Since the three phases are shifted by 120°, and there are four poles in the motor, or two electrical cycles per revolution, the commands to the windings are:

$$\text{Phase 1} = \text{Sin } 2\omega t$$
$$\text{Phase 2} = \text{Sin } (2\omega t + 120^\circ)$$
$$\text{Phase 3} = \text{Sin } (2\omega t + 240^\circ)$$

Since this calculation is accomplished only once per sample period, the appropriate weighting factor can vary considerably from the first computation time to the next. The solution is to base the weighting factors on a period base at one-half sample later. This is a velocity lead on the commutation. To optimize this, the sine functions are stored in memory. For this scheme to work, the microprocessor must "know" the relationship between the brushless motor phases and the internal drive scheme. This is accomplished by the resolver feedback. The resolver interface consists of sine and cosine reference waveforms and a phase-shifted feedback which contains absolute position data. This signal is sent directly to the microprocessor through a resolver-to-digital converter, returning a velocity

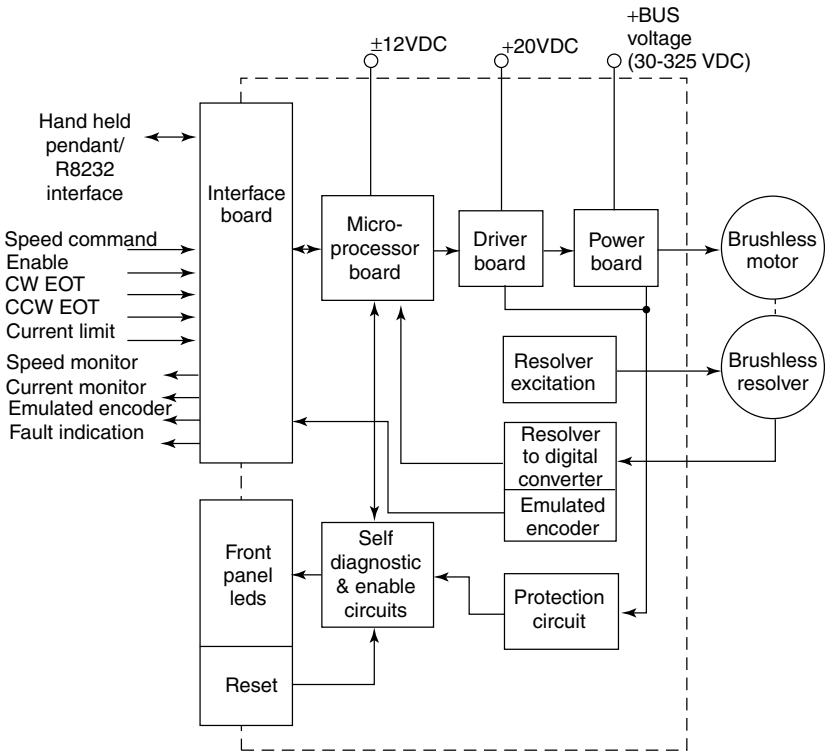

Fig. 8. Basic system operation of an intelligent brushless servo control. (CW = clockwise; CCW = counterclockwise; EDT = end of travel.) (*Pacific Scientific, Rockford, Illinois*.)

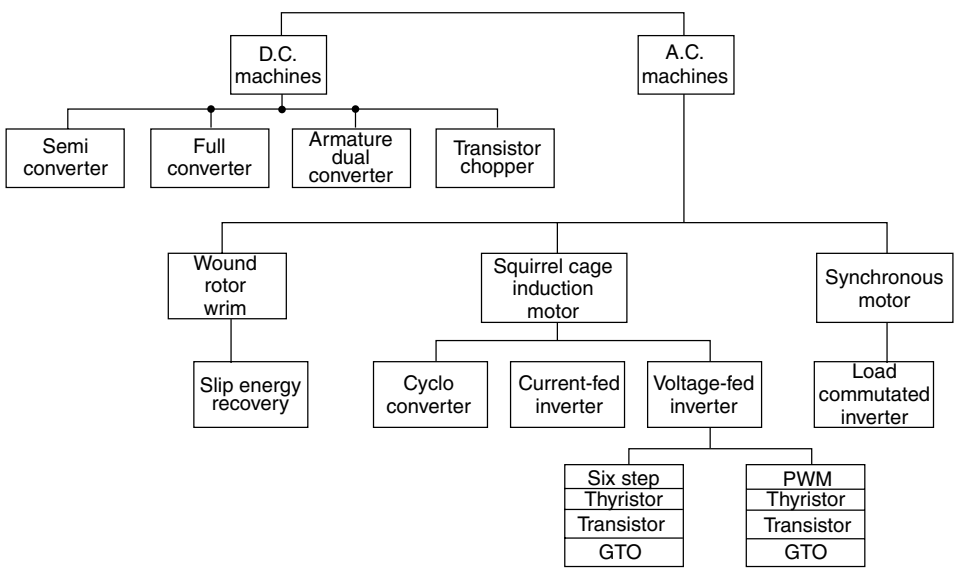

Fig. 9. General-purpose solid-state variable speed drive. (WRIM = wound rotor induction motor; GTO = gate-turn-off thyristors; PWM = pulse-width modulation.)

per sampling period. This feedback has proven superior for improvement of dynamics and straightforwarding for controllability.

The intelligent digital microprocessor-based control system, coupled with brushless motors, constitutes an excellent solution for most applications. This combination has the ability to produce higher torque at higher speeds. The numerous specific advantages have been previously described in detail.

Solid-State Variable-Speed Drives[2]

The past two decades have seen rapid growth in the availability and usage of solid-state variable speed drives. Today, there is a profusion of types which are suitable for virtually every type of electrical machine from the subfractional to the multithousand horsepower rating. See Fig. 9. Despite the diversity, there are two common properties of these drives. (1) All of them accept commonly available A.C. input power of fixed voltage and frequency and through switching power conversion, create an output of suitable characteristics to operate a particular type of electric machine, i.e., they are *machine specific*. (2) All of them are based on solid-state switching devices. Even though many of the power conversion principles have been known as long as fifty years, when they were developed using mercury arc rectifiers, it was not until the invention of the thyristor in 1957 that variable speed drives became practical.

The thyristor (SCR) is a four-layer semiconductor device, which has many of the properties of an ideal switch. It has low leakage current in the off-state, a small voltage drop in the on-state, and takes only a small signal to initiate conduction (power gains of over 10^6 are common). When

[2] By Richard H. Osman, Engineering Manager, A.C. Drives, Robicon Corporation (A Barber-Colman Company), Pittsburgh, Pennsylvania.

applied properly, the thyristor will last indefinitely. After its introduction, the current and voltage ratings increased rapidly. Today it has substantially higher power capability than any other solid-state device, and dominates power conversion in the medium and higher power ranges. The major drawback of the thyristor is that it cannot be turned off by a gate signal, but the anode current must be interrupted in order for it to regain the blocking state. The inconvenience of having to commutate the thyristor in its anode circuit at a rather high energy level has encouraged the development of other related devices as power switches.

Development of Power-Switching Devices

Transistors predate thyristors, but their use as high-power switches was relatively restricted (compared to thyristors) until the ratings reached 50 A and 1,000 V in the same device, since the early 1980s. These devices are three-layer semiconductors which exhibit linear behavior, but are used only in saturation or cut off. In order to reduce the base drive requirements, most transistors used in variable speed drives are Darlington types. Even so, they have higher conduction losses and greater drive power requirements than thyristors. Nevertheless, because they can be turned on or off quickly via base signals, they are attractive candidates for drives within the scope of the transistor ratings, particularly for pulse-width-modulated inverters.

Gate-Turn-Off Thyristors. More recently, successful attempts to modify thyristors to permit them to be turned off by a gate signal have been made. These devices are four-layer types and are called *gate-turn-off thyristors*, or simply GTO's. Power GTO's have been around since at least 1965, but only relatively recently (1981) have devices rated more than a few tens of amps become available. Present GTO's have about the same forward drop as a Darlington transistor (twice that of a conventional thyristor). GTO's require a much more powerful gate drive, particularly for turn-off, but the lack of external commutation circuit requirements makes them desirable for inverter use. GTO's are available at higher voltage and current ratings than power transistors. Unlike transistors, once a GTO has been turned on or off with a gate pulse, it is not necessary to continue the gate signal due to the internal positive feedback mechanism inherent in four-layer devices.

Technological Base. The three aforementioned devices (thyristor, transistor, and GTO) form the technological base on which the solid-state variable-speed drive industry rests today. There are other devices in various stages of development which may or may not become significant depending on their cost and availability in large current (>50 A) and high voltage (1,000 V) ratings. These include: (1) the metal oxide semiconductor field effect transistor (MOSFET); (2) the insulated gate transistor; and (3) the static induction thyristor.

It has not yet been possible to construct *power MOSFET's* which have acceptably low ON resistance while still having the 1,000 V rating necessary for reliable power conversion at the 500 VAC level. Therefore, their use has been limited to small drives (under 10 HP). Power MOSFET's are the fastest power switching devices (100 ns) of the lot, and they also have very high gate impedance, thus greatly reducing the cost of drive circuits.

The *insulated gate transistor* is a combination of a power bipolar transistor and a MOSFET which combines the best properties of both devices. A most attractive feature is the very high input impedance, which permits them to be driven directly from lower power logic sources. Unfortunately, their ratings are not very impressive, being limited to a few tens of amperes and about 600 volts.

Static induction thyristors (SR's) are claimed to have the voltage and current ratings of GTO's, but with a much higher gate impedance so as to reduce driver requirements. The validity of these claims has not been proved in commercial use because SR's are just emerging from the development laboratory.

Variable-Speed Drive Hardware Development

Parallel to the development of power switching devices, there have been very significant advances in hardware for controlling variable speed drives. These controls are a mixture of analog and digital signal processing.

The advent of integrated circuit operational amplifiers and integrated circuit logic families made possible dramatic reductions in the size and cost of the drive control, while permitting more sophisticated and complex control algorithms without a reliability penalty. These developments occurred during the 1965–1975 period. Further consolidation of the control circuits occurred after that as large scale integrated circuits (LSI) became available. In fact, the pulse-width modulation (PMW) control technique was not practical until the appearance of LSI circuits because of the immense amount of combinational logic required. A significant trend has been the introduction of *microprocessors* into drive control circuits. While it is doubtful whether microprocessors will significantly reduce control circuit cost, there is general agreement that they are greatly expanding the capability of drive controls. The performance enhancements include: (1) more elaborate and detailed *diagnostics* due to the ability to store data relating to drive internal variables, such as current, speed, firing angle, and so on; (2) the ability to *communicate both ways* with user's central computers about drive status; (3) the ability to make *drive tuning adjustments* via keypads with parameters such as loop gains, ramp rates, current limit stored in memory rather than pot settings; (4) *self-tuning* drive controls; and (5) more adept techniques to overcome *power circuit nonlinearities*. The possibilities are large and are just beginning to become commercial realities.

D.C. Drives

The introduction of the thyristor had the most immediate impact in the D.C. drive area. Ward-Leonard (motor-generator) variable speed drives were quickly supplanted by thyristor D.C. drives of the type shown in Fig. 10 for reasons of lower cost, higher efficiency, and lower maintenance cost. This type of power circuit with three thyristors and three diodes in a three-phase bridge is generally referred to as a *semiconverter*. By phase control of the thyristors, it behaves as a programmable voltage source. Therefore, speed variation is obtained by adjustment of the armature voltage of the D.C. machine. Because the phase control is fast and precise, critical features like current limit are easily obtained. In fact, almost all thyristor DC drives today are configured as current regulators with a speed or voltage outer loop. The semiconverter is suitable for one-quadrant drives as it produces only one direction of current and output voltage. Input power factor is dependent on speed.

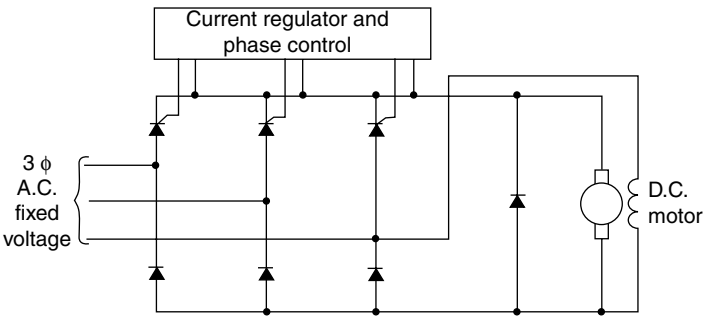

Fig. 10. Thyristor D.C. drive-3-phase semiconverter.

Six-Thyristor Full Converter. As the cost differential between thyristors and diodes narrowed, the semiconverter was largely displaced by the six-thyristor full converter as shown in Fig. 11. This circuit arrangement (the Graetz circuit) has become the workhorse of the electrical variable speed drive industry as will be pointed out. The control techniques are very much the same as in the semiconverter. However, the full converter offers lower output ripple and the ability to regenerate, or return energy to the A.C. line. The system can be made into a four-quadrant drive by the addition of a bidirectional field controller. Torque direction is determined by field current direction. Due to the large field inductance, torque reversals are fairly slow (100–500 ms) but adequate for many applications.

Dual Armature Converter. For the best response of thyristor D.C. drives, the dual armature converter of Fig. 12 is preferred. This is simply two converters. See Fig. 11, connected back to back. Torque direction is determined by the direction of armature current, and since this is a low-inductance circuit, reversal can be accomplished in 10 ms (typically). Obviously, only one converter is conducting at one time with the other group of six thyristors not being gated. This is called "*bank selection*."

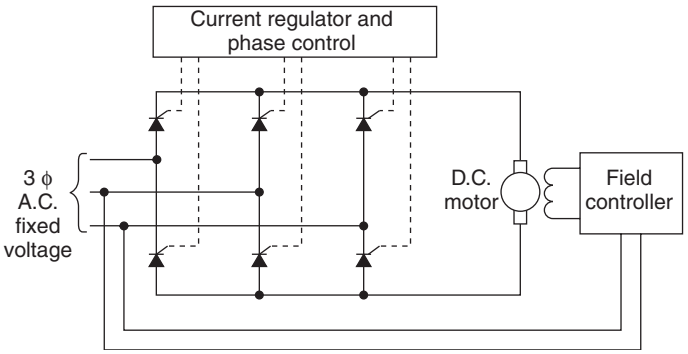

Fig. 11. Thyristor D.C. drive-3 phase full converter.

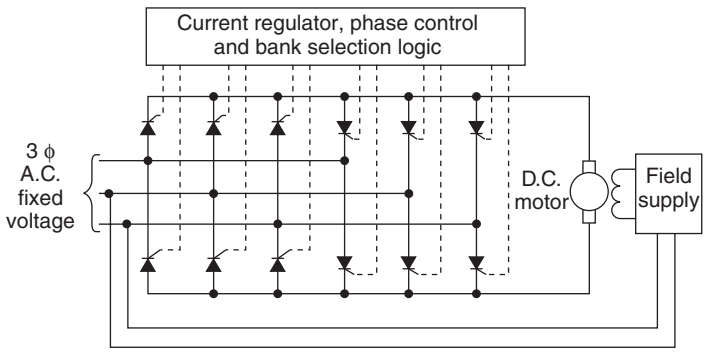

Fig. 12. Thyristor D.C. drive-armature dual converter.

Summary of Thyristor D.C. Drives. The three types of thyristor D.C. drives just described all share a common property in that the devices are turned off by the natural polarity reversal of the input line. This is called *natural* or *line commutation*. Thus, the inability to turn off a thyristor from the gate is no practical drawback in these circuits. Consequently, they are simple and very efficient (typically 98.5%) because the device forward drop is small compared to the operating voltage. These drives can be manufactured to match a D.C. machine of any voltage (commonly 500 V) or horsepower (0.5 to 2,500 HP, typically).

For certain types of applications, typically machine tool axis drives and tape transport drives, the response of phase controlled thyristor drives is not fast enough. A special class of D.C. drives has been developed. A fixed D.C. bus is developed from the line via a rectifier and capacitor filter. This voltage source is applied to the armature through power transistors. The voltage is modulated by duty cycle (or pulse width) control. The devices usually operate in the 1–5 kHz range. These specialty drives usually operate from 120 or 240 VAC and rarely exceed 10 HP. Frequently, they are applied with permanent magnet field D.C. machines.

A.C. Drives

The impact of the new solid-state switching devices was even larger on the A.C. variable speed drives, but it occurred somewhat later in time as compared to D.C. drives. A.C. drives are machine specific and more complex than D.C. drives. Solid-state variable-speed drives have been developed and marketed for wound-rotor induction motors (WRIM's), synchronous motors, and cage-type induction motors.

Historically, WRIM-based variable speed drives were commonly in use long before solid-state electronics. These drives operate on the principle of deliberately creating high-slip conditions in the machine and then disposing of the large rotor power which results. This is done by varying the resistance seen by the rotor windings.

Slip-Energy Recovery System. A more modern WRIM drive is shown in Fig. 13. This is called the *slip-energy recovery system* or *static Kramer drive*. The output of the rotor is rectified, and this D.C. voltage is coupled to the line via a thyristor converter. The line commutated converter is current regulated which effectively controls torque. Efficient, stepless speed control results. Very large (>1,000 HP) drives can be built, as the stator may be wound for medium voltage, while the rotor operates at 400–400 V maximum. The power conversion equipment may be downsized if a narrow range (100% to 70%) of control is adequate, for example in fan drives. The performance drawbacks are a poor system power factor if not corrected; and no above-synchronous-speed operation.

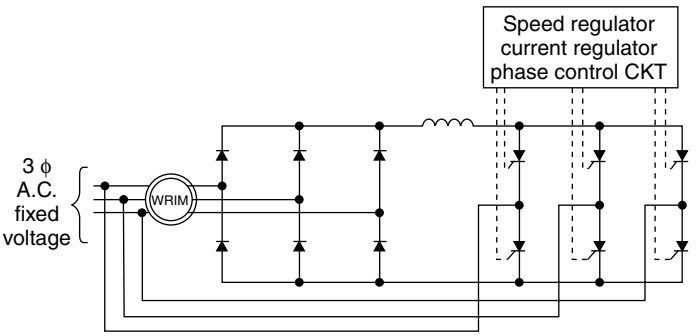

Fig. 13. Slip energy recovery system-wound rotor inductor motor. (WRIM = wound rotor induction motor; CKT = circuit.)

The WRIM is the most expensive A.C. machine. This has made WRIM-based variable speed drives noncompetitive as compared to cage induction motor (IM) drives or load commutated inverters using synchronous machines. It appears that the WRIM will become a casualty of the tremendous progress in A.C. variable speed drives as applied to cage induction motors.

Load Commutated Inverter. As shown in Fig. 14, the load commutated inverter is based on a synchronous machine. It uses two thyristor bridges, one on the line side and one on the machine side. All devices are naturally commutated, because the back EMF of the machine commutates the load side converter. This requires the machine to operate with a leading power factor and, therefore, it requires substantially more field excitation and a special exciter compared to a normally applied synchronous motor. This also results in a reduction in the torque for a given current. The machine side devices are fired in exact synchronism with the rotation of the machine, so as to maintain constant torque angle and constant commutation margin. This is done either by rotor position feedback, or by phase control circuits driven by the machine terminal voltage. The line side converter is current regulated to control torque. A choke is used between converters to smooth the link current. Load commutated inverters (LCI's) came into commercial use about 1980, and are used mainly on very large drives (1,000–10,000 HP). At these power levels, multiple series devices are employed (typically 2.4 to 4 kV input) and conversion takes place directly at 2.4 or 4 kV or higher. The efficiency is excellent and reliability has been very good. Although they are capable of regeneration, LCI's are rarely used in 4-quadrant applications because of the difficulty in commutating at very low speeds where the machine voltage is negligible. Operation above line frequency is straightforward.

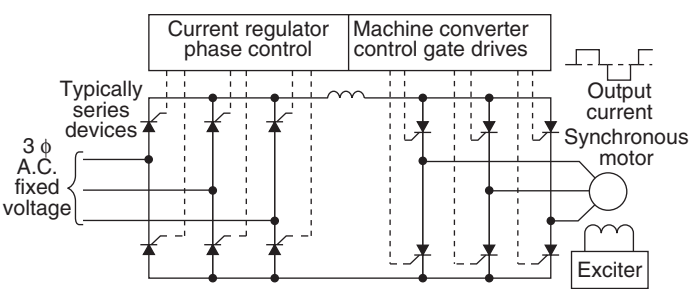

Fig. 14. Load-commutated inverter (LCI).

Induction Motor Variable Speed Drives

Induction motor variable speed drives have the greatest diversity of power circuits. (See Fig. 9.) Because the squirrel cage induction motor is the

least expensive, least complex, and most rugged electric machine, great effort has gone into drive development to exploit the machine's superior qualities. Due to its very simplicity, it is the least amenable to variable speed operation. Since it has only one electrical input port, the drive must control flux and torque simultaneously through this single input. As there is no access to the rotor, the power dissipation there raises its temperature — so very low-slip operation is essential.

Cycloconverter. One approach in an IM drive is to "synthesize" an A.C. voltage waveform from sections of the input voltage. This can be done with three dual converters and the circuit is called a *cycloconverter*. See Fig. 15. The output voltage is rich in harmonics, but of sufficient quality for IM drives as long as the output frequency does not exceed $\frac{1}{3}$ to $\frac{1}{2}$ of the input. The thyristors are line commutated, but there are 36 of them. (Sometimes half-wave circuits are used which need only 18 devices, but more harmonics result.) The cycloconverter is capable of heavy overloads and 4-quadrant operation, but it has a limited output frequency and poor input power factor. For special low-speed high horsepower (>1,000) applications, such as cement-kiln drives, the cycloconverter has been used.

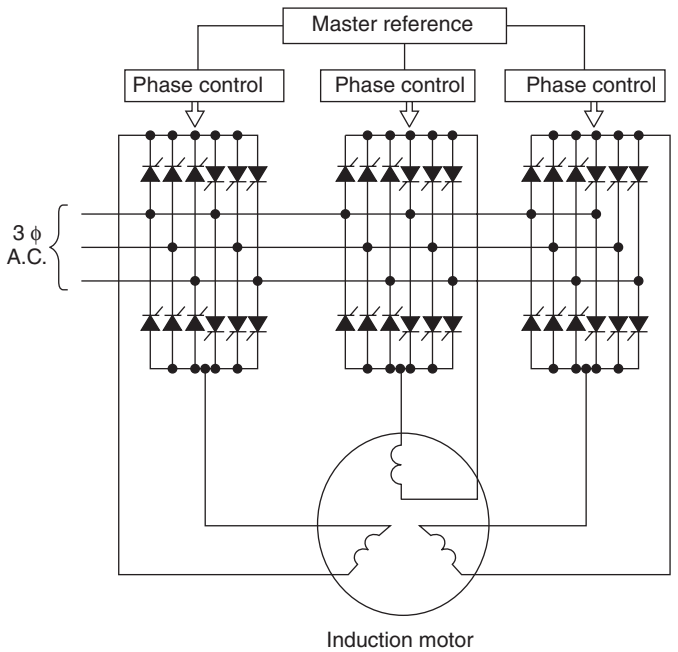

Fig. 15. Cycloconverter induction motor drive.

Autosequentially Commutated Current-Fed Inverter. Still another approach to an IM drive is to generate a smooth D.C. current and feed that into different parts of windings of the machine so as to create a discretely rotating magnetomotive force (MMF). This type of inverter is called the *autosequentially commutated current fed-inverter* (ASCI). See Fig. 16. This circuit was invented later than other inverters and is much more popular in Europe and Japan than in the United States. Once again, the input stage is a three-phase thyristor bridge which is current regulated. A link choke smooths the current going to the output stage. There, a thyristor bridge distributes the current into the motor windings with the same switching function as the input bridge, except at variable frequency. (Notice the similarity to the LCI.) The current waveform is a quasi-square wave whose frequency is set by the output switching rate and whose amplitude is controlled by the current regulator. The capacitors and rectifiers are used to store energy to commutate the thyristors, since the induction motor cannot provide this energy and remain magnetized, in contrast to the synchronous motor. This type of drive has simplicity, good efficiency (95%), excellent reliability, and four-quadrant operation up to about 120 Hz. Harmonics in the output current are reasonably low, giving a form factor of 1.05 (same as the LCI).

Moreover, harmonic currents are not machine dependent and decrease at light load. The input power factor is load and speed dependent, but much better than the cycloconverter. Above 100 HP, the ASCI is very cost effective. Because they are constructed with SCR's, they have recently (1984) become available at 2.4 and 4 kV direct conversion for very large (>1,000 HP) units. It is almost always possible to retrofit an existing motor with this type of drive. Due to the controlled current properties, this drive is virtually immune to damage from ground faults, load shorts and commutation failures.

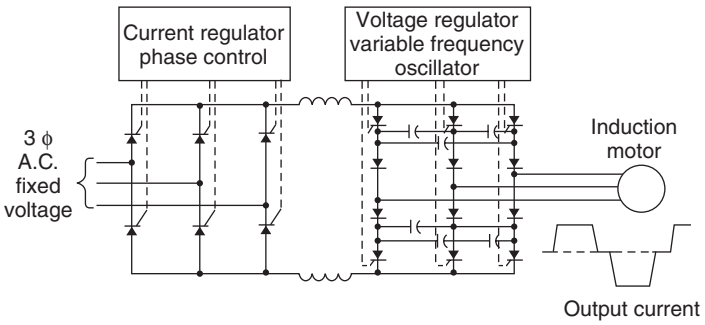

Fig. 16. Autosequentially commutated current-fed inverter (ASCI).

Since MMF (current) is directly controlled and the drive is regenerative, ASCI's can readily be equipped with field oriented controls for the most demanding four-quadrant operation.

Field-Oriented Controls. Special mention should be made of A.C. induction motor drives with field oriented controls. They are the state of the art. The control technique keeps track of the flux and MMF vectors inside the machine in order to provide a fast and precise torque response to an external reference. In addition, they are 4-quadrant drives, capable of producing either direction of torque in either direction of rotation. They are the A.C. drives of choice for the most demanding applications such as traction drives and machine tool axis drives.

Voltage-Source Inverter. The third approach to IM drives is to generate a smooth D.C. voltage and apply that to different combinations of the machine windings so as to create a rotating flux. This circuit is called a *voltage-source inverter* (VSI). An implementation using thyristors is shown in Fig. 17. This circuit was the first application of thyristors to IM drives. The input is a 3-phase thyristor bridge which feeds a capacitor filter bank forming a controlled low-impedance voltage source. The output stage consists of six main thyristors (1–6) in a bridge with antiparallel diodes. There are six auxiliary or commutating thyristors (11–16) which together with the *L-C* circuits, impulse commutate the main devices. The output waveform is a quasi-square wave of voltage whose amplitude is set by the D.C. link voltage. Here the output frequency is determined by the output switching rate, and the output voltage is set by the voltage regulator on the input converter. In order to reduce the size of the commutating *L-C*, special thyristors with fast turn-off times are required — in contrast to the ordinary phase control types used in D.C. drives, LCI's, and ASCI's. Despite the complexity, these drives have had a reasonably good reliability record. They have good efficiency (typically 95% at full speed, full load), speed dependent power factor, and can operate at very high frequencies (180 Hz and up). Regeneration to the line is not possible. Many of these units are in service, and they are still available from 50 to 55 HP, typically at 460 VAC. They are not available at over 600 V.

Transistors and GTO's in Voltage-Source Inverter. In order to reduce the cost and complexity of the VSI shown in Fig. 17, the thyristors and their commutation circuits have been replaced with transistors or with GTO's. The resulting circuit is shown in Fig. 18. The performance features are about the same as the thyristor version, but size and weight are substantially reduced. Although the conduction losses are higher due to the higher "on" voltages, commutation losses are reduced substantially — so efficiencies remain in the 95% range. The transistor version has been available since about 1982 at 460 VAC input; 230-volt units have been available since the mid-1970s. Presently, 100 HP transistor drives with single output devices are available; up to 300 HP with parallel output devices can be obtained.

Since GTO's have somewhat higher ratings, drives from 50 to 500 HP at 460 VAC are now available. It is difficult to forecast which device will be more successful, but transistors are much more widely used up to

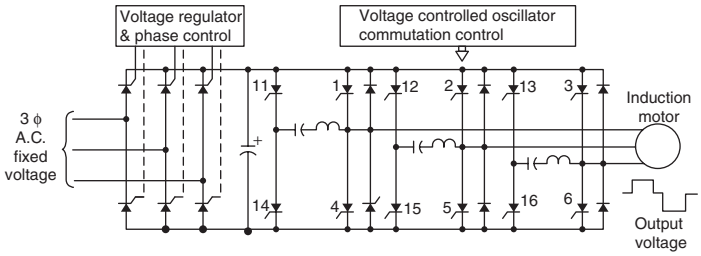

Fig. 17. Voltage-source inverter; six-step thyristor, impulse commutated.

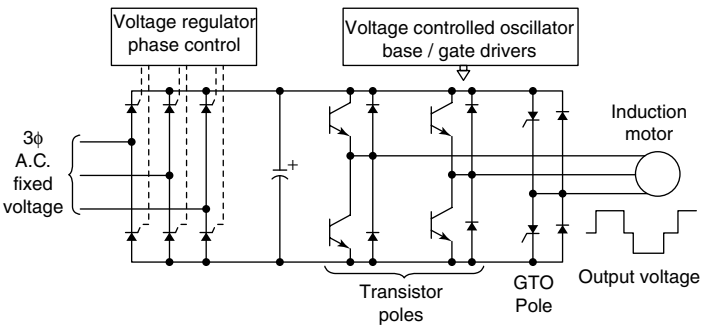

Fig. 18. Voltage-source inverter, six-step transistor or gage-turn-off thyristor (GTO).

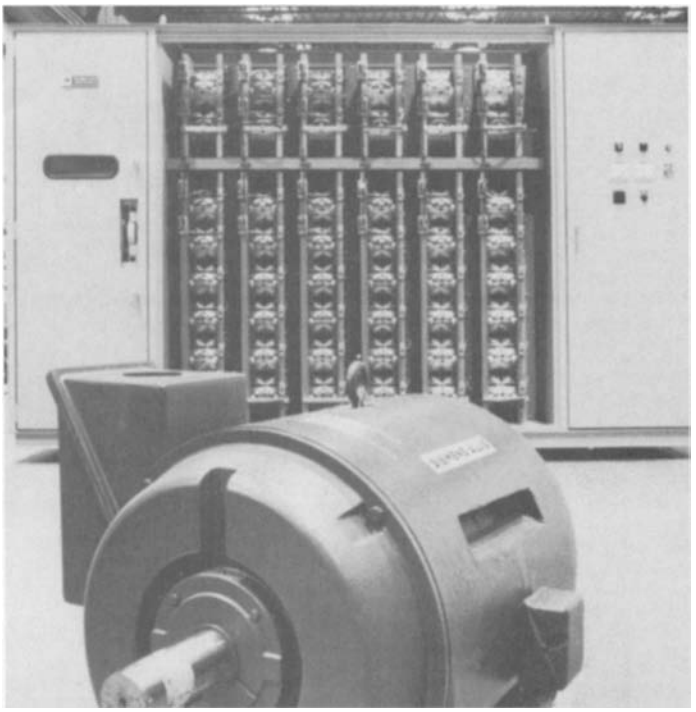

Fig. 20. Representative 2500HP, A.C. variable-frequency drive. (*Robicon Corporation, Pittsburgh, Pennsylvania*.)

100 HP than GTO's. There will be a three-way competition in the future among GTO, transistor, and thyristor drives in the 100–500 HP range to capture the bulk of the market. GTO and transistor costs will have to be substantially reduced to challenge thyristor designs at the upper end of this range.

Pulse-Width Modulated (PWM) Drives. The induction motor drives discussed thus far are all similar in that the amplitude of the output is controlled by the input converter. Another category of voltage source inverters controls both the frequency and amplitude by the output switches alone. A representative circuit based on transistors is shown in Fig. 19. Note that the input converter is replaced with a diode bridge so that the D.C. link operates at a fixed, unregulated voltage. The diode front end gives virtually unity power factor, independent of load and speed. This type of drive is called *pulse-width-modulated* (PWM).

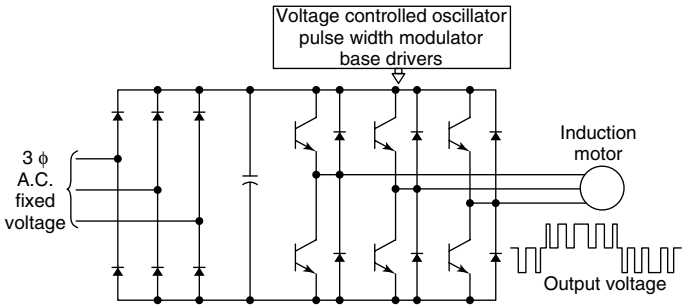

Fig. 19. Pulse-width modulated (PWM) inverter-transistor implementation.

An output voltage waveform is synthesized from constant amplitude, variable-width pulses at a high (1–3 kHz) frequency so that a sinusoidal output is simulated; the lower harmonics (5,7,11,13,17,19, ...) in six-step waveforms are not present in sophisticated PWM's. One advantage is smooth torque, low harmonic currents, and no cogging. Some PWM designs merely encode the six-step square wave, but this results in having the worst features of both PWM and six-step designs. Although this approach eliminates the phase control requirements and cuts the front end losses somewhat, there are offsetting drawbacks. Since every switching causes an energy loss in the output devices and their suppressors, the total losses at high speed go up considerably over six-step (six switches per cycle) if the same devices are used. To overcome this, many versions revert to six-step at 60 Hz. The output devices are stressed much more severely than in six-step. Many PWM designs do not have a voltage regulator; at any given output frequency, they deliver a preset fraction of the input voltage. If the input fluctuates, so does the output. Finally, the high-frequency switching may cause objectionable acoustic noises in the motor. There are both transistor and GTO PWM units on the market today in the range of 1–3,000 HP at 460 VAC. The transistor versions have a better reliability record. As with all voltage source inverters, regeneration to the line is not inherent.

A representative industrial solid-state variable speed drive is given in Figs. 20. See also **Stepper Motors**.

SESAME SEED OIL. See **Vegetable Oils (Edible)**.

SET (Mathematics). A collection of numbers or symbols considered as a whole. For example, the set of all prime numbers or the set of all matrices with determinant equal to unity. Geometrically, the symbols in a set determine a *domain*.

SET (Permanent). When a solid has been strained beyond the elastic limit and the deforming stress is completely removed, in general the strain does not decrease ultimately to zero but to some nonvanishing value, known as a permanent set.

SETTLING TIME. The time required, following the initiation of a specified stimulus to a system, for the output to enter and remain within a specified narrow band centered on its steady-state value. See diagram that accompanies entry on **Response (Instrument)**. The stimulus may be a step impulse, ramp, parabola, or sinusoid. For a step or impulse, the band is often specified as $\pm 2\%$. For nonlinear behavior, both magnitude and pattern of the stimulus should be specified.

SEWELLEL. See **Rodentia**.

SEX. The state of an individual as determined by its adaptations for a special part in biparental reproduction and modifications of the process. Also a category of individuals adapted for a special part in reproduction. The usual sexes are male and female. Neuter individuals exist among colonial invertebrates, including both sexless forms and abortive females whose limited reproductive powers are not exercised under normal conditions. Sex is also expressed in hermaphrodite animals which carry on the usual processes of sexual reproduction but have male and female organs in the same individual.

The differentiation of the sexes is associated with the development of two kinds of gametes in the process of sexual reproduction. Organs and ducts capable of producing the larger egg cells of the female and providing them with quantities of food material make up a reproductive system much different from that which produces the minute male spermatozoa and the seminal fluid in which they are discharged. The development of the external genitalia for internal insemination also results in conspicuous differences, since the male has a projecting penis or other intromittent organ, while the female has the terminal portion of the genital ducts specialized for the reception of this organ. In the mammals, the mammary glands of the female also constitute a conspicuous sexual distinction. These organs may be classed as essential and accessory organs of reproduction, the former category including the gonads and ducts and the latter such parts as the external genitalia and the mammary glands.

Sexes also differ in more or less conspicuous secondary sexual characters such as the beard of man, which are definitely associated with sex but have no direct part in reproduction.

The sexes of most animals are specialized in behavior as well as in structure for the performance of reproductive acts, for accessory functions such as the building of nests, and for subsequent duties of parental care. All of these phases of sexual differentiation are intricately variable among the many species of animals.

SEX (Flower). See **Flower**.

SEX-INFLUENCED INHERITANCE. Inheritance influenced by sex, but not restricted to one sex or the other. Baldness in man is often given as a possible case of sex-influenced inheritance. Baldness is supposed to be dominant in men and recessive in women. Hence, a man will be bald if he carries only one gene for baldness, but a woman must carry two such genes before she will be bald. The horns of sheep are also good examples. The horned condition is due to a gene that is dominant in the males and recessive in the females. The Dorset sheep are also homozygous for the gene for horns, so both sexes have horns. The Suffolk sheep are homozygous for the gene for hornless. When the two breeds are crossed, the male offspring all have horns and the females are all hornless. When these first generation offspring are crossed, the offspring show a ratio of 3 horned to 1 hornless in the males and 1 horned and 3 hornless in the females. This is to be expected on the basis of the method of inheritance of a sex-influenced gene.

SEX-LIMITED INHERITANCE. A condition where certain genes are expressed in only one sex, although they may be carried by both sexes. The human beard is a good example. It normally shows only in males, although a man inherits the characteristics of his beard just as much from his mother as from his father. Breast development in a woman and not in a man is another example. In general, the development of these traits in mammals is conditioned by the sex hormones. A woman who takes male sex hormones will develop a beard as a result of the action of the latent genes she has carried all her life. In cattle, the qualities of milk production are transmitted just as much from the bull as from the cow. The most outstanding cases of sexual dimorphism resulting from sex-limited genes is to be found in the birds. The brilliant plumage of the male pheasant or peacock stands out in great contrast to the drab pattern of feathers found in the female.

In invertebrate animals, sex-limited genes respond to the chromosomal make-up of the individual cells. Butterflies often show such great differences in the two sexes that they would never be taken for the same species had they not been seen mating. When a gynandromorph is found of the bilateral type, all of the tissue on one side of the body will show the typical male pattern, but that on the other side will show the female pattern. There is no mixing of traits as would be the case if sex hormones flowed to all parts of the body and influenced the expression of the genes.

SEX-LINKED INHERITANCE. A pattern of inheritance resulting from genes on the nonhomologous portion of the X-chromosome of most animals, but it can also be the genes on the nonhomologous portion of the W-chromosome of the animals with WZ sex determination. In the former case, the female carries two of each of the sex-linked genes, whereas the male carries only one of each. The males, therefore, express all of their sex-linked genes, and the females express those genes that are dominant or homozygous recessive, or intermediate in their expression. A male receives all of his sex-linked genes from the female parent; a female receives a sex-linked gene of each kind from both parents. Hemophilia, bleeder's disease, is a typical sex-linked gene in man. It is recessive, but shows when present on a man's single X-chromosome. Hence, half of the sons of a heterozygous woman will have hemophilia, but all of the daughters will be normal because they will receive a gene for normal blood clotting from their father. The gene for hemophilia was prevalent in the royal families of Europe. See Fig. 1. Color blindness is another human trait resulting from a sex-linked gene.

The first experimental evidence of sex linkage was found in 1910 when Morgan discovered a white-eyed mutant of *Drosophila melanogaster*. When white-eyed males were mated with normal red-eyed females, the F_1 generation displayed all red eyes. However, the F_2 generation included both red and white eyes in the proportion of 3 red to 1 white. This ratio suggested that the mutant gene for white eyes was recessive. The important observation was that the only males of the F_2 generation had white eyes. Therefore, the recessive gene for white eyes expressed itself only in males. Sex-linked genes in males are referred to as *hemizygous* since only one member of an allelic pair of genes is required for expression.

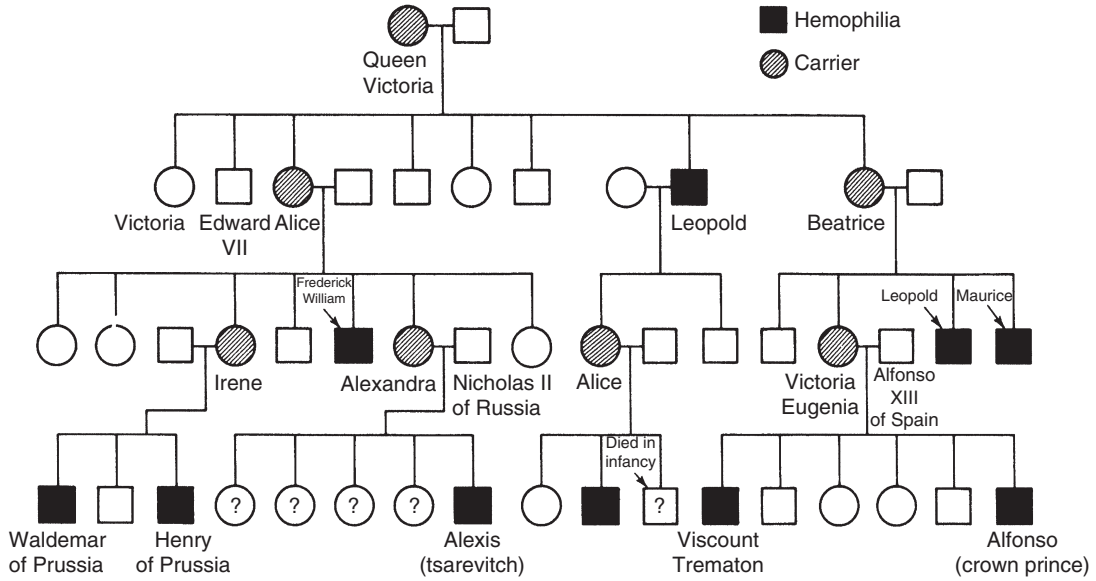

Fig. 1. Pedigree of hemophilia in the royal families of Europe. The gene apparently arose as a mutation in the immediate ancestry of Queen Victoria of England and spread through the royal families of Europe, with a great impact on history.

In birds the condition is reversed: the male has the two W-chromosomes and carries two of each sex-linked gene, whereas the female has a single W-chromosome and will express all the sex-linked genes. See also **Genetics and Gene Science (Classical)**; and **Heredity**.

ANN C. DE BALDO, Ph.D., Assoc. Prof., College of Public Health, University of South Florida, Tampa, FL

SEXTANS. A minor southern constellation located near the equator.

SEXTANT. The sextant is a light, portable instrument designed for the purpose of measuring the angular distance between the two objects. It represents the most recent stage in a succession of portable devices for angular measurement advancing from the astrolabe through the cross-staff down to the modern instrument. The immediate predecessor of the sextant was the quadrant (the "hog-yoke" of the sailing ship era), but the design of this instrument is very similar to that of the sextant used today. Since the sextant is used by navigators for the purpose of measuring the apparent altitude of celestial objects, the opinion is prevalent that it is purely a navigational instrument. Such is far from the case, and the instrument is of value to explorers, surveyors, or any person who desires to measure angular distance.

The optical system of the sextant (and quadrant) is shown in the accompanying diagram. The mirror A (called the horizon glass) is divided into two sections by a line parallel to the plane of the instrument. The upper section is unsilvered, so that an observer looking through the telescope T can see directly through A to an object in the direction H. The mirror B (called the index mirror) may be rotated about an axis perpendicular to the plane of the instrument and coincident with the center of the graduated arc CD. Attached to the index mirror is a vernier arm, which sweeps along the arc.

With the mirror B strictly parallel to A, the observer will see two superimposed images of the object in the direction H. One of these is the direct image observed through the upper section of the horizon glass, and the other is a reflected image with light traveling along the path $HBAT$. Under these conditions, the index C should read zero; in case this is not so, an "index correction" must be applied to all observations with the instrument.

In case the angular distance between an object in the direction H and another in the direction S (angle SBH) is desired, the observer moves the index arm along the arc until an image of S (light path $SBAT$) is superimposed on the direct image of H. Application of the laws of reflection of light will show that the angle CBD through which the mirror is turned in one-half the angle SBH. To obviate the necessity of dividing each reading of the instrument by two, the arc is so graduated that when CBD is actually 60° the index will read 120°.

To obtain the altitude of a celestial object at sea, the instrument is directed toward the visible horizon and the index arm moved until the desired object is in the field of view. Now the sextant is rotated back and forth about the optic axis of the telescope (the line HAT in Fig. 1), and the image of the celestial object will apparently swing back and forth along a short arc. The index arm is now carefully adjusted until the celestial object is just tangent to the horizon at the lowest point of its apparent swing. Under these conditions the reading of the sextant will give the sextant altitude measured along the vertical circle through the object.

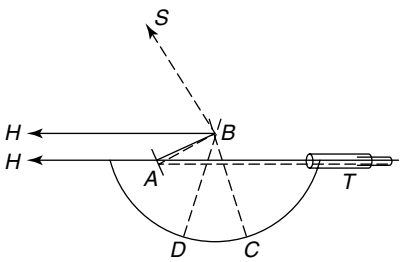

Fig. 1. Optical system of sextant.

To overcome situations where it is difficult or impossible to see the horizon clearly, a small bubble made visible in the instrument's optical system is used as an indication of vertical. A gyro vertical also has been used as a horizon reference.

SEXUALLY TRANSMITTED DISEASES. Once known universally as venereal diseases (VD), sexually transmitted diseases (STDs) are transmitted through close, intimate, and sexual contact. STDs afflict an estimated 200 to 400 million people worldwide, and the incidence of infection is rising. The costs of dealing with these diseases run into the billions of dollars annually.

In the United States, more than 65 million people are currently living with and incurable sexually transmitted disease (STD). An additional 15 million people become infected with one or more STDs each year, roughly half of whom contract lifelong infections (Cates). Yet, STDs are one of the most under-recognized health problems in the country today. Despite the fact that STDs are extremely widespread, have severe and sometimes deadly consequences, and add billions of dollars to the nation's healthcare costs each year, most people in the United States remain

unaware of the risks and consequences of all but the most prominent STD — the human immunodeficiency virus or HIV.

While extremely common, STDs are difficult to track. Many people with these infections do not have symptoms and remain undiagnosed. Even diseases that are diagnosed are frequently not reported and counted. These "hidden" epidemics are magnified with each new infection that goes unrecognized and untreated.

More than 25 diseases are spread primarily through sexual activity, and the trends for each disease vary considerably, but together these infections comprise a significant public health problem.

The latest estimates indicate that there are 15 million new STD cases in the United States each year (Cates). Approximately one-fourth of these new infections are in teenagers. And while some STDs, such as syphilis, have been brought to all time lows, others, like genital herpes, gonorrhea, and chlamydia, continue to resurge and spread through the population.

Because there is no single STD epidemic, but rather multiple epidemics, discussions about trends over time and populations affected must focus on each specific STD. More is known about the frequency and trends of some STDs than others, since many of the diseases are difficult to track. Not including HIV, the most common STDs in the U.S. are chlamydia, gonorrhea, syphilis, genital herpes, human papillomavirus, hepatitis B, trichomoniasis, and bacterial vaginosis. The latest estimates of incidence and prevalence are provided in Table 1.

TABLE 1. INCIDENCE AND PREVALENCE OF STDs

	Incidence (Estimated number of new cases every year)	**Prevalence**[1] (Estimated number of people currently infected)
Chlamydia	3 million	2 million
Gonorrhea	650,000	Not available
Syphilis	70,000	Not available
Herpes	1 million	45 million
Human Papillomavirus (HPV)	5.5 million	20 million
Hepatitis B	120,000	417,000
Trichomoniasis	5 million	Not available
Bacterial Vaginosis[2]	Not available	Not available

[1]No recent surveys on national prevalence for gonorrhea, syphilis, trichomoniasis or bacterial vaginosis have been conducted.
[2]Bacterial vaginosis is a genital infection that is not sexually transmitted but is associated with sexual intercourse.
Source: Cates, 1999.

Chlamydia

Chlamydia is a common sexually transmitted disease (STD) caused by *Chlamydia trachomatis*, a bacterium, which can damage a woman's reproductive organs. Because symptoms of chlamydia are mild or absent, serious complications that cause irreversible damage, including infertility, can occur "silently" before a woman ever recognizes a problem.

Chlamydia is the most commonly reported infectious disease in the United States and may be one of the most dangerous sexually transmitted diseases among women today. While the disease can be easily cured with antibiotics, millions of cases go unrecognized. If left untreated, chlamydia can have severe consequences, particularly for women. Up to 40 percent of women with untreated chlamydia will develop pelvic inflammatory disease (PID), and one in five women with PID becomes infertile. Chlamydia also can cause prematurity, eye disease, and pneumonia in infants. Moreover, women infected with chlamydia are three to five times more likely to become infected with HIV, if exposed.

Seventy-five percent of women and 50 percent of men with chlamydia have no symptoms. The majority of cases therefore go undiagnosed and unreported. The number of reported cases about 660,000 cases in 1999, is merely the tip of the iceberg.

- An estimated three million people contact chlamydia each year (Cates).
- Chlamydia is believed to be declining overall in the United States, primarily because of increased efforts to screen and treat women for chlamydia. Chlamydia is estimated to have declined from well over four million annual infections in the early 1980s to the current level of three million annual infections (Cates).
- Reported chlamydia rates in women greatly exceed those in men largely because screening programs have been primarily directed at women. True rates are probably far more similar for women and men.
- Since 1994, there has been increased funding available for chlamydia screening in publicly funded family planning and STD clinics. The percentage of women testing positive for chlamydia (chlamydia positivity) in family planning clinics by state provides a good indication of where the disease remains most widespread. The highest level of infection tends to be seen in areas where screening and treatment.
- have not been as widely implemented. The greatest declines have generally been in areas of the country with the most effective and prolonged screening programs.
- From 1988 to 1999, the Pacific Northwest — Washington, Oregon, Idaho, and Alaska — witnessed a 62 percent decline in infection among women tested for chlamydia in family planning clinics.
- In the Mid-Atlantic States — Delaware, Washington, DC, Maryland, Pennsylvania, Virginia, and West Virginia — similar trends are occurring, with a decline of 16 percent since 1994 (DSTDP, CDC).
- From 1997 to 1999, chlamydia test positivity in family planning clinics actually increased in eight out of 10 regions. However, these reported increases are most likely due to changes in newly available and better laboratory tests and expanded screening programs to populations with higher levels of disease (DSTDP, CDC).

Reducing the level of chlamydia will require continued expansion of screening and treatment among women and new efforts to reach men. While men experience symptoms and seek treatment on their own more often than women, half of men with chlamydia are asymptomatic. Reaching these men with treatment is critical to stem the spread of chlamydia and its severe consequences.

It is also critical to reach those at greatest risk, primarily young people, with programs to help reduce their risk of infection through safer sexual behaviors. See also **Chlamydia**.

For more information on Chlamydia, see the Division of Sexually Transmitted Diseases (CDC): http://www.cdc.gov/nchstp/dstd/Fact_Sheets/FactsChlamydiaInfo.htm

Gonorrhea

Gonorrhea is caused by *Neisseria gonorrhoeae*, a bacterium that can grow and multiply easily in mucous membranes of the body. Gonorrhea bacteria can grow in the warm, moist areas of the reproductive tract, including the cervix (opening to the womb), uterus (womb), and fallopian tubes (egg canals) in women, and in the urethra (urine canal) in women and men. The bacteria can also grow in the mouth, throat, and anus.

Gonorrhea is a sexually transmitted bacterial disease. Reported gonorrhea rates declined steadily until the late 1990s. From 1985 to 1996, rates of the disease decreased nearly 10 percent annually (Fox, CDC). However, rates stabilized between 1996 and 1997, and between 1997 and 1999, gonorrhea rates increased by nine percent (DSTPD, CDC). This increase, combined with signs of an increase in gonorrhea among gay and bisexual men, is reason for concern.

Rates of infection remain high among adolescents, young adults, and African Americans. Gonorrhea remains a major cause of pelvic inflammatory disease (PID) and subsequent infertility and tubal pregnancies in women. Additionally, studies have shown that gonorrhea can facilitate HIV transmission and may be contributing significantly to the spread of HIV in the south. There is a critical need to reach populations that remain at high risk for gonorrhea with intensified prevention and treatment efforts. Gonorrhea can be easily cured, if detected early, and the long-term consequences can be prevented.

- An estimated 650,000 cases of gonorrhea occur each year in the United States (Cates).
- Cases reported to CDC are believed to represent about half of all annual infections. While an underestimate of actual cases, these reports provide a good indication of trends in the disease.
- The reported gonorrhea rate in the United States remains the highest of any industrialized country and is roughly 50 times that of Sweden and eight times that of Canada.

- Researchers have seen alarming indications that gonorrhea may be on the rise among gay and bisexual men — men who have sex with men (MSM). In the mid-1980s, reports of increased condom use and reduced risky sexual practices accompanied dramatic decreases in rectal gonorrhea among MSM in several cities (Fox, CDC). Yet, data from cities throughout the country suggest that this trend may be reversing, and that gonorrhea cases may be resurging with the prospect of facilitating the spread of HIV in the gay community.

The rise in gonorrhea rates should serve as a wake-up call to people at risk, including gay and bisexual men, that high-risk sexual behaviors continue to have very real consequences. See also **Gonorrhea and Gonococcemia**.

For more information on Gonorrhea, see the Division of Sexually Transmitted Diseases (CDC): http://www.cdc.gov/nchstp/dstd/Fact_Sheets/FactsGonorrhea.htm

Syphilis

Syphilis is a complex sexually transmitted disease (STD) caused by the bacterium *Treponema pallidum*. It has often been called "the great imitator" because so many of the signs and symptoms are indistinguishable from those of other diseases.

Syphilis is passed from person to person through direct contact with a syphilis sore. Sores occur mainly on the external genitals, vagina, anus, or in the rectum. Sores also can occur on the lips and in the mouth. Transmission of the organism occurs during vaginal, anal, or oral sex. Pregnant women with the disease can pass it to the babies they are carrying. Syphilis **cannot** be spread by toilet seats, door knobs, swimming pools, hot tubs, bath tubs, shared clothing, or eating utensils.

In the United States, over 35,600 cases of syphilis were reported by health officials in 1999, including 6,650 cases of primary and secondary syphilis (a decline of 5.4% from 1998) and 556 cases of congenital syphilis in newborns. More cases occur each year than come to the attention of health officials. Of the nine states with the highest 1999 syphilis rates (2–5 times higher than the national rate of 2.5 cases per 100,000), eight were in the South. Although syphilis rates remain higher in the South than in other regions, the South had a 32% decline in the primary and secondary syphilis rate from 1997 to 1999, illustrating that the greatest improvements in disease control have taken place where syphilis incidence has been the greatest. In 1999, 25 counties accounted for 50% of all primary and secondary syphilis cases. Two hundred sixty-five counties had syphilis rates above the U.S. Public Health Service's Healthy People 2000 objective of 4 cases per 100,000. These 265 counties (9% of the total number of counties in the U.S.) accounted for approximately 74% of the total primary and secondary syphilis cases reported in 1999.

In 1999, syphilis occurred primarily in persons aged 20 to 39, and the reported rate in men was 1.5 times greater than the rate in women. The incidence of syphilis was highest in women aged 20 to 29 years and in men 30 to 39. Some fundamental societal problems, such as poverty, inadequate access to health care, and lack of education are associated with disproportionately high levels of syphilis in certain populations. Cases of primary and secondary syphilis in 1999 had the following race or ethnicity distribution: African Americans 75%, whites 16%, Hispanics 8%, and others 1%. Syphilis reflects one of the most glaring examples of racial disparity in health status, with the rate for African Americans nearly 30 times the rate for whites.

Symptoms

Primary Stage. The time between infection with syphilis and the start of the first symptom can range from 10–90 days (average 21 days). The primary stage of syphilis is usually marked by the appearance of a single sore (called a chancre), but there may be multiple sores. The chancre is usually firm, round, small, and painless. It appears at the spot where syphilis entered the body. The chancre lasts 3–6 weeks, and it will heal on its own. If adequate treatment is not administered, the infection progresses to the secondary stage.

Secondary Stage. The second stage starts when one or more areas of the skin break into a rash that usually does not itch. Rashes can appear as the chancre is fading or can be delayed for weeks. The rash often appears as rough, red or reddish brown spots both on the palms of the hands and on the bottoms of the feet. The rash also may also appear on other parts of the body with different characteristics, some of which resemble other diseases. Sometimes the rashes are so faint that they are not noticed. Even without treatment, rashes clear up on their own. In addition to rashes, second-stage symptoms can include fever, swollen lymph glands, sore throat, patchy hair loss, headaches, weight loss, muscle aches, and tiredness. A person can easily pass the disease to sex partners when primary or secondary stage signs or symptoms are present.

Late Syphilis. The latent (hidden) stage of syphilis begins when the secondary symptoms disappear. Without treatment, the infected person still has syphilis even though there are no signs or symptoms. It remains in the body, and it may begin to damage the internal organs, including the brain, nerves, eyes, heart, blood vessels, liver, bones, and joints. This internal damage may show up many years later in the late or tertiary stage of syphilis. Late stage signs and symptoms include not being able to coordinate muscle movements, paralysis, numbness, gradual blindness and dementia. This damage may be serious enough to cause death.

Diagnosis and Treatment

A health care provider can diagnose syphilis by using dark field microscopy to examine material from infectious sores. If syphilis bacteria are present in the sore, they will show up with a characteristic appearance.

A blood test is another way to determine whether someone has syphilis. Shortly after infection occurs, the body produces syphilis antibodies that can be detected by an accurate, safe and inexpensive blood test. A low level of antibodies will stay in the blood for months or years even after the disease has been successfully treated. Because untreated syphilis in a pregnant woman can infect and possibly kill her developing baby, every pregnant woman should have a blood test for syphilis.

A single dose of penicillin, an antibiotic, will cure a person who has had syphilis for less than a year. Larger doses are needed to cure someone who has had it for longer than a year. For people who are allergic to penicillin, other antibiotics are available to treat syphilis. There are no home remedies or over-the-counter drugs that will cure syphilis. Penicillin treatment will kill the syphilis bacterium and prevent further damage, but it will not repair any damage already done. Persons who receive syphilis treatment must abstain from sexual contact with new partners until the syphilis sores are completely healed. Persons with syphilis must notify their sex partners so that they also can be tested, and, if necessary, receive treatment.

Having had syphilis does not protect a person from getting it again. Antibodies are produced as a person reacts to the disease, and, after treatment, these antibodies may offer partial protection from getting infected again, if exposed right away. Even though there may be a short period of protection, the antibody levels naturally decrease in the blood, and people become susceptible to syphilis infection again if they are sexually exposed to syphilis sores. See also **Syphilis**.

Genital Warts (Human Papillomavirus HPV)

Genital HPV infection is a sexually transmitted disease (STD) that is caused by human papillomavirus (HPV). Human papillomavirus, or HPV, is the name of a group of viruses that includes more than 100 different strains or types. Over 30 of these are sexually transmitted, and they can infect the genital area, like the skin of the penis, vulva, labia, or anus, or the tissues covering the vagina and cervix.

Some of these viruses are considered "high-risk" types and may cause abnormal Pap smears and cancer of the cervix, anus, and penis. Others are "low-risk," and they may cause mild Pap smear abnormalities and genital warts. Genital warts are single or multiple growths or bumps that appear in the genital area, and sometimes form a cauliflower-like shape.

Approximately twenty million people are currently infected with HPV. Fifty to 75% of sexually active men and women acquire genital HPV infection at some point in their lives. About 5.5 million Americans get a new genital HPV infection each year.

The types of HPV that infect the genital area are spread primarily through sexual contact. Most HPV infections have no signs or symptoms; therefore, most infected persons are completely unaware they are infected,

yet they can transmit the virus to a sex partner. Rarely, pregnant women can pass HPV to their baby during vaginal delivery. A newborn that is exposed to HPV during delivery can develop warts in the larynx (voice box).

Most people who have a genital HPV infection do not know they are infected. The virus lives in the skin or mucus membranes and usually causes no symptoms. Other people get visible genital warts. See also **Gonads**.

Genital warts usually appear as soft, moist, pink or red swellings. They can be raised or flat, single or multiple, small or large. Some cluster together forming a cauliflower-like shape. They can appear on the vulva, in or around the vagina or anus, on the cervix, and on the penis, scrotum, groin, or thigh. Warts can appear within several weeks after sexual contact with an infected person, or they can take months to appear.

Genital warts are diagnosed by inspection. Visible genital warts can be removed, but no treatment is better than another and no single treatment is ideal for all cases.

For more information on Human Papillomavirus (HPV), see the Division of Sexually Transmitted Diseases (CDC): http://www.cdc.gov/std/

Genital Herpes (Herpes Simplex Virus HSV)

Herpes is a sexually transmitted disease (STD) caused by the herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2). Most individuals have no or only minimal signs or symptoms from HSV-1 or HSV-2 infection. When signs do occur, they typically appear as one or more blisters on or around the genitals or rectum. The blisters break, leaving tender ulcers (sores) that may take two to four weeks to heal the first time they occur. Typically, another outbreak can appear weeks or months after the first, but it almost always is less severe and shorter than the first episode. Although the infection can stay in the body indefinitely, the number of outbreaks tends to go down over a period of years.

HSV-1 and HSV-2 can be found and released from the sores that the viruses cause, but they also are released between episodes from skin that does not appear to be broken or to have a sore. A person almost always gets HSV-2 infection during sexual contact with someone who has a genital HSV-2 infection. HSV-1 causes infections of the mouth and lips, so-called "fever blisters." A person can get HSV-1 by coming into contact with the saliva of an infected person. HSV-1 infection of the genitals almost always is caused by oral-genital sexual contact with a person who has the oral HSV-1 infection.

Results of a recent, nationally representative study show that genital herpes infection is common in the United States. Nationwide, 45 million people ages 12 and older, or one out of five of the total adolescent and adult population, are infected with HSV-2.

HSV-2 infection is more common in women (approximately one out of four women) than in men (almost one out of five). This may be due to male-to-female transmission being more efficient than female-to-male transmission. HSV-2 infection also is more common in blacks (45.9%) than in whites (17.6%). Race and ethnicity in the United States correlate with other, more fundamental determinants of health such as poverty, access to good quality health care, behavior for seeking health care, illicit drug use, and living in communities with a high prevalence of STDs.

Since the late 1970s, the number of Americans with genital herpes infection has increased 30%. The largest increase is currently occurring in young white teens. HSV-2 infection is now five times more common in 12- to 19-year-old whites, and it is twice as common in young adults ages 20 to 29 than it was 20 years ago.

HSV-2 usually produces only mild symptoms or signs or no symptoms at all. However, HSV-2 can cause recurrent painful genital sores in many adults, and HSV-2 infection can be severe in people with suppressed immune systems. Regardless of severity of symptoms, genital herpes frequently causes psychological distress in people who know they are infected.

In addition, HSV-2 can cause potentially fatal infections in infants if the mother is shedding virus at the time of delivery. It is important that women avoid contracting herpes during pregnancy because a first episode during pregnancy causes a greater risk of transmission to the newborn. If a woman has active genital herpes at delivery, a cesarean delivery is usually performed. Fortunately, infection of an infant from women with HSV-2 infection is rare.

In the United States, HSV-2 may play a major role in the heterosexual spread of HIV, the virus that causes AIDS. Herpes can make people more susceptible to HIV infection, and it can make HIV-infected individuals more infectious.

Most people infected with HSV-2 are not aware of their infection. However, if signs and symptoms occur during the first episode, they can be quite pronounced. The first episode usually occurs within two weeks after the virus is transmitted, and the sores typically heal within two to four weeks. Other signs and symptoms during the primary episode may include a second crop of sores, or flu-like symptoms, including fever and swollen glands. However, most individuals with HSV-2 infection may never have sores, or they may have very mild signs that they do not even notice or that they mistake for insect bites or a rash.

Most people diagnosed with a first episode of genital herpes can expect to have several symptomatic recurrences a year (typically four or five). These recurrences usually are most noticeable within the first year following the first episode.

The signs and symptoms associated with HSV-2 can vary greatly. Health care providers can diagnose genital herpes by visual inspection if the outbreak is typical, and by taking a sample from the sore(s). HSV infections can be difficult to diagnose between outbreaks. Blood tests which detect HSV-1 or HSV-2 infection may be helpful, although the results are not always clear cut.

There is no treatment that can cure herpes, but antiviral medications can shorten and prevent outbreaks during the period of time the person takes the medication. See also **Herpes Simplex Virus Diseases**.

Hepatitis B (HBV)

Hepatitis B (HBV) virus is a serious viral disease that attacks the liver, and can cause extreme illness and even death. An acute HBV infection is a newly acquired, symptomatic infection. In some people, the infection resolves and the virus is cleared. However, many will remain chronically infected with the virus after the symptoms associated with their new infection have subsided. People chronically infected with HBV face an increased risk of developing chronic liver disease, including cirrhosis (scarring) and liver cancer, and for transmitting HBV infection to others.

According to the Third National Health and Nutrition Examination Survey [NHANES III], about five percent of the U.S. population has ever been infected with hepatitis B, with an estimated 200,000 infections occurring each year (Coleman). Of these, it is believed that 120,000 infections are acquired through sexual transmission annually, mostly among young adults. An estimated 417,000 people are currently living with chronic sexually acquired HBV infection.

Infants and young children have the highest risk of chronic infection.

An estimated 5,000 to 6,000 deaths occur each year from chronic hepatitis B-related liver disease.

Hepatitis B vaccinations have been recommended for people with risk factors for HBV infection since the vaccine became available in 1981. However, many teens and young adults at risk through sexual or drug-related behavior have not been vaccinated for HBV. Intensified efforts to vaccinate high-risk groups are urgently needed.

In 1997, 10,416 cases of acute hepatitis B were reported to the CDC. However, reported cases dramatically underestimate the actual number of people who are infected with hepatitis B virus each year, an estimated 200,000.

A recent study demonstrates the high degree of under-vaccination among those at high risk. Among acute hepatitis B cases reported by sentinel counties in 1996, 70 percent had a missed opportunity for vaccination in the past. Of these, 42 percent had been treated for an STD in the past, 31 percent had been in prison or jail at some time in their lifetime, and 25 percent reported sexual or household contact with an HBV-infected person (Mast, CDC).

See also **Liver**.

Trichomoniasis

Trichomoniasis is a common sexually transmitted disease (STD) that is spread through penis-to-vagina intercourse or vulva-to-vulva contact with an infected partner. Women can acquire the disease from infected men or women, whereas men usually contract it only from infected women.

Trichomoniasis is caused by the single-celled protozoan parasite *Trichomonas vaginalis*. The vagina is the most common site of infection in women, and the urethra is the most common site of infection in men.

Trichomoniasis is the most common curable STD in young, sexually active women. An estimated 5 million new cases occur each year in women and men.

Most men with trichomoniasis do not have signs or symptoms. Men with symptoms may have an irritation inside the penis, mild discharge, or slight burning after urination or ejaculation.

Many women do have signs or symptoms of infection. In these women, trichomoniasis causes a frothy, yellow-green vaginal discharge with a strong odor. The infection may also cause discomfort during intercourse and urination. Irritation and itching of the female genital area and, in rare cases, lower abdominal pain can also occur.

Trichomoniasis in pregnant women may cause premature rupture of the membranes and preterm delivery. The genital inflammation caused by trichomoniasis might also increase a woman's risk of acquiring HIV infection if she is exposed to HIV. Trichomoniasis in a woman who is also infected with HIV can increase the chances of transmitting HIV infection to a sex partner.

To diagnose trichomoniasis, a health care provider must perform a physical examination and laboratory test. In women, a pelvic examination can reveal small red ulcerations on the vaginal wall or cervix. Laboratory tests are performed on a sample of vaginal fluid or urethral fluid to look for the disease-causing parasite. The parasite is harder to detect in men than in women.

Trichomoniasis can usually be cured with the prescription drug metronidazole given by mouth in a single dose. The symptoms of trichomoniasis in infected men may disappear within a few weeks without treatment. However, an infected man, even a man who has never had symptoms or whose symptoms have stopped, can continue to infect a female partner until he has been treated. Therefore, both partners should be treated at the same time to eliminate the parasite. Persons being treated for trichomoniasis should avoid sex until they and their sex partners complete treatment and have no symptoms. Metronidazole can be used by pregnant women.

See also **Gonads**.

Bacterial Vaginosis (BV)

Bacterial vaginosis (BV) is the most common vaginal infection in women of childbearing age. Women with BV often have an abnormal vaginal discharge with an unpleasant odor. Some women report a strong fish like odor, especially after intercourse. The discharge is usually white or gray; it can be thin. Women with BV may also have burning during urination or itching around the outside of the vagina, or both. Some women with BV report no signs or symptoms at all.

The cause of BV is not fully understood. BV is associated with an imbalance in the bacteria that are normally found in a woman's vagina. The vagina normally contains mostly "good" bacteria, and fewer "harmful" bacteria. BV develops when there is a change in the environment of the vagina that causes an increase in harmful bacteria.

Not much is known about how women get BV. Women who have a new sex partner or who have had multiple sex partners are more likely to develop BV. Women who have never had sexual intercourse are rarely affected. It is not clear what role sexual activity plays in the development of BV, and there are many unanswered questions about the role that harmful bacteria play in causing BV. Women do not get BV from toilet seats, bedding, swimming pools, or from touching objects around them.

Scientific studies suggest that BV is common in women of reproductive age. In the United States, as many as 16% of pregnant women have BV. This varies by race and ethnicity from 6% in Asians and 9% in whites to 16% in Hispanics and 23% in African Americans. BV is generally more commonly seen in women attending STD clinics than in those attending family planning or prenatal clinics.

A health care provider must examine the vagina for signs of BV (e.g., discharge) and perform laboratory tests on a sample of vaginal fluid to look for bacteria associated with BV.

Although BV will sometimes clear up without treatment, all women with symptoms of BV should be treated to avoid such complications as PID. Treatment is especially important for pregnant women. All pregnant women, regardless of symptoms, who have ever had a premature delivery or low birth weight baby should be considered for a BV examination and be treated when necessary. All pregnant women who have symptoms of BV should be checked and treated. Male partners generally do not need to be treated. However, BV may spread between female sex partners.

BV is treatable with antimicrobial medicines prescribed by a health care provider. Two different medicines are recommended as treatment for BV: metronidazole or clindamycin. Either can be used with non-pregnant or with pregnant women, but the recommended dosages differ. Women with BV who are HIV-positive should receive the same treatment as those who are HIV-negative. BV can recur after treatment.

The Role of STD Detection and Treatment in HIV Prevention

Testing and treatment of sexually transmitted diseases (STDs) can be an effective tool in preventing the spread of HIV, the virus that causes AIDS. An understanding of the relationship between STDs and HIV infection can help in the development of effective HIV prevention programs for persons with high-risk sexual behaviors.

Individuals who are infected with STDs are at least two to five times more likely than uninfected individuals to acquire HIV if they are exposed to the virus through sexual contact. In addition, if an HIV-infected individual is also infected with another STD, that person is more likely to transmit HIV through sexual contact than other HIV-infected persons (Wasserheit).

There is substantial biological evidence demonstrating that the presence of other STDs increases the likelihood of both transmitting and acquiring HIV (Fleming, Wasserheit).

Increased Susceptibility. STDs probably increase susceptibility to HIV infection by two mechanisms. Genital ulcers (e.g., syphilis, herpes, or chancroid) result in breaks in the genital tract lining or skin. These breaks create a portal of entry for HIV. Nonulcerative STDs (e.g., chlamydia, gonorrhea, and trichomoniasis) increase the concentration of cells in genital secretions that can serve as targets for HIV (e.g., CD^{4+} cells).

Increased Infectiousness. Studies have shown that when HIV-infected individuals are also infected with other STDs, they are more likely to have HIV in their genital secretions. For example, men who are infected with both gonorrhea and HIV are more than twice as likely to shed HIV in their genital secretions than are those who are infected only with HIV. Moreover, the median concentration of HIV in semen is as much as 10 times higher in men who are infected with both gonorrhea and HIV than in men infected only with HIV.

Evidence from intervention studies indicates that detecting and treating STDs can substantially reduce HIV transmission at the individual and community levels.

STD Treatment Reduces an Individual's Ability to Transmit HIV. Studies have shown that treating STDs in HIV-infected individuals decreases both the amount of HIV they shed and how often they shed the virus (Fleming, Wasserheit).

STD Treatment Reduces the Spread of HIV Infection in Communities. Two community-level, randomized trials have examined the role of STD treatment in HIV transmission. Together, their results have begun to clarify conditions under which STD treatment is likely to be most successful in reducing HIV transmission. First, continuous interventions to improve access to effective STD treatment services is likely to be more effective in reducing HIV transmission than intermittent interventions through strategies such as periodic mass treatment. Second, STD treatment is likely to be most effective in reducing HIV transmission where STD rates are high and the heterosexual HIV epidemic is young. Third, treatment of symptomatic STDs may be particularly important.

The first community trial, conducted in a rural area of Tanzania, demonstrated a decrease of about 40% in new, heterosexually transmitted HIV infections in communities with continuous access to improved treatment of symptomatic STDs, as compared to communities with minimal STD services, where incidence remained about the same (Grosskurth, Mosha, Todd, et al.). However, in the second trial conducted in Uganda, a reduction in HIV transmission was not demonstrated when the STD control approach was community-wide mass treatment administered to everyone every 10 months in the absence of regular access to improved STD services (Wawer, et al.).

What are the Implications for HIV Prevention Programs?

Strong STD prevention, testing, and treatment can play a vital role in comprehensive programs to prevent sexual transmission of HIV. Furthermore, STD trends can offer important insights into where the HIV epidemic may grow, making STD surveillance data helpful in forecasting where HIV rates are likely to increase. Better linkages are needed between HIV and STD prevention efforts nationwide in order to control both epidemics.

In the context of persistently high prevalence of STDs in many parts of the United States and with emerging evidence that the U.S. HIV epidemic increasingly is affecting populations with the highest rates of curable STDs, CDC's Advisory Committee on HIV and STD Prevention (ACHSP) has recommended the following:

Early detection and treatment of curable STDs should become a major, explicit component of comprehensive HIV prevention programs at national, state, and local levels.
In areas where STDs that facilitate HIV transmission are prevalent, screening and treatment programs should be expanded.
HIV and STD prevention programs in the United States, together with private and public sector partners, should take joint responsibility for implementing these strategies.

The ACHSP also notes that early detection and treatment of STDs should be only one component of a comprehensive HIV prevention program, which also must include a range of social, behavioral, and biomedical interventions.

See also **Acquired Immune Deficiency Syndrome (AIDS)**.

STDs and Pregnancy

Women who are pregnant can become infected with the same sexually transmitted diseases (STDs) as women who are not pregnant. Pregnancy does not provide women or their babies any protection against STDs. In fact, the consequences of an STD can be significantly more serious, even life threatening, for a woman and her baby if the woman becomes infected with an STD while she is pregnant. As the list of diseases known to be sexually transmitted continues to grow, it is increasingly important that women be aware of the harmful effects of these diseases and know how to protect themselves and their children against infection.

STDs can be transmitted from a pregnant woman to the fetus, newborn, or infant before, during, or after birth. Some STDs (like syphilis) cross the placenta and infect the fetus during its development. Other STDs (like gonorrhea, chlamydia, hepatitis B, and genital herpes) are transmitted from the mother to the infant as the infant passes through the birth canal. HIV infection can cross the placenta during pregnancy, infect the newborn during the birth process, and, unlike other STDs, infect an infant as a result of breast-feeding.

Harmful effects on the baby may include stillbirth, low birth weight, conjunctivitis (eye infection), pneumonia, neonatal sepsis (infection in the blood stream), neurologic damage (such as brain damage or motor disorder), congenital abnormalities (including blindness, deafness, or other organ damage), acute hepatitis, meningitis, chronic liver disease, and cirrhosis. Some of these consequences may be apparent at birth; others may not be detected until months or even years later.

STDs affect women of every socioeconomic and educational level, age, race, ethnicity, and religion. The CDC STD Treatment Guidelines (1997) recommend that pregnant women be screened for the following STDs:

- Chlamydia
- Gonorrhea
- Hepatitis B
- HIV
- Syphilis

Pregnant women should request these tests specifically because some doctors do not routinely perform them. New and increasingly accurate tests continue to become available. Even if a woman has been tested in the past, she should be tested again when she becomes pregnant.

Bacterial STDs (like chlamydia, gonorrhea, and syphilis) can be treated and cured with antibiotics during pregnancy. There is no cure for viral STDs such as genital herpes and HIV, but antiviral medication for herpes and HIV may reduce symptoms in the pregnant woman. In addition, the risk of passing HIV infection from mother to baby is dramatically reduced by treatment. For women who have active genital herpes lesions at the time of delivery, a cesarean section may be performed to protect the newborn against infection.

Pelvic Inflammatory Disease (PID)

Pelvic inflammatory disease (PID) is a general term that refers to infection of the fallopian tubes (tubes that carry eggs from the ovary to the womb) and of other internal reproductive organs in women. It is a common and serious complication of some sexually transmitted diseases (STDs). Inside the lower abdominal cavity, PID can damage the fallopian tubes and tissues in and near the uterus and ovaries. Untreated PID can lead to serious consequences including infertility, ectopic pregnancy, abscess formation, and chronic pelvic pain.

Each year in the United States, more than one million women experience an episode of acute PID. More than 100,000 women become infertile each year as a result of PID, and a large proportion of the ectopic pregnancies occurring every year are due to the consequences of PID. More than 150 women die from this infection every year.

PID occurs when bacteria move upward from a woman's vagina or cervix into the internal reproductive organs. Sexually active women in their childbearing years are most at risk. Many different organisms can cause PID, but most cases are associated with gonorrhea and chlamydia, two very common bacterial STDs. It is estimated that 10% to 80% of women with either of these STDs will develop symptomatic PID.

Symptoms of PID vary from none to severe. Particularly when it is caused by chlamydial infection, PID may produce only mild symptoms or no symptoms at all, even while it is seriously damaging the internal reproductive organs. Because of the vague symptoms, PID goes unrecognized both by women and by their health care providers about two thirds of the time. Women who do have symptoms of PID most commonly have lower abdominal pain. Other signs and symptoms include fever, unusual vaginal discharge that may have a foul odor, painful intercourse, painful urination, irregular menstrual bleeding, and pain in the right upper abdomen (rare).

Early and complete treatment can help prevent complications of PID. Without treatment, PID can cause permanent damage to the female internal reproductive organs. Infection-causing bacteria can silently invade the fallopian tubes, causing normal tissue to turn into scar tissue. Scar tissue blocks or interrupts the normal movement of eggs into the uterus. If the fallopian tubes are totally blocked by scar tissue, an egg will not be fertilized by sperm or move to the uterus to develop into a baby. Totally blocked fallopian tubes cause a woman to be infertile. Infertility can also occur if the fallopian tubes are partially blocked or even slightly damaged. About one in five women with PID becomes infertile. If a woman has multiple episodes of PID, her chances of becoming infertile are increased.

In addition, a partially blocked or slightly damaged fallopian tube may cause a fertilized egg to get stuck in the tube. This fertilized egg may begin to grow in the tube as if it were in the womb. This is an ectopic pregnancy, which is a pregnancy in the fallopian tube or elsewhere outside the uterus. As it grows, an ectopic pregnancy can rupture the fallopian tube and cause severe pain, internal bleeding, and even death. Scarring in the fallopian tubes and other pelvic structures can also cause chronic pelvic pain (pain that lasts for months or even years). Women with repeated episodes of PID are more likely than women with a single episode to suffer infertility, ectopic pregnancy, or chronic pelvic pain.

PID is difficult to diagnose because the symptoms are often subtle and mild. Many episodes of PID go undetected because the woman or her health care provider fails to recognize the implications of mild or nonspecific symptoms. Because there are no precise tests for PID, a diagnosis is usually based on clinical findings. If symptoms such as lower abdominal pain are present, a health care provider should perform a physical examination to determine the nature and location of the pain and check for fever, abnormal vaginal or cervical discharge, and for evidence of gonorrhea or chlamydia infection. If the findings suggest PID, treatment is necessary.

If more information is necessary, the health care provider may order other tests to identify the infection-causing organism or to distinguish between PID and other problems with similar symptoms. A pelvic

ultrasound is a procedure that may be helpful in evaluating someone for PID. An ultrasound can view the pelvic area to see whether the fallopian tubes are enlarged or whether an abscess is present. In some cases, a laparoscopy may be necessary to confirm the diagnosis. A laparoscopy is a minor surgical procedure in which a thin, flexible tube with a lighted end (laparoscope) is inserted through a small incision in the lower abdomen. This procedure enables the doctor to view the internal pelvic organs and to take specimens for laboratory studies, if needed.

PID can be cured with antibiotics. If women have pelvic pain and other symptoms caused by PID, it is critical that they seek care immediately. Prompt antibiotic treatment can prevent severe damage to pelvic organs. The longer women delay treatment for PID, the more likely they are to be infertile or to have an ectopic pregnancy in the future because of damage to the tubes. However, antibiotic treatment does not reverse any damage that has already occurred to the reproductive organs.

Because of the difficulty in identifying organisms infecting the internal reproductive organs and because more than one organism may be responsible for an episode of PID, PID is usually treated with at least two antibiotics that are effective against a wide range of infectious agents. These antibiotics can be given by mouth or by vein. The symptoms may go away before the infection is cured. Even if symptoms do go away, women should finish taking all of the medicine. This will help prevent the infection from returning. Women on treatment for PID should be re-evaluated by their health care provider two to three days after starting treatment to be sure the antibiotics are working to cure the infection. In addition, women's sex partners should be treated to decrease the risk of re-infection, even if the partners have no symptoms. Many women with PID have sex partners who have no symptoms, although their sex partners may be infected with the organisms that can cause PID.

About one fourth of women with suspected PID must be hospitalized. Hospitalization may be recommended if the woman is severely ill (e.g., high fever) or pregnant; if she cannot take oral medication and needs intravenous antibiotics; if the diagnosis is uncertain; or in some cases, if she is infected with HIV (human immunodeficiency virus, the virus that causes AIDS). If symptoms continue or if an abscess does not resolve, surgery may be needed. Complications of PID, such as chronic pelvic pain and scarring are difficult to treat but are sometimes improved with surgery.

SEXUAL SELECTION. A form of natural selection in which the sex of the individual plays an important part in the selection. In birds, we often find an extreme sexual dimorphism because of the effects of such selection. The male may have brilliant plumage, whereas the female may be much more drab in her plumage. This is supposed to have arisen because of the elaborate courtship of many birds in which the males display their plumage, and it is thought there is some degree of selection of mates by the females. In other species of animals, where the males have battles for possession of the females, as in the fur seals and the moose, selection favors strength and fighting ability in the males. See Fig. 1.

SEYCHELLES PALM. See **Palm Trees**.

SEYFERT GALAXY. Any galaxy having a very bright nucleus showing a high excitation spectrum with rather broad emission lines. Recently, some Seyfert Galaxies have been shown to be radio galaxies. See also **Galaxy**.

SFERICS. (Also spelled spherics). The study of atmospherics, especially from a meteorological point of view. This involves techniques of locating and tracking atmospherics sources and evaluating received signals (waveform, frequency, etc.) in terms of source.

SFERICS FIX. The estimated location of a source of atmospherics, presumably a lightning discharge.

Fig. 1. Sexual selection in the fur seals. The bull in the upper left has collected his harem of devoted females through countless victorious battles with other males. At the extreme right, an envious bachelor male looks on.

SFERICS OBSERVATION. An evaluation, from one or more sferics receivers, of the location of weather conditions with which lightning is associated. Such observations are more commonly obtained from networks of two or three widely spaced stations. Simultaneous observations of the azimuth of the discharge are made at all stations and the location of the storm is determined by triangulation.

SFERICS RECEIVER. An instrument that measures, electronically, the direction of arrival, intensity, and rate of occurrence of atmospherics. In its simplest form the instrument consists of two orthogonally crossed antennas. Their output signals are connected to an oscillograph so that one loop measures the north-south component whereas the other measures the east-west component. These are combined vertically to give the azimuth. Also called *lightning recorder*.

SHACKLE. A shackle is a piece used for connecting together two parts. The parts so connected can have some relative motion permitted by the shackle, but at the same time the extent of their freedom is limited by the restraining action of the shackle.

SHAD. See **Gizzard Shad**; and **Herring**.

SHADBUSH. See **Rose Family**.

SHALE. A fine-grained sedimentary rock whose original constituents were clays or muds. It is characterized by thin laminae breaking with an irregular curving fracture, often splintery, and parallel to the often indistinguishable bedding planes.

The fine particles that compose shale can remain suspended in water long after the larger and denser particles of sand have deposited out. Shales are typically deposited in very slow moving water and are often often found in lake and lagoonal deposits, in river deltas, on floodplains, and offshore of beach sands. See also **Delta**; and **Floodplain**.

SHALLOW CONVECTION PARAMETERIZATION. The representation in a numerical model of the turbulent transports of heat and moisture by nonprecipitating cumulus clouds with cloud tops below 3,000 meters (9,843 feet) above the surface. These shallow cumulus clouds are found all over the globe but they, and their associated turbulent transports, are of particular significance in the trade wind region where they provide the heat and moisture that maintains the thermodynamic structure of the lower troposphere.

See also **Parameterization**.

SHAMAL. See **Winds and Air Movement**.

SHANNON. In information theory, a unit of logarithmic measures of information equal to the decision content of a set of two mutually exclusive events expressed by the logarithm to base two; e.g., the decision content of a character set of 8 characters equals 3 Shannons. Synonymous with information content binary unit. (*American National Dictionary for Information Processing*.) See also **Information Theory**.

SHANNON FORMULA. A theorem in information theory that states that a method of coding exists whereby C binary digits per second may be transmitted with arbitrarily small frequency of error where C is given by

$$C = B \log_2 \left(1 + \frac{S}{N}\right)$$

and no higher rate can be transmitted; B is the bandwidth, and S/N is the signal-to-noise ratio. See also **Information Theory**.

SHAPE-MEMORY ALLOYS. Shape-memory alloys (SMAs) when deformed can produce strains as high as 8%. Heating results in a phase transformation and associated recovery of all the accumulated strain, a phenomenon known as shape-memory. This strain recovery can occur against large forces, resulting in their use as actuators. Associated with this behavior is the superelastic or pseudoelastic effect (SE) wherein large and completely recoverable strains are generated mechanically rather than thermally. Whereas the alloys are primarily nonferrous, some ferrous alloys also exhibit shape memory. Applications of SMAs include those as tubes and valves in piping systems for power plants, ships, and the petroleum industry; use as explosive bolts in the aerospace and construction industry; as packaging devices for electronic materials; and as dental materials, prosthetics, and biomedical devices. Shape-memory alloys may be found in sensors in automobiles, in consumer products, and generally in smart materials and adaptive structures.

Phenomenology

As the name suggests, the shape-memory effect (SME) refers to a phenomenon wherein a material on being mechanically deformed and then heated, "remembers" and returns to a preset shape. Associated with this behavior is the superelastic or pseudoelastic effect (SE) wherein large and completely recoverable strains are generated mechanically rather than thermally. Both these effects are associated with the martensite transformation, a first-order displacive transformation usually related to the hardening of steel. In steel, an alloy heated to the temperature where the elevated temperature face-centered cubic (fcc) austenite phase is stable, is rapidly cooled to produce the hard martensite phase. In SME alloys, however, the martensite transformation is thermoelastic and the martensite forms and disappears on heating and cooling over a relatively small temperature range. The intermetallic phase in these alloys undergoes a displacive, shear-like transformation when cooled below a critical temperature designated as M_S (martensite start). Upon further cooling, to a temperature designated as M_F (martensite finish), the transformation is complete and the alloy is said to be in its martensitic state. When this martensite is deformed, it undergoes a strain that is completely recovered when the alloy is heated. This recovery is due to a reverse transformation to the corresponding austenite phase. The recovery process starts at the temperature A_S (austenite start) and is completed at a higher temperature, A_F (austenite finish). This is a first-order phase transformation and there is hysteresis associated with the formation of martensite and its reverse transformation to the elevated temperature parent austenite phase. The temperatures M_S, M_F, A_S, and A_F depend on the particular alloy, alloy composition, and processing.

The martensite in shape-memory alloys (SMAs) may also be isothermally generated by applying stress at a temperature above M_S. Large strains are usually associated with this stress-induced transformation. Upon unloading (or removal of the stress), the stress-induced martensite (SIM) is no longer stable and reverts to the parent austenite phase with concomitant recovery of all the strain. The strains involved are typically large (up to 8%) when compared to similar material systems and are different in that they do not involve elasticity associated with conventional stretching of interatomic bonds. Hence, the superleastic or pseudoelastic nomenclature. Above a temperature designated as M_D, martensite cannot be generated, no matter how high the stress.

Another property associated with SMAs is the linear superelastic effect (LSE), which is distinguished from the SE. Many of the martensitic alloys, when deformed well beyond the point where the initial single coalesced martensite has formed, exhibit a stress-induced martensite-to-martensite transformation. In this mode of deformation, strain recovery occurs through the release of stress, not by a phase change. This behavior has been exploited for medical devices and typical stress–strain responses are linear with reduced hysteresis.

SME and SE are unique in the operative mode of mechanical deformation. Conventional metallic materials deform elastically (by stretching the interatomic bonds) or plastically (by rearranging the atomic lattice through dislocation, slip or grain boundary motion). Mechanical deformation in SMAs involves phase transformation and/or twinning and results in the SME and/or the SE. Twinning is an imperfection in polycrystals involving the intergrowth of two or more polycrystal grains so that each grain in a twinned system is a reflected image of its neighbor. In essence, twinning is a special type of grain boundary defect where a polycrystal grain is joined to its mirror image. Additionally, these alloys exhibit excellent damping properties. Damping is the property that causes a vibration, once induced in a material, to decay. Bell bronzes have a specific damping capacity of $<1\%$, a gray cast iron formulated for use as a machine-tool bed for resistance to vibration might have a specific damping capacity of 10%. By contrast, SMAs can have a damping capacity of $>40\%$. This characteristic can be exploited in smart or adaptive materials. See also **Smart Materials**. Damping is the result of the high mobility of the interfaces between martensite variants or plates (crystallographic orientations). When martensite is stressed, the deformation is accompanied by the growth and shrinkage of martensite variants or the motion of twin boundaries. When subjected to an oscillating stress these mobile boundaries move back and forth, giving rise to a frictional loss that accounts for the damping.

Simple shape-memory behavior, ie, one-way memory, may be extended to two-way memory. When a deformed martensite is heated to austenite to recover its original shape, it is a one-time event; to repeat the sequence the SMA must be cooled and the martensite must again be deformed. In two-way memory, the part spontaneously changes from one shape to another upon cooling or heating. This behavior, requiring a special conditioning or biasing of the martensite, is effected by limiting the number of martensite variants that form upon cooling through the application of an external stress during the transformation. The stress favors the initial formation of selected variants, similar to the stressing of a martensite group causing the selective growth and shrinkage of suitably oriented plates. Limiting the number of variants formed reduces the self-accommodating feature of the transformation and increases the residual internal stress. By repeating the cycle a number of times, referred to as the training process, the restricted variant group and its associated internal stress spontaneously revert to the parent phase on heating and then to a singular martensite on cooling.

Crystallography and SMA Systems

The SME was first reported in 1951 involving a Au–Cd alloy. Many other alloys exhibiting this behavior have since been discovered. It was, however, the discovery of the SME in the near-equiatomic Ni–Ti alloy that led to large-scale commercial applications. This alloy is usually called Nitinol, after Ni–Ti Naval Ordinance Laboratory where it was first investigated. Nitinol and its variations are the most frequently employed shape-memory alloys, although two other SMA systems based on Cu–Zn–Al and Cu–Al–Ni, also find use in special applications. Nitinol is relatively expensive, owing to the extremely tight composition control required to prepare an alloy having specific transformation temperatures. A difference of 1 at.% in the relative Ni and Ti compositions can shift transformation temperatures by up to $\sim 150\,^{\circ}\mathrm{C}$ ($\sim 302\,^{\circ}\mathrm{F}$). Copper-based SMAs were developed as less expensive alternatives. Although these alloys were employed for a period as actuators of various designs, shortcomings related to fatigue strength and thermodynamic stability restrict use. Certain ferrous alloys, have also been discovered. These are potentially less expensive SMA candidates, but have not achieved broad commercial use.

SME involves a martensitic transformation from an ordered parent phase to an ordered martensite that is crystallographically reversible and

thermoelastic, although there are a few exceptions to the requirement of ordering for nonferrous alloys, and more exceptions for the ferrous SMAs. In some alloy systems, the various martensites are internally faulted or internally twinned and can possess different crystal structures, the most common being 2H, 3R, 9R, 18R, monoclinic, and rhombohedral. An initial parent phase transforms to self-accommodating martensite plates, which can be characterized eg, by six plate groups, each plate group consisting of four variants. Owing to the self-accommodating nature of the transformation, the average shape deformation in a particular plate group is near zero. A body-centered cubic (bcc) parent phase that initially transforms to an ordered B2 or DO_3 phase is the dominant precursor or parent for SMAs. This is a result of the comparatively large thermodynamic difference that exists between the transformation from bcc to 2H, 3R, 9R, 18R, and monoclinic martensites and the typical ferrous martensites that transform from an fcc austenite to a bcc or bct martensite.

The SME can be illustrated by the Cu−Zn system, one of the first SMAs to be studied. A single orientation of the bcc β-phase on cooling goes through an ordering process to a B2 phase. In a disordered alloy, the lattice sites are randomly occupied by both types of atoms, but on ordering, the atoms locate at particular atomic sites, yielding what is called a superlattice. When the B2 phase is cooled below the M_F, it transforms to self-accommodating variants of ordered martensite. The habit planes for the transformation are symmetrically disposed around the {110} family of planes, of which there are six in the cubic system. Thus, for the (011) plane the four variants are (2 11 12), (2 12 11), (2 12 11), and (2 11 12). These are termed the plate group. The six {110} planes of the bcc parent then yield a total of 24 martensite variants. When the martensite group is deformed, the deformation proceeds by the gradual conversion of four variants to a single martensite plate. The surviving orientation depends on the strain direction, and the growth or shrinkage of the variants is such as to minimize the strain energy accumulation. In other words, the surviving variant is the one that allows the greatest extension in the applied stress direction. This varies with the nature of the strain, tension, compression, bending, or torsion. Once a group becomes a single variant, it can change its orientation to that of an adjacent group by the process of twinning. Upon heating, the reverse transformation from martensite to the β-phase occurs between A_S and A_F, and the single crystal (plate) of martensite transforms to the single β-crystal having the original orientation of the parent phase.

In the case of Cu−Zn and other systems that have relatively complex ordered martensite structures (9R or 18R), the reverse transformation is crystallographically restricted. This means that although there are many variants that can form on transformation from parent to martensite, only a single parent orientation is possible in the reverse, or shape-recovery, transformation. A detailed discussion of the crystallography of martensitic transformations and lattice-invariant shear is available. When a martensite group is deformed to coalesce into a single orientation, the dominant mechanism is twinning, where each twin is actually an alternate variant of the martensite crystal. Thus, for the four variants that cluster about the (110) habit plane, each orientation is a twin of another, and by the degenerate variant-twin relationship, a group of martensite plates from a single parent crystal can, on deformation, coalesce to a single crystal (single variant) of martensite. The parent phase, usually ordered B2 or DO_3, transforms to one of the martensite crystal forms that exhibit shape memory. Examples are 2H, Cu−Al−Ni, Cu−Sn, and Ag−Cd; 3R, Ni−Al; 9R, Cu−Zn; 18R, Cu−Zn−Al; and the monoclinic, NiTi.

A distinction exists in the habit and deformation characteristics of the 2H and 3R types and the 9R and 18R martensites. The former are internally twinned and deformation occurs by detwinning of a variant plate. The latter are internally faulted and deformation proceeds by variant-to-variant coalescence, followed by group-to-group coalescence. Although these structural differences exist, the self-accommodating habit-plane grouping with respect to a {011} plane is common to all systems exhibiting the SME. The 9R martensite is derived from a B2 parent; the 18R transforms from a DO_3 superlattice. The difference in stacking of {110} planes in these two structures results from the requirement for an invariant plane strain that involves a restricted stacking of close-packed planes. In order to obtain the required plane strain condition, both the 9R and 18R contain stacking faults to provide the necessary accommodation. The atomic displacements required to yield these structures combine the processes of shuffling and shear. The 3R martensite twin plane is identical to the 9R and 18R fault plane. For the case of 2H martensites, no such twin-fault correspondence exists, and the twin is derived from a different parent {110} plane.

Applications of the SME

Applications for nonferrous shape-memory alloys can be categorized into the following: one-way SMA devices, virtual two-way devices using one-way SMAs, two-way SMA applications, and SIM/superelastic devices. Ferrous alloy devices are considered separately. Over 20,000 patents have been issued on applications for SMAs; the actual number of these that have resulted in commercially successful products, however, is probably only ∼100. Some of the limitations that impact the chances for broad commercial acceptance of these alloys are (*1*) recoverable strain, depending on the alloy, varying from 1 to 8%; (*2*) cyclic strain limit, ie., the required fatigue life determines the permissible shape recovery from 4 to <0.5%; (*3*) cyclic stability, ie, some alloys exhibit a change in transformation temperature after many cycles of shape recovery; (*4*) temperature limitations, ie, the maximum shape-recovery temperature known for an alloy requiring long-term exposure is ∼130 °C (∼266 °F); (*5*) hysteresis, ie, alloys having a set hysteresis are required for various applications and the alloys available do not always meet the requirement; (*6*) processibility, ie, compositional control is exacting and the hot and cold working of these alloys is quite difficult compared to conventional alloys; and (*7*) fabricability, where the ease of forming a device or the available room temperature ductility of the alloy is not always satisfactory.

One-Way SMA Applications. The first successful application for nitinol (alloyed with Fe) was as a tube coupling for titanium hydraulic tubing in Grumman F-14 aircraft. In this application, a coupling is fabricated having an inner diameter smaller than the tube to be joined. The coupling is then cooled to its martensitic state and expanded by ∼8% so that it fits over the tube. On warming to the shape-recovery temperature, the coupling transforms to austenite, shrinks and produces a joint having a very high reliability. The original couplings required cooling to cryogenic temperature and after expansion were maintained at this temperature until installation. A newer alloy, NiTi alloyed with Nb, has a very wide hysteresis that allows the alloy, after cryogenic expansion, to be stored at room temperature. Upon installation, the coupling is heated to ∼100 °C for recovery, creating the joint. A primary consideration in the use of SMA couplings is the range of temperatures to which it is to be exposed. High temperature use is limited by stress relaxation and thermodynamic stability; the low temperature limit is dictated by the M_S temperature of the alloy, the temperature where loosening occurs. SMA couplings of this type have been installed in chemical and petroleum plants, power plants, and in piping systems aboard ships.

By using the wide hysteresis alloy, seals of various types have been developed based on the closing force of a wire ring of suitable diameter. Such seals are used for a wide variety of electronic device closures, eg, the attachment of shielding on electrical cables, and as closures on thin-wall cylindrical packages used in the semiconductor industry. These seals avoid the heat of soldering, brazing, or welding; thus, there is less chance of damage to the temperature-sensitive electronic components. Using couplings similar to the tube coupling, SMA fiber optic connectors have been produced that provide the necessary accuracy of axial alignment and a good hermetic seal, and do not require excessive heat for installation.

SMA actuators are particularly advantageous in that: (*1*) They integrate sensory and actuation functions. The SMA element inherently senses a change in temperature and actuates by undergoing a shape change as a result of a phase transformation. Consequently, the need for external electronic sensors and control is eliminated. (*2*) They function in a clean, debris-less, spark-free manner. The shape change that is responsible for the actuator displacement is again an inherent material property. It is not associated with moving parts that require lubrication or electrical signals with a potential to spark. (*3*) They have high power/weight and stroke length/weight ratios. The operating range includes strain and stress limits of 8% and 700 MPa, respectively, depending on the number of required cycles. (*4*) They posses the ability to function in zero-gravity environments with small, controlled accelerations. The displacement strains are a result of a thermally- induced phase transformation that can be controlled by controlling the heat transfer rate (eg, through appropriate insulation). In many of the operations of spacecraft, it is necessary to separate the craft

from its mooring before launch, and then to separate the booster and subsequent stages from the payload. The most frequently employed device for these procedures is an explosive bolt. These are also used in a variety of safety-release and closure systems in industrial plants. As these devices are considered hazardous, the installation involves many precautions. In addition, a severe electrical storm can induce voltages in the system sufficient to activate the explosive charge accidentally. An SMA device has been developed that consists of a prestrained cylinder surrounding a bolt that has a machined notch in its surface. When the SMA device is electrically heated above A_F it expands, causing the bolt to fracture at the notch, releasing the load. The electrical energy required is well above that which can be generated by an accidental static electric charge pickup.

Virtual Two-Way Devices Using One-Way SMAs. Although alloys such as NiTi are considered to be one-way SMAs, by using a bias elastic spring to provide the reverse motion (a recocking), a two-way device can be designed. A typical linear actuator consists of a shape-memory spring that produces motion and force in one direction and a steel spring that opposes this motion. When heated, the SMA spring has sufficient force to overcome the bias, but when the system cools, the bias spring has greater force and causes a reverse motion. A salient feature of SMA devices is that the modulus of elasticity increases with increasing temperature. This is quite unlike conventional materials. The modulus difference between the martensitic structure and the parent-phase austenitic structure is typically 300%. Virtual two-way devices have found many applications, eg, as electrical connectors in computer systems. At the high operating frequencies (>100 MHz) of modern computers there are problems of cross-talk between adjacent channels, noise, switching delays, and signal velocity, requiring very close pin spacing, shielding, and high contact force. The high forces needed in these multipin connectors make it difficult to make the male–female connection without damage to the contact surfaces. A device that opens and closes the jaws of the female component, thus providing what is termed a zero-insertion-force (ZIF) connector, is readily produced using SMA actuators. The closing force is provided by a SMA spring-like member when at ambient temperature. If the device is cooled by a cold jet of inert gas to below M_S, its modulus decreases as it transforms to martensite and a second spring then opens the connector, allowing easy insertion of the male connector. When the connector warms back to the normal operating temperature, it closes with the required high force, providing a low contact resistance connection. Other versions of this device have been employed for military electronics requiring resistance to loosening under severe vibration conditions.

Circuit breakers have severe demands on performance and reliability, and the bimetals usually employed in the tripping mechanism have several disadvantages. As their motion on heating is very small, the circuit breaker, depending on its size and capacity, must be calibrated to ensure that at the prescribed trip current the circuit breaker opens. In addition, because the force output of a bimetal is modest, a large circuit breaker may require the use of a cascading series of spring-actuated levers to provide the required interruption force and speed. One of the salient features of shape-memory actuators is that they produce larger motions and forces in a lighter and smaller device than wax motors, solenoids, bimetals, or electric motors. Shape-memory actuators do, however, have one disadvantage, ie, a relatively low cyclic speed. Although a shape-memory device can be heated in milliseconds or less to provide the shape recovery, the reverse cycle of cooling is limited by convective, conductive, or radiation heat transfer, thus placing a practical limit on all but very small actuators typically having a cyclic rate of ~4 Hz. By using very thin wires and optimizing the cooling rates, frequencies of up to 30 Hz have been demonstrated in a laboratory setting.

Some notable examples exist of SMA actuators that perform a function far more efficiently than alternatives, in some cases, a function that cannot be performed by other actuator devices. An automatic transmission fluid temperature controller for Mercedes Benz cars is one example. Smooth gear shifting at low temperatures is assured by the control of the transmission fluid pressure, allowing full fluid flow only when the proper operating temperature is reached. Other automotive applications have been designed that take advantage of the compact, simple actuators that are possible using the high force and large strain capability of SMAs. Many devices have been demonstrated, eg, engine controls, climate controls, mirror motions, windshield wipers, cooling fan control, and retractable headlights. The best available NiTi SMAs have an upper actuation limit of ~80–120 °C (~176–248 °F), and summer under-the-hood temperatures of cars operating in North America and in many other countries can reach >125 °C (>257 °F). Although the Cu–Al–Ni family of SMAs can be alloyed to give an A_S temperature in excess of 150 °C (302 °F), the long-term thermodynamic stability of these alloys is considerably lower.

Other successful actuators have been developed for various domestic safety devices. One such device is a shape-memory-actuated valve that fits in line with a bathroom sink, tub, or shower, and in the event that through some system imbalance or malfunction the water discharge approaches the temperature that would cause scalding, the valve automatically shuts off the flow and does not allow water flow to resume until the temperature is safe. A similar thermally triggered valve has been developed for shutting off the flow in industrial gas or fluid lines in the event of an excessive temperature or a fire. Shape-memory actuators are also candidate actuators to replace the glass bulb or fusible link in overhead fire extinguisher systems. Regulations stress the protection of human life, requiring that the sprinkler actuation speed be decreased to 14 s, well within the capability of an inexpensive SMA device but more difficult to achieve in the conventional trip devices.

Space exploration presents a unique array of problems, involving in-space construction of structures, deployment of large antennas, control of antenna geometry, actuators for robotic devices, and control elements for a broad variety of scientific experimental apparatus. SMA joining techniques have been designed for the robotic assembly of large space structures. Usually, these structures are truss-like members having many struts that must be joined using a minimum of energy and extravehicular work by the astronauts. SMA couplings that can be attached and then detached to move to a new location are possible. These could be a useful tool for this area of space engineering. One problem inherent in space structures is vibration, which can impact on the function of space experiments and the accuracy of instruments. Large flexible structures, once put in motion by some external or internal force or shift of mass, have by themselves no substantial damping, operating in the vacuum of space. In essence, a smart material is one that can change its characteristics in such a way as to correct a condition that degrades its performance. These systems have incorporated into their structures sensors, controllers, and actuators. The detector, sensing a vibration, sends a signal to a microprocessor–controller that in turn energizes some form of actuator to change the local structural dynamics, causing the vibration to decrease or be canceled. Shape-memory wires and ribbons embedded in the composite materials of construction have proved to be very effective. The wire or ribbon is prestrained before being embedded and then held under constraint while the composite, typically a graphite epoxy, is cured. When these SMA actuators are electrically heated, they attempt to recover their original dimensions. Owing to the constraint offered by the composite to which the SMAs are bonded, however, they can only produce an in-plane stress that alters the modal response of the structure, reducing its vibrational amplitude. In addition to acoustic and vibration control, SMA actuators are also used in smart materials for shape control, for eg, changing the contour of an airfoil or hydrofoil, fine-tuning the contour of an antenna, and changing the focal point of microwave reflectors. The design of smart materials and adaptive structures has required the development of constitutive equations that describe the temperature, stress, strain, and percentage of martensite volume transformation of a shape-memory alloy. These equations can be integrated with similar constitutive equations for composite materials to make possible the quantitative design of structures having embedded sensors and actuators for vibration control. The constitutive equations for one-dimensional (1D) systems as well as a (3D) representation have been developed to a certain extent.

Superelastic and Pseudoelastic Devices. Medical instruments and devices have become an important application for shape-memory alloys. Both shape recovery and superelastic behavior are exploited in biocompatible nitinol. The first application that has achieved broad acceptance is the use of pseudoelastic SMA wire for orthodontic arch wires. These wires, attached to the teeth by small adhesively bonded clips, provide the correcting force for adjusting the position of teeth. The wires have a resistance to permanent deformation, which translates into much faster correction of the misalignment and far fewer periodic adjustments by the orthodontist. The use of traditional bridges and plates for teeth replacement

is giving way to tooth implant procedures. This involves the attachment of a metal peg in the jaw bone and when the two are stabilized, the new tooth is attached to the peg. By using conventional implant techniques it can take >6 months for the metal implant to stabilize before the replacement tooth is attached. By using shape-memory implant posts that lock into the bone immediately, reduces the time for the procedure to days. In maxillofacial surgery, which often involves reshaping the mandible and other cranial bones, shape-memory bone fasteners are proving superior to the usual screwed metal plates. If the SMA plate is prestrained and then attached to the two bone elements, as it warms to body temperature it pulls the mating surfaces into intimate contact, accelerating the healing process. Fractures in other bones such as in the arms and legs have benefitted from this procedure. Often fractures are associated with detachment of tendons that are normally difficult to reattach to the bone. Shape-memory anchors can make this a simple procedure. A small anchor with shape-memory wings is forced into a small hole drilled in the bone, and the wings provide secure locking in the hole. The tendon is then sutured to the anchor and in time attaches itself to the bone. If it is not dissolved or trapped, an embolism moving from the lower extremities can be life-threatening. A shape-memory trap has been devised that, when deployed in the vena cava, is like a multileaved mesh that traps a traveling embolism, retaining it until medication can dissolve it. Introduced in a folded form by a catheter, the mesh is prevented from deploying by subjecting it to a flow of cold saline water. Once in place, it is released from the catheter and, warmed by body heat, opens into its final shape. A variety of procedures have been developed to improve spinal fusion. Shape-memory rings are used to separate adjacent vertebrae and allow bone implants or bone chips to be inserted to develop the solid fusion section.

NiTi superelastic wires have a remarkable resistance to kinking or developing permanent deformation after bending. This feature is exploited in the long thin wires used to guide a catheter to its required position in the body. The wires allow safe introduction of a catheter through the sometimes tortuous passages of veins and arteries in cardiology procedures such as angioplasty. This flexibility and resistance to kinking of superelastic SMAs also makes possible superior needles and probes for arthroscopic procedures. Breast lesions, once located by radiology, are difficult to identify when the surgeon operates to remove them. A superelastic probe having a curved hook end can be introduced by a hypodermic needle during radiography and when the needle is retracted the curved end keeps the probe, in place, thus identifying the location of the lesion.

Currently, shape-memory stents are beginning to find widespread application in the human body. Stents, spiral tubular spring-like devices used to restore the patency of a vessel such as an artery, various ducts, and even the esophagus, have been made using conventional polymers and metals, but with only partial success. The ability to make such a device of SMA ribbon or wire in coiled form, then stretch it almost straight to allow its placement in a catheter for introduction to the desired location, and then on deployment have the ribbon reform into a rigid coil that supports the vessel walls, is a great advance. This type of stent has also been demonstrated to be a fast and effective repair device for an abdominal aortic aneurysm.

In addition to these medical applications, superelastic wires in very large quantities have been used for eyeglass frames, where their resistance to accidental damage and light weight are attractive features. Another large market is in the cellular telephone. The short antenna of superelastic shape-memory wire is very resistant to kinking and bending damage. A substantial tonnage market for superelastic memory alloy wire also exists for stiffening wire in brassieres. Resistance to permanent bending during machine washing and drying is provided by the SMA.

Ferrous SMAs. Ferrous shape-memory alloys have potential as low cost, readily fabricated one-way devices. These alloys, with one exception, do not form thermoelastic martensite. The alloy family of greatest interest, Fe–Mn–Si, forms martensite on cooling. However, if this martensite is deformed, it does not exhibit shape memory on heating to the A_F temperature. On the other hand, if the alloy is subjected to sufficient stress, an epsilon martensite forms by the SIM reaction. This deformation is recovered on heating, yielding a one-way shape-memory behavior. The basic alloy does not have the corrosion resistance required for many industrial applications, and to improve this feature, the alloy has been further alloyed with Ni, Cr, and Co. The recoverable strain is modest when the alloy is subjected to its first deformation and recovery cycle, but on subsequent cycling, more or less similar to the training cycles used to impart two-way memory, the recoverable strain increases and up to 4% shape recovery has been achieved. This is sufficient for many applications, although the stress generated on shape recovery is only a modest 250 MPa (36,250 psi). If this can be increased to ~700 MPa (101,500 psi), a very interesting application is possible: The use of prestrained ferrous SMA rods as prestressing tendons to produce prestressed concrete structures.

SHAPE-MEMORY POLYMERS. Besides finding high performance materials, material scientists concentrate on designing "intelligent" and "self-repairing materials". In this context, materials showing a thermally induced shape-memory effect like metallic alloys, or gels have been studied intensively, and a class of polymers showing shape-memory behavior has found growing interest. See also **Shape-Memory Alloys**. The relatively easy manufacturing and programming of shape-memory polymers makes these materials a cheap and efficient alternative to well-established metallic alloys. These polymers usually far surpass the recovery properties of shape-memory alloys which can recover deformations of 8% at maximum. Considering the importance of polymeric materials in our daily life, a very broad spectrum of possible applications for intelligent polymers opens up, covering an area from minimally invasive surgery to high performance textiles, and to self-repairing plastic components in all kinds of technical devices.

Stimuli-sensitive implant materials have a high potential for applications in minimally invasive surgery. Degradable implants could be inserted into the human body in a compressed (temporary) shape through a small incision where they obtain their shape relevant for the specific application after warming up to body temperature. After a defined time period, the implant is degraded. In this case, subsequent surgery to remove the implant is not necessary. For applications in biomedicine, it is necessary to have tailor-made shape-memory polymers whose thermal, mechanical, or degradation properties can be varied over a wide range. A substantially new development in this context is polymer systems. These are families of polymers, in which macroscopic properties can be controlled by a specific variation of molecular parameters. In this way shape-memory polymers having a specific combination of properties required for specific applications can be obtained by slight variation of the molecular structure and chemical composition.

Shape-memory polymers are stimuli-responsive materials. Upon application of an external stimulus, they have the ability to change their shape. A change in shape initiated by a change in temperature is called thermally induced shape-memory effect. The shape-memory effect results from the polymer's structure, ie, its morphology in combination with a certain processing and programming technology. Therefore, shape-memory behavior can be observed for several polymers that may differ significantly in their chemical composition.

The process of programming and recovering the shape of a polymer is shown schematically in Figure 1. The polymer is processed into its *permanent shape* by conventional methods. Afterward, it is deformed and the desired *temporary shape* is fixed. The later process is called

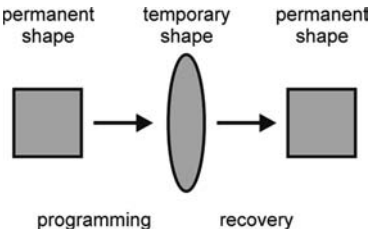

Fig. 1. Schematic demonstration of the thermally induced one-way shape-memory effect. By the programming process, the permanent shape is transferred to the temporary shape. Heating up of the sample to a temperature above the switching transition T_{trans} initiates the recovery of the permanent shape.

programming. The programming process either consists of heating the sample, deforming and cooling the sample, or drawing the sample at a low temperature (cold drawing). The permanent shape is now stored while the sample is in the temporary shape. Heating the programmed polymer above a temperature higher than the transition temperature T_{trans} results in activating the shape-memory effect. Consequently, the recovery of the memorized, permanent shape can be observed. Cooling of the polymer below the transition temperature leads to solidification of the material. However, the polymer sample does not return to its temporary shape. The described effect is called a "one-way" shape-memory effect. The programming process including a mechanical deformation can be repeated. The new temporary shape is not necessarily supposed to match the temporary shape resulting from the former programming process.

Molecular Mechanism

All shape-memory polymers discussed here are elastomers. On the molecular level, they represent polymer networks consisting of segment chains that are connected by netpoints. The netpoints can be formed by entanglements of the polymer chains or intermolecular interaction of certain polymer blocks. These cross-links are called physical netpoints. Cross-links in the form of covalent bonds form chemical netpoints. An elastomer exhibits a shape-memory functionality if the material can be stabilized in the deformed state in a temperature range that is relevant for the particular application. This state can be achieved by using the network chains as a kind of molecular switch. For this purpose, it should be possible to limit the flexibility of the segments as a function of the temperature. This process is supposed to be reversible. The ability to incorporate a control function into the material provides a thermal transition T_{trans} of the network chains in the temperature range of interest for the particular application. At temperatures $> T_{trans}$ the chain segments are flexible, whereas the flexibility of the chains below this thermal transition is at least partly limited. In the case of a transition from the rubber-elastic, i.e., viscous to the glassy state, the flexibility of the entire segment is limited.

The mechanism of the thermally induced shape-memory effect of linear block copolymers is based on the formation of a phase-separated morphology with one phase acting as molecular switch. The phase showing the highest thermal transition T_{perm} is by the formation of physical netpoints, on the one hand providing the mechanical strength of the material especially at $T < T_{perm}$, and on the other hand the fixation determining the permanent shape. The materials are divided into two categories according to the thermal transition of the particular switching segment the shape-memory effect is based on. Either T_{trans} is a melting temperature T_m or a glass-transition temperature T_g. In case of a melting temperature, one observes a relatively sharp transition in most cases, whereas glass transitions always extend over a broad temperature interval. In case there is no sufficient phase separation between the hard segment determining block (block A) and the switching segment determining block (block B), mixed glass transition temperatures $T_{g,\,mix}$ between the glass transition of the hard segment and the switching segment determining blocks may occur. Mixed-glass transition temperatures are also qualified to act as switching transitions for the thermally induced shape-memory effect. Table 1 gives an overview about possible combinations of hard segment and switching segment determining blocks in linear, thermoplastic shape-memory polymers.

In chemically cross-linked shape-memory networks, the permanent shape is stabilized by the covalent netpoints. In analogy to linear block copolymers with shape-memory, the temporary shape of covalently cross-linked shape-memory networks can either be fixed by crystallizable segment chains or by a glass transition of the segment chains that is in the temperature range of interest.

Cyclic, Thermomechanical Characterization

The shape-memory effect can be quantified by cyclic, thermomechanical investigations. Typically, measurements are performed by means of a tensile tester equipped with a thermochamber. In the course of this experiment, different test programs are applied that differ, eg, in the programming procedure (cold drawing at $T < T_{trans}$ or temporary heating up of the polymer sample to a temperature $T > T_{trans}$), or in the control parameter of the tensile tester (stress or strain controlled). A single cycle includes the programming of the sample and the recovery of its permanent shape.

A typical test program is described in the following: the test piece is heated up to a temperature T_{high} that is above the switching temperature T_{trans} and is elongated to the maximum strain ε_m. In case of thermoplastics, it is important not to exceed the highest thermal transition T_{perm}. Otherwise, the polymer sample would melt. The sample is cooled down below the transition temperature T_{trans} to a temperature T_{low} under constant strain ε_m. In this way, the temporary shape is fixed. Retracting the clamps of the tensile tester to the original distance of 0% strain causes the sample piece to bend. After increasing the temperature to $T_{high} > T_{trans}$ the sample contracts and the permanent shape is recovered. The cycle can begin again.

The result of such a measurement is usually presented in a tensile stress (σ) strain (ε) curve, which is why this test protocol is often called a "two-dimensional measurement".

Important quantities to be determined describing the shape-memory properties of the material for a certain maximum strain ε_m are the *strain recovery rate* R_r and the *strain fixity rate* R_f. Both can be determined according to the Eq. 1 and 3. The strain recovery rate R_r quantifies the ability of the material to memorize its permanent shape and is a measure

TABLE 1. POSSIBLE COMBINATIONS OF HARD AND SWITCHING SEGMENT DETERMINING BLOCKS IN LINEAR, THERMOPLASTIC BLOCK COPOLYMERS WITH THERMALLY INDUCED SHAPE-MEMORY EFFECT

Thermal transition determining the permanent shape at T_{perm}	Block A hard segment determining block		segment determining Block B switching block		Phase-segregated block copolymers	
	Highest thermal transition	Second thermal transition	Highest thermal transition	Second thermal transition	T_{perm}	
Melting point	T_{mA}	T_{gA}	T_{mB}	T_{gB}	T_{mA}	T_{mB}, T_{gA}, T_{gB}
$T_{perm} = T_{mA}$	T_{mA}	T_{gA}	T_{mB}	T_{gB}	T_{mA}	T_{mB}, T_{gmix}
	T_{mA}	T_{gA}	T_{gB}		T_{mA}	T_{gA}, T_{gB}
	T_{mA}	T_{gA}	T_{gB}		T_{mA}	T_{gmix}
Glass transition	T_{gA}		T_{mB}	T_{gB}	T_{gA}	T_{mB}, T_{gB}
	T_{gA}		T_{mB}	T_{gB}	T_{gA}	T_{mB}, T_{gmix}
$T_{perm} = T_{gA}$	T_{gA}		T_{gB}		T_{gA}	T_{gB}

of how far a strain that was applied in the course of the programming $\varepsilon_m - \varepsilon_p(N-1)$, is recovered in the following shape-memory transition. For this purpose, the change in strain that is applied during programming in the Nth cycle $\varepsilon_m - \varepsilon_p(N-1)$ is compared to the change in strain that occurs with the shape-memory effect $\varepsilon_m - \varepsilon_p(N)$:

$$R_r(N) = \frac{\varepsilon_m - \varepsilon_p(N)}{\varepsilon_m - \varepsilon_p(N-1)} \quad (1)$$

where $\varepsilon_p(N-1)$ and $\varepsilon_p(N)$ represent the strain of the sample in two successively passed cycles in the stress-free state before yield stress is applied. The *total strain recovery rate* $R_{r,tot}$ is defined as the strain recovery after N passed cycles referred to the original shape of the sample piece:

$$R_{r,tot}(N) = \frac{\varepsilon_m - \varepsilon_p(N)}{\varepsilon_m} \quad (2)$$

The *strain fixity rate* R_f describes the ability of the switching segment to fix the mechanical deformation that has been applied during the programming process. It describes how exactly the sample can be fixed in the stretched shape after a deformation to ε_m. The resulting temporary shape $\varepsilon_u(N)$ always differs from the shape achieved by deformation.

$$R_f(N) = \frac{\varepsilon_u(N)}{\varepsilon_m} \quad (3)$$

The *strain fixity rate* R_f is given by the ratio of the strain in the stress-free state after the programming step in the Nth cycle $\varepsilon_u(N)$ and the maximum strain ε_m.

As the first cycles can differ from each other. With an increasing number of cycles the curves become more similar. The process of deformation and recovery of the permanent shape becomes highly reproducible. The changes in the first cycles are attributed to the history of the sample piece. In this respect, processing and storage play an important role. During the first cycles, a reorganization of the polymer on the molecular scale takes place as a reaction on the deformation in a certain direction. Single polymer chains arrange in a more favorable way with regard to the deformation direction. Covalent bonds may be broken during this process. An important variable that cannot be determined by a two-dimensional measurement is T_{trans}. In contrast to the two-dimensional measurement, here, the sample piece is cooled down in a controlled way (constant cooling rate) at a constant tensile stress σ_m. The change in strain in this program step is influenced by the temperature dependence of the thermal expansion coefficient of the stretched polymer and volume effects, which is based on the thermal transition T_{trans}, eg, a crystallization process. Having reached T_{low}, the strain is reduced until a stress-free state is reached. The sample is now heated up to T_{high} at a constant heat rate. In the course of this experiment the tensile stress is kept constant at 0 MPa, this means that the clamps are following the shape change of the test piece. In this way, the shape change caused by the shape-memory effect is recorded as a function of the temperature. From the interpretation of the ε–T Plane in the ε–T–σ diagram not only T_{trans} but also the temperature interval can be determined in which the shape-memory effect takes place.

Examples

The following examples show thermally induced shape memory. The first three examples are exclusively physically cross-linked. These examples are two polyurethanes representing thermoplastic shape-memory polymers with $T_{trans} = T_m$ or T_g, and a high molecular weight, amorphous polynorbornene. Examples of covalently cross-linked shape-memory networks are so-called "heat-shrinkable" materials and a shape-memory network with a crystallizable switching segment ($T_{trans} = T_m$) that has been developed for biomedical application.

Polyurethanes and Poly (ε-caprolactone) Switching Segment. Polyesterurethanes with a hard segment determining block of 4,4′-methylenebis(phenylisocyanate) (MDI) [CAS: 101-68-8] and 1,4-butanediol [CAS: 110-63-4] can be synthesized via the prepolymer method. The highest thermal transition T_{perm} corresponding to the melting temperature of the hard segment determining blocks is found in the range between 200 and 240 °C (392 and 464 °F). Poly(ε-caprolactone)diols with a number average molecular weight (M_n) between 1600 and 8000 form the switching segments. The switching temperature for the shape-memory effect can be varied between 44 and 55 °C (111 and 131 °F) depending on the weight fraction of the switching segments (variation between 50 and 90 wt.%) and the molecular weight of the used poly(ε-caprolactone)diols. In polyurethanes with a high molecular weight of the used poly(ε-caprolactone), the switching segment determining blocks can crystallize optimally and so the temporary shape is set ideally. Moreover, a high weight fraction of hard segment determining blocks guarantees an optimum stabilization of the permanent shape. As a consequence, polyurethanes that combine a high molecular weight of the used poly(ε-caprolactone) and a high weight fraction of hard segment determining blocks show the best shape-memory properties. The strain recovery rate comes up to 98% at maximum strains ε_m of 80%.

Nonetheless, the shape-memory properties are strongly influenced by the degree of the applied strain. The strain recovery rates reached decrease to rates of 80% with applied strains of 250%. Decisive factors influencing the recovery properties, besides the crystallinity of the switching segments, are the formation and stability of the hard segment forming domains especially in the temperature range above the melting temperature of the switching segment crystallites. For a content of hard segment forming domains <10 wt.%, the hard segment domains are not able to form stable physical cross-links. During the initial three cycles, a slight increase in the switching temperature can be observed. This behavior is interpreted in terms of the destruction of weak netpoints, followed by an increasing formation of an ideal elastic network.

Polyurethanes with Poly(*t*etrahydrofuran). [CAS: 24979-97-3]. Materials with a mixed glass-transition temperature $T_{g,mix}$ are systems with [poly(THF)] switching segment blocks having number average molecular weights of 250 and 650 and a hard segment forming phase based on MDI and 1,4-butanediol. The hard segment is made using the prepolymer method. The highest thermal transition T_{perm} corresponds with the melting temperature of the hard segment determining blocks. The block copolymers exhibit a $T_{g,mix}$ in the range between 16 and 54 °C (61 and 129 °F) in case of the switching segment with a molecular weight of $M_n = 250$ depending on the hard-segment content (hard-segment content between 57 and 95 wt.%), a $T_{g,mix}$ between −13 and 38 °C (9 and 100 °F) for the switching segment with a molecular weight $M_n = 650$ (hard-segment content between 32 and 87 wt.%), and a $T_{g,mix}$ of −36–22 °C (−33–72 °F) for the switching segment with molecular weight of $M_n = 1000$ (content of hard-segment determing blocks between 23 and 81 wt.%). If poly(THF)diols with molecular weight of $M_n = 2000$ or $M_n = 2900$ are used one cannot observe a mixed T_g due to the good separation of the different blocks. Here, the occurring glass-transition temperatures T_g are also dependent on the hard segment content due to the hard segments' property to hinder the mobility of the switching segment chains. The shape recovery rate increases with increasing hard-segment content reaching values up to 99% for the material with a switching segment with $M_n = 250$ and a hard-segment content of 75 wt.%. For materials with a switching segment with $M_n = 650$ complete recovery is not reached until a hard segment content of 86%. After ∼100 repetitions, a constant shape recovery rate of 95% is reached.

Polynorbornene. [CAS: 25038-76-0]. Norsorex is a linear, amorphous polynorbornene having shape-memory properties. It was developed by the companies CdF Chemie/Nippon Zeon in the late 1970s. The molecular weight of this polynorbornene is ∼3,000,000. It is produced via a ring-opening metathesis polymerization of norbornene [CAS: 498-66-8] using a tungsten–alkylidene catalyst. This polynorbornene has a content of 70–80 mol% of trans-linked norbornene units and a glass-transition temperature between 35 and 45 °C (95 and 113 °F). The shape-memory effect of this strictly amorphous material is based on the formation of a physically cross-linked network due to entanglements of the high molecular weight, linear polymer chains. The thermal transition from the glassy state to the rubber elastic state can be used as switching transition. Consequently, upon reaching the glass-transition temperature T_g the material softens abruptly. If the chains are stretched quickly in this state and the material is rapidly cooled down again below T_g the glass transition temperature, as an answer to this, the polynorbornene chains can neither slip off each other rapidly enough nor can entanglements disentangle. By rapid cooling, the induced elastic stress can be frozen within the material. After heating

up again above T_g, due to the thermally induced shape-memory effect, a recovery of the material's shape can be observed. The described Norsorex is not inevitably purely amorphous. There are reports of a high molecular weight polynorbornene with a high content of trans-linked norbornene units showing a tendency toward strain-induced crystallization. Due of this observation, the possibility that crystallites acting as physical netpoints contribute to the shape-memory effect must not be excluded.

"Heat-Shrinkable" Polymers. Since the 1960s, polyethylene [CAS: 9002-88-4] covalently cross-linked by means of ionizing radiation has found broad application as heat shrink foil or tubing especially for the insulation of electric wires or as protection against corrosion of pipe lines. These materials are marketed under the term "heat shrinkable materials". The mechanism of the heat shrinking process corresponds to the thermally induced shape memory effect. The permanent shape is fixed by covalent cross-links. The switching process is controlled by the melting temperature of the polyethylene crystallites.

Biodegradable Polymer Networks with Shape Memory. Based on oligo(ε-caprolactone)diol representing the component to form a crystallizable switching segment, a polymer system with a AB polymer network structure has been developed. For that purpose, oligo(ε-caprolactone)diols have been functionalized with methacrylate [CAS: 79-41-4] end groups that can undergo a polymerization reaction. The comonomer of choice is *n*-butyl acrylate [CAS: 141-32-2] because of the low T_g of pure poly(*n*-butyl acrylate) of $-55\,^{\circ}C$ ($-67\,^{\circ}F$); this supposedly determines the amorphous network chains of the expected network. The molecular weight of the used oligo(ε-caprolactone)dimethacrylate cross-linking agent and the content of the comonomer butyl acrylate represent the molecular parameters controlling crystallinity, T_{trans}, and mechanical properties. The number average molecular weights of the oligo(ε-caprolactone)dimethacrylates used were 2000 and 10,000. The cross-link density in the case of the oligo(ε-caprolactone)dimethacrylate ($M_n = 2000$) was varied by addition of 11–90 wt.% and for the oligo(ε-caprolactone)dimethacrylate ($M_n = 10{,}000$) by addition of 20–71 wt.% butyl acrylate. The cross-link density increases with decreasing content of butyl acrylate. The butyl acrylate content influences the thermal properties of the formed AB network especially for the oligo(ε-caprolactone)dimethacrylate with a molecular weight of 2000. Here, only in the case of a very low content of butyl acrylate of 11 wt.%, a melting point at a $T_m = 25\,^{\circ}C$ ($77\,^{\circ}F$) can be observed. The corresponding homonetwork of oligo(ε-caprolactone) dimethacrylate has a melting point at $T_m = 32\,^{\circ}C$ ($0\,^{\circ}F$). All the other networks of this series were found to be completely amorphous. For the networks of butyl acrylate and oligo(ε-caprolactone)dimethacrylate with a number average molecular weight of 10,000, the melting point decreases up to 5 K to $46\,^{\circ}C$. With increasing butyl acrylate content. With increasing butyl acrylate content the mechanical properties of both materials with oligo(ε-caprolactone) segments with number average molecular weights of 2000 and 10,000 change in such a way that the values of the elastic modulus the tensile strength σ_{max}, and the tensile stress at break σ_R decrease for about an order of magnitude. The absolute values are one order of magnitude higher for the series with the oligo(ε-caprolactone) segments with number average molecular weights of 10,000. In cyclic, thermomechanical tensile tests for the network with oligo(ε-caprolactone) segments ($M_n = 10{,}000$) strain fixity rates between 95 and 85% and strain recovery rates from 98 to 93% could be obtained. After three thermocycles all materials reached a constant strain recovery rate of 99%. In in vitro tests these shape-memory networks appear to be promising in their biocompatibility.

SHAPLEY, HARLOW (1885–1972). Shapley was an American astronomer who is especially remembered as the man who discovered that the Milky Way galaxy was much larger than originally thought and that Earth's solar system was at not the center of the galaxy.

Interestingly, Shapley had planned to study journalism in college but switched to astronomy. He did graduate work at the Princeton Observatory. His dissertation was on properties of stars known as eclipsing binary stars. Later he expanded his thesis and published it making a significant contribution to the field of astronomy.

Shapley made some of his most important discoveries while researching at the Mount Wilson Observatory in Pasadena, California. Shapley found that Cepheid variables were pulsating stars. He was able to determine a star's absolute brightness and then by comparing this to its observed brightness, he was able to calculate how far away the star was. From this measuring system, Shapley determined the placement of Earth's solar system in the Milky Way. He was also able to estimated that the center of the galaxy was located fifty thousand light-years from the sun.

In 1921, Shapley returned to Harvard Observatory and became its director. He was elected to the National Academy of Sciences in 1924 and in 1926 received the Draper Medal.

Shapley is credited with making Harvard Observatory the leading astronomy educational center in the United States during the 1920s. Shapley recruited scientists worldwide and was instrumental in helping to bring many German Jewish scientists to America. After World War II, he helped form the United Nations Educational, Scientific and Cultural Organization. He is sometimes criticized for urging the United States to have scientific exchange and cooperation with the Soviets. Although his feelings on this issue were unpopular at the time, he was elected president of the American Association for the Advancement of Science. He spent his later years traveling and lecturing on astronomy and philosophy. He wrote the popular book, *Through Rugged Ways to the Stars*.

SHARED TIME CONTROL. In an automatic control system, control action in which one controller divides its computation or control time among several control loops rather than acting on all loops simultaneously.

SHARKS (Chondrichthyes). Of the order *Selachii*, there are several families of sharks. A shark is a carnivorous fish with a cartilaginous skeleton. The mouth opens on the ventral surface of the head and is armed with many rows of sharp teeth attached to the skin and similar in structure to the placoid scales of the body. The tail is of the heterocercal form, having two lobes with the backbone extending into the upper lobe. The openings of the gill slits are separate. Of the principal families of sharks, there are: (1) the frilled shark (*Chlamydoselachidae*); (2) the sixgill and sevengill cowsharks (*Hexanchidae*); (3) sand sharks (*Carchariidae*); (4) goblin sharks (*Scapanorhynchidae*); (5) mackerel sharks (*Isuridae*); (6) thresher sharks (*Alopiidae*); (7) the basking shark (*Cetorhinidae*); (8) the whale shark (*Rhincodontidae*); (9) catsharks (*Scyliorhinidae*); (10) false catsharks (*Pseudotriakidae*); (11) smooth dogfishes (*Triakidae*); (12) the requiem sharks (*Carcharhinidae*); (13) hammerhead sharks (*Sphynidae*); (14) hornsharks (*Heterodontidae*); (15) saw sharks (*Pristiophoridae*); (16) spiny dogfishes (*Squalidae*); (17) spineless dogfishes (*Dalatiidae*); (18) the alligator dogfish (*Echinorhinidae*); (19) the angel sharks (*Squatinidae*); and (20) carpet and nurse sharks (*Orectolobidae*).

Because of their danger and threat of danger, sharks have received much attention — over the many hundreds of years that people have been swimming in the seas, whether for recreation or as the result of accidents at sea. However, the interest in the dangers of sharks increased markedly with the advent several years ago of diving (for military or constructional purposes), and particularly with the great expansion of skin diving as a hobby and sport. The lore pertaining to the true danger and the habits of sharks with relation to the presence of people obviously would consume many books. Sharks are well known for their curiosity. The problem, of course, is to differentiate between their curiosity and their possible more serious, aggressive intentions.

Many sharks are docile by nature and require certain stimuli to alter their temperament from one of curiosity to one of aggression and attack. An almost certain stimulus is the presence of blood or fish juices in the water. Thus, in shark-infested waters, a diver never should retain any speared or otherwise injured fishes in the vicinity of skin-diving operations. Records indicate that sharks may be interested only in the injured fishes and not

in the persons nearby, but that, in seeking out the source of fish juices and blood, the sharks may make mistakes and thus cause injury to persons in the area. Also, sharks do not like to be disturbed — they do not like to have objects in their way and they do not like to be touched, as for example a skin diver attempting to catch a shark by the tail. A shark may suddenly reverse direction in such a situation and attack the diver. Because of the sensitive and unpredictable temperaments of many sharks, the diver never should consider a shark "friendly" or become careless as the result of past interesting and uneventful encounters with sharks. For example, it has been postulated by some authorities that just as among people, there will be found the occasional psychotic shark that does not conform to normal habits and patterns of behavior. In all situations, of course, the size of the shark as an index of potential danger should always be considered. It is a good rule to consider any shark that is over 10 feet (3 meters) in length as a potential source of trouble.

Sharks are also known to be rather indiscriminate when they are feeding. Experiments with sharks in large aquariums, for example, have indicated that during a feeding "frenzy," a shark may easily mistake an undesirable food item for the items that it really wants most. Feeding sharks in captivity always must be done with precaution. The sharks, obviously, are not aware of where their food ends and where the feeder's hand begins. Further, during a period of feeding excitement, a captive shark may attack and eat other creatures in the aquarium that it normally would not bother.

Some authorities have suggested that there may be as many persons injured by shark bumps as by shark bites. There is considerable postulation in attempts to describe the reasons behind such statistics. ("Shark Attack" by V.M. Coppleson, published by Angus and Robertson, Sydney, Australia, 1959).

There appears to be a correlation between the temperature of the water and the feeding habits of some sharks. Statistics tend to show that fewer shark attacks occur in waters below 60 °F (~16 °C) and that the number goes up in waters above 70 °F (~20°C). This correlates with the fact that the sharks most dangerous to people are found in tropical waters. Also, shark attacks in temperate waters are usually limited to summer months. This fact, of course, could be easily explained because there are more people in the water during the summer than at other times. In the study by Dr. Coppleson, it is also pointed out that shark attacks in Australian waters tend to occur in mid-afternoon. Statistics also show that sharks prefer male to female human victims (a ratio of 20:1).

Much investigation has gone into the development of shark repellents. This topic has always been of interest to the military (abandonment of aircraft over shark-infested waters; activities of naval divers, etc.). One relatively successful repellent developed during World War II was copper acetate containing a nigrosene dye (ratio of 20–80%). This was found quite effective with Atlantic sharks, but quite ineffective with Pacific sharks. This difference still requires further investigation. It has been noted that captive sharks often will not feed if the aquarium water contains copper compounds introduced for controlling parasites. Apparently, these compounds cause an irritation of the sharks' nostrils, thus disturbing their sense of smell and consequent desire for food.

Because of its preference for deep waters, the data on the frilled shark are not extensive. The number of specimens caught has been limited. The adult attains a length of about $6\frac{1}{2}$ feet (2 meters), the young are born alive, the coloring is brown with no particular markings.

The more primitive sixgill and sevengill cowsharks are identified by counting the gill openings on each side of the head. The main groups of sharks always possess five gill openings per side. Coloring of cowsharks varies from gray to brown with no particular markings. A giant sixgill shark was caught in English waters over a hundred years ago. It measured over 26 feet (7.9 meters) in length. This is the largest sixgill shark on record. They are widely distributed in Atlantic and Pacific waters. The young are born alive, seldom exceeding 16 inches in length. The sixgills apparently prefer deep water during daytime hours, but frequent the surface after dark for feeding. The Pacific sevengill is the broad-headed *Notorhynchus maculatum*. It prefers offshore waters and is rarely seen in shallow water. The shark is dark gray with black spots. There is a nursery ground of these sharks in the southern end of San Francisco Bay, an exception to their preference for deeper water. Generally, the sevengills are not considered edible.

Although much remains to be learned about sharks, a number of past misconceptions have been exposed in recent years. For example, sharks are not ravenous eaters. Grey reef adults feed only once in six or even twelve days. Species living on the sea bottoms go without food for weeks, and the big basking sharks found in British waters appear to starve all winter. Nor, as once believed, do sharks depend entirely upon their sense of smell. This sense, of course, is extremely acute. It has been estimated that sharks can detect (by smell) dilutions of one part in a million. Their sense of hearing also registers sounds hundreds of meters away. Although the shark's vision is lacking in resolution of details, it does perform well under poor lighting conditions. Sharks also are able to sense electric fields in surrounding waters and may use this sense as one means of navigation. Although sharks must continue to swim to avoid sinking, only the very slightest movements are required by some species. It has been observed that the Australian gray nurse shark can virtually hover. It has been noted that the great white maneating shark can nearly pivot on its nose. The outstanding buoyancy of some shark species is attributed to very large livers containing light oils and fats, which act as swim bladders. At one time, it was believed that sharks had to keep moving in order to breathe, requiring a continuous flow of water past the gills, but it has been shown that many species, including some of the largest, such as the tiger and bull sharks, can achieve temporary breathing through muscular pumping.

The sand shark is a dangerous-looking creature with large mouth and wicked teeth. The sand tiger shark typifies one's visions of a dangerous, wicked shark. There are no records of attack on people on the American side of the Atlantic, but it is highly feared in South African waters. The largest recorded specimen measured about $10\frac{1}{2}$ feet (3.2 meters) in length, with a weight of over 300 pounds (136 kilograms).

Of the mackerel sharks, the most famous is the great white shark (*Carcharodon carchiarias*), also known as the maneater or maneating-shark. According to records, one of the largest maneaters was caught off Port Fairey, Australia in 1870. The jaws of this shark are preserved and on display at the British Museum. The shark has been reported as measuring about $36\frac{1}{2}$ feet (11.1 meters) in length. However, the majority of maneaters caught have ranged between 20 and 25 feet (6.1 and 7.6 meters) in length. The bodies of these sharks are massive and hence a shark of only 17 feet (5.2 meters) in length may weigh up to nearly 3,000 pounds (1361 kilograms). The weight record may be held by a 21-foot (6.4 meters) shark caught in Cuban waters. It is estimated to have weighed about 7,000 pounds (3175 kilograms). J.E. Randall (*Science*, **181** (4095), 169–170 (1973)) casts some doubts over these previously reported dimensions.

The temperament of the maneater is considered very bad — with the vicious habit of considering just about anything it sees as edible. Some of the contents found in the stomachs of captured maneaters have included the remains (in some cases, the intact bodies) of large dogs, seals and sea lions themselves weighing in excess of 100 pounds (45.3 kilograms), and, interestingly, other sharks that may measure up to 7 feet (2.1 meters) in length.

The mako or sharp-nosed mackerel shark is known for its great activity once hooked, displaying marlin-like maneuvers and swimming much faster than its relative, the maneater. The *Isurus oxyrhinchus* is the Atlantic mako. The largest specimen on record attained a length of about 12 feet (3.6 meters) and weighed around 1,200 pounds (544 kilograms). The *Isurus glauca* is the Indo-Pacific mako. Both species of makos prefer tropical seas. The makos tend to gulp their food, as evidenced by finding large intact items in their stomachs. In one instance, a 120-pound (54.4-kilogram) swordfish was found in the stomach contents of a Bahaman mako which weighed over 700 pounds (317.5 kilograms). Other species of mako sharks include the *Lamna nasus* (common Atlantic mackerel shark, sometimes called porbeagle); and the *Lamna ditropis* (Pacific mackerel shark).

The thresher shark is noted for a very long whip-like tail. This may equal the length of the body, providing the fish with power and maneuverability. They are of offshore, tropical distribution. Large specimens run about 20 feet (6.1 meters) in length and weigh up to about 1,000 pounds (453.6 kilograms). The number of species of thresher sharks is quite limited.

The basking shark is well named because of its apparent preference to spend much time simply floating along the surface or cruising at very slow speeds. The second-largest known shark is *Cetorhinus maximus*, the giant basking shark, with recorded lengths up to 45 feet (13.7 meters). Very much like a mackerel shark, the basking shark differs in its preference for plankton rather than carnivorous food. It is believed that the young are born alive, probably up to 6 feet (1.8 meters) in length. Although

found worldwide in temperate waters, there are significant concentrations reported in waters off southern California and Europe. Fishing for basking sharks is considered important commercially, notably because of the value placed upon their large livers (yielding oil). For example, a liver weighing over 850 pounds (386 kilograms) may be found in an 8,500-pound (3856-kilogram) shark about 30 feet (9.1 meters) in length. Unfortunately, the liver oil contains no vitamins, but it is used for various tanning processes.

Regarded as the largest of fish, the whale shark attains a length of 45 feet (13.7 meters) at minimum. There have been numerous reports and writings over the years pertaining to the docile nature of these large creatures. Although the whale shark feeds on very small substances for food, such as small fishes, squid, and crustaceans, it nevertheless possesses numerous small teeth. The sharks feed in a vertical position. In American Atlantic waters, the population center is around the Caribbean. There is a concentration in the Pacific off the Gulf of California. Whale sharks also have been seen in the Red Sea and off the Philippines.

Catsharks have beautiful stripes, bars, and mottling, prefer inshore waters, and reach a maximum length of about 3 feet (1 meter). They are elasmobranches (cartilaginous skeleton, plate-like scales, lack of air bladder). The common European spotted dogfishes (*Scyliorhinus caniculus* and *S. stellaris*) are catsharks (even though named dogfishes). The *S. retifer*, also called the chain dogfish, is found in the waters off New Jersey. The South African "skaamoog" (*Holohalaelurus regani*) has markings suggestive of Egyptian hieroglyphics. The *Cephaloscyllium*, which attains a length of about 4 feet (1.2 meters), ranges the eastern Pacific, but is absent from Atlantic waters. The *Cephaloscyllium uter* is also known as a swell shark and occurs from Monterey Bay in California to Lower California waters. Its name is derived from the fact that, upon being pulled from the water, it imbibes large quantities of air, sometimes swelling to twice its normal size. If released to the water, the air is expelled and the fish returns to normal dimensions.

Only two species of the false catsharks are known. These sharks are quite large and prefer deep water. They are rarely seen. The identifying marking of these sharks is the long base of the dorsal fin. The largest specimen from the Atlantic measured somewhat less than 10 feet (3 meters). Of the specimens captured, all have been taken from waters ranging from 1,000 to 5,000 feet (305 to 1524 meters) in depth.

Small in size, usually less than 5 feet (1.5 meters) in length, there are relatively few species of the smooth dogfishes, which are more or less intermediate between nurse sharks and catsharks. Very abundant in American Atlantic coastal waters is the *Mustelus canis*, ranging from as far south as Uruguay northward to Cape Cod. They have been carefully studied and their biological traits and life history are well known. The smooth dogfish is known for its ability to change its coloration. It is not considered edible. *Rhinotriacis henlei* is the most abundant of sharks in American Pacific coastal waters. Other members of the family of smooth dogfishes (*Triakidae*) include the spotted shark (*Mustelus punctulatus*) found in the Mediterranean and the waters of South Africa. Achieving a length of about 6 feet (1.8 meters), this shark is covered with tiny black spots, hence its name. The *Triakis semifasciata* (leopard shark) is found in American Pacific coastal waters, ranging from Lower California northward as far as Oregon. San Francisco Bay is a nursery ground for this species.

There are well over 60 species of requiem sharks (*Carcharhinidae*). They enjoy the characteristics of typical sharks. The *Galeocerdo cuvieri* (tiger shark), shown in Fig. 1, is omnivorous, eating birds, fishes, animals, garbage, coal, turtles and so on. Its base color is a grayish-brown with a lighter-colored undersurface. There usually is some mottling along the upper surfaces. The tiger shark attains a length of about 18 feet (5.4 meters) in American waters; probably about 14 feet (4.2 meters) in Australian waters. The weight may be as much as 1,400 pounds (635 kilograms). Preferring deep water, the tiger shark on occasion will follow prey into shallow waters. Commonly found in the Caribbean and the waters around Florida, the species is not known along the northern European coasts or in the Mediterranean.

During World War II, shark livers became an important source of vitamins as the result of the blockading of Norway, since cod-liver oil was previously obtained from Norway. Thus, so-called soupfin sharks were commercially sought, even on the California coast, until about 1950 when low-cost synthetic vitamins appeared. The best sharks for liver were the soupfin (*Galeorhinus zyopterus*) and the dogfish (*Squalus acanthias*). The

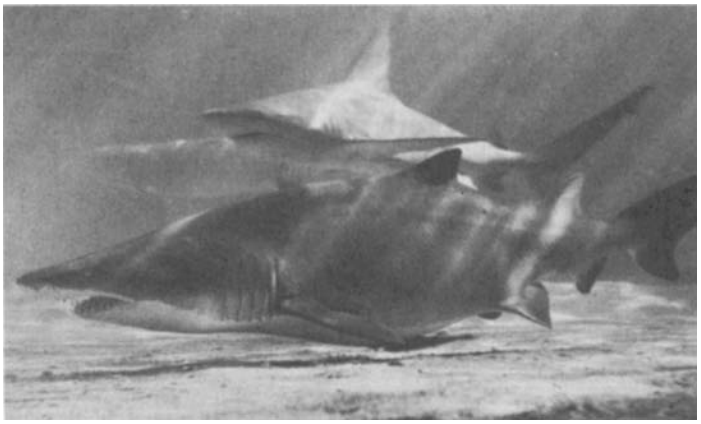

Fig. 1. Tiger shark. (*A.M. Winchester.*)

Galeorhinus australis (Australian school sharks) bears resemblance to the American Pacific soupfin. However, the latter is not considered a food fish, whereas the school shark is important commercially.

The great blue shark is also a requiem shark, well named because of the indigo blue coloration of its upper surfaces. It attains a length of nearly 13 feet (3.9 meters) and is long, slender, and streamlined, with a sharp nose. It is considered a sporting fish, but not edible. Common along the American Atlantic coast is the lemon shark (*Negaprion brevirostiris*), frequenting the waters from Brazil as far northward as North Carolina. These sharks reach a length of from 7 to 11 feet (2.1 to 3.3 meters). They prefer inshore shallow waters. Biological studies of the lemon shark have been carried out at Florida's Cape Haze Marine Laboratory. The silky shark (*Carcharhinus floridanus*) is also a requiem shark and is abundant along both Atlantic and Pacific coasts. Of interest, despite its abundance, is the fact that it was not officially identified and catalogued until 1953. The white-tip shark (*Carcharhinus longimanus*) with a gray coloration is probably the most common of sharks in the Atlantic and Pacific coastal waters. It reaches a length of about 13 feet (3.9 meters).

A number of sharks can tolerate brackish water and may live for awhile in fresh water, but the only known species that lives permanently in fresh water is the maneating *Carcharhinus nicaraguenis* which inhabits Lake Nicaragua. This shark is gray with a very heavy body, reaching a maximum length of about 8 to 10 feet (2.4 to 3 meters).

Because of the most unusual and well-named head, the hammer-head shark (*Sphyrnidae*) is readily identified. It is interesting to note that in a large specimen of, say, 15 feet (4.5 meters) in length and weight up to 1,500 pounds (680 kilograms) the eyes will be separated from each other by as much as 3 feet (1 meter). Because of its peculiarly shaped head, another member of this family of sharks is called the "shovel-head." Hammerheads prefer tropical seas, but move north into temperate waters in the summer. In 1959, there was an epidemic of shark attacks on the West Coast of the United States, attributed in the main to hammerheads. The unusual shape of the hammer-type head has aroused much biological interest. Some experts postulate that the hammer may serve as a balancing mechanism. Because hammerheads do not survive long in captivity, studies have been difficult.

Sharks and Humans

Sharks are a subject of great fascination to humans, no doubt because of the perception that they pose a threat to us. In fact, given the many millions of people who engage in various forms of aquatic recreation, the number of confirmed deadly shark attacks is actually relatively low (although the attacks that do occur receive wide attention). Attacks have most commonly happened along the coastlines of Australia, South Africa and the USA, all of which have large populations of coastal shark species. In an average year, about 20 human deaths worldwide can be attributed to sharks (while at the same time we catch and kill millions of sharks, often as incidental, wasteful bycatch).

Shark attacks are, therefore, uncommon, and in many cases may even be accidental on the part of the shark. The attacks can be divided into two types –provoked, in which the shark is reacting to a perceived threat, and

unprovoked, which are more mysterious. Certain species, such as the grey reef shark (*Carcharhinus amblyrhynchos*), are more aggressive than others, and may attack if approached too closely. Other aggressive species include the tiger (*Galeocerdo cuvier*), bull (*Carcharhinus leucas*), blue (*Prionace glauca*), hammerhead (*Sphyrna* species) and great white (*Carcharodon carcharias*) sharks. Often aggressive species signal their intent by body language, including arching their back into a hump. One hypothesis is that sharks mistake people in the water for favourite prey, including the observation that surfers resemble seals when viewed from below. This idea remains controversial and may be an oversimplification.

Some simple precautions will reduce the unlikely possibility of being attacked by a shark. Swimmers, divers, surfers, etc., should avoid shallow, murky water near river mouths at dawn or dusk, or at night, conditions under which a number of attacks have occurred. Recently, researchers in South Africa have experimented with electromagnetic fields as a means of repelling sharks; while some promising results have been obtained, the effectiveness of these devices is still inconclusive.

Sharks are also beneficial to humans in many ways. A number of species are caught for food, and shark meat has gained in popularity in recent years (to the detriment of some overharvested species). Shark skin is an effective abrasive, and is also used to make wallets, shoes and other products. Shark liver oil is thought by many to have health benefits, and the corneas from shark eyes have been used for corneal transplants in humans. Recent research has, however, cast serious doubt on the effectiveness of shark cartilage derivatives as a treatment for cancer.

Sharks occupy an important position in the art and traditional religious beliefs of many sea-based cultures. Such beliefs are particularly strong among the native islanders of the Pacific, and in the Aboriginal culture of Australia, where sharks are greatly revered and respected.

Conservation

In recent years it has become increasingly clear that the populations of many shark species are in sharp decline. The primary cause of this is commercial overfishing; sharks are caught deliberately in very large numbers, and are also killed as accidental bycatch in other fisheries. Much of the mentality that contributed to this current state of affairs arose in the 1970s, when sharks were both popularized and demonized in the popular media, most notoriously in the book and film versions of 'Jaws'. We now have a better and more sophisticated appreciation of the crucial role that sharks and rays play as predators, and in some cases scavengers, in helping to maintaining healthy balanced ecosystems.

Reduced population levels are of particular concern in sharks because of their long gestation periods and low reproductive rates. To address this issue, shark biologists and marine conservation groups have strongly urged that shark fishing be reduced to sustainable levels, that the wasteful practice of 'finning' (killing sharks only for their fins) be halted, and that critical habitats, such as shallow-water nursery areas, be preserved and protected. There are some promising recent signs that this problem is being taken seriously. For example, South Africa, Australia and the USA have taken steps to protect the spectacular but threatened great white shark *Carcharodon carcharias*, and a number of countries are working towards restricting the commercial catch of declining shark species so that their populations have a chance to recover. Organizations actively involved in shark research and conservation include the American Elasmobranch Society, http://www.flmnh.ufl.edu/fish/Organizations/aes/aes.htm, the European Elasmobranch Association, http://www.glaucus.org.uk/sharks1.htm, and the Pelagic Shark Research Foundation, http://www.pelagic.org/.

SHARPEY-SCHAFER, EDWARD ALBERT (1850–1935). Edward Sharpey-Schafer was a English physiologist, whose early work in histology and embryology was eclipsed by his later research in endocrinology, particularly the suprarenal and pituitary extracts and internal secretions of the pancreas.

Sharpey-Schafer's father, a naturalized German who worked as a merchant in the City of London, and his English mother sent their third son, Edward Albert, to University College London (UCL), where he qualified in medicine in 1874. Sharpey-Schafer was befriended and inspired by William Sharpey: Professor of Anatomy and Physiology at UCL. In 1918 Schafer added Sharpey's name to his own in recognition of their relationship. Sharpey retired from UCL the year Sharpey-Schafer qualified. J.S. Burdon-Sanderson succeeded Sharpey in the newly endowed Jodrell Chair of Physiology and Sharpey-Schafer became assistant professor. In turn, he succeeded Burdon-Sanderson in 1883, moving in 1899, again as Professor of Physiology, to the University of Edinburgh, where he remained until retirement in 1933: the year of his election to the Royal Society of Edinburgh. He had already been elected a Fellow of the Royal Society in 1878 and received a knighthood in 1913. See also **Sharpey, William (1802–1880)**.

Throughout his career Sharpey-Schafer was an avid experimentalist. At the age of 77 he was his own subject in his ongoing research into nerve section and regeneration. He was a champion of experimental medicine and spoke with feeling against anti-vivisectionists opposed to animal experimentation. In 1876 he was a founder member of the Physiological Society, turning historian 50 years later to write the society's jubilee history, much of which he composed from personal knowledge of the science and scientists.

Initially Sharpey-Schafer worked in the fields of histology and embryology, although one of his strengths was a broad interest in all aspects of physiology. His textbook *Essentials of Histology* (1885) became a standard. He joined in debates about the likelihood of nerve cells forming nerve nets. His research on the nervous plexus in *Aurelia aurita* demonstrated that nerve fibers were distinct, but fiber-to-fiber transmission was possible and the fibres in effect functioned as a net. Other neurological investigations involved the study of cerebral localization in collaboration with Victor Horsley.

Sharpey-Schafer's later endocrinological work was his most significant. He conducted his study of the effects of suprarenal and pituitary extracts in collaboration with the physician George Oliver, who was keen to learn the effects of oral doses of these crude products currently in vogue. They determined that most were inactive. However, intravenous suprarenal extract, a product of the medulla and not the cortex of the adrenal gland, produced increased arterial blood pressure and arterial constriction, and initiated the vagal reflex as well as increasing cardiac rate and force in vagotomized animals. Intravenous pituitary extract, produced the "pressor effect," the suppression of urine. He continued to work on pituitary extracts, making them the subject of his 1909 Croonian Lectures to the Royal Society. See also **Adrenaline and Noradrenaline**; and **Endocrine System**.

Sharpey-Schafer also worked on the pancreas. His histological investigations of the islets of Langerhans led him to conclude that these cells functioned collectively as an organ of internal secretion, the products of which were responsible for the effects of the pancreas on carbohydrate metabolism. In 1913 during his Lane lectures at Stanford University he reintroduced the term "insuline" for the as yet undetermined product now known as the hormone insulin. See also **Insulin**.

SHARPEY, WILLIAM (1802–1880). William Sharpey was a British histologist and physiologist known as the "Father of Modern Physiology in Britain."

Sharpey was born in Forfar, Scotland and studied at Edinburgh University. He graduated Doctor of Medicine in 1823. After graduation he undertook further studies in London, Paris, Germany and Italy with the aim of preparing himself for a career as a teacher of medical science. On his return to Edinburgh, Sharpey engaged in microscopic research — he was one of the first British workers to make intensive use of the achromatic microscopes that became available around 1830. He also began teaching in the Edinburgh extramural anatomy school in partnership with Allen Thomson. Sharpey offered lectures on anatomy while Thomson dealt with physiology.

In 1836 Sharpey was appointed Professor of Anatomy and Physiology at what was then called the University of London, and later became University College; he remained in this post until 1874. His course encompassed histology and came to include elements of experimental physiology. While in London Sharpey was active in a number of scientific and medical bodies, serving as Secretary of the Royal Society from 1853–1872.

He earned this sobriquet not for outstanding contributions to scientific research, but through his activities as a teacher and facilitator of the careers of others who were to have a major impact on the field. In particular, Michael Foster, one of Sharpey's protégés, was to go on to found an internationally renowned school of experimental physiology in Cambridge. SHASTA FIR. See **Fir Trees**.

SHAULA (λ Scorpii). Ranking twenty-third in apparent brightness among the stars, Shaula has a true brightness value of 1,700 as compared with unity for the sun. Shaula is a blue-white, spectral type B star and is located in the constellation Scorpius, a zodiacal constellation. Estimated distance from the earth is 300 light years. See also **Constellations**.

SHEAR. A force that lies in the plane of an area or a parallel plane is called a shearing force. It is the force that tends to cause the plane of the area to slide on the adjacent planes.

The vertical shear for any section of a simple beam is the magnitude of the resultant of the transverse loads on either side of the section. Transverse loads are those which are at right angles to the length of the beam. If the loads are inclined, the vertical components, only, should be used in computing the vertical shear. The resisting shear at any section is the internal force that opposes the shearing action of the external loads. It is numerically equal to the external shear but in the opposite direction. Vertical shear, which is always accompanied by bending movement at a section of a beam, is numerically equal to the rate of change of this moment with respect to distance along the beam. This shear is arbitrarily assumed to be positive if the resultant of the vertical loads to the left of a section acts in an upward direction. In a symmetrically loaded simple beam the shear is equal to zero at the center of the beam. See also **Elasticity**.

In addition to vertical shear in a beam, there is always a horizontal shear which is a result of the difference in the flexural stresses (see also **Flexure**) between any two vertical planes. The tendency of adjacent horizontal planes to slide upon each other is caused by horizontal shear. The effect may be better understood by visualizing a beam composed of flat planks laid one on top of the other. As the beam bends, due to the applied loads, the bottom of one plank will slide upon the top surface of the one beneath it unless this effect is restrained by friction, nails, bolts, or other fastenings.

The unit stresses resulting from vertical shear are called vertical shearing stresses. At any point in a beam, these stresses are numerically equal to the horizontal shearing stresses. The variation of the unit shearing stresses over the cross section of a rectangular beam is parabolic, being equal to zero at the top and bottom surfaces and a maximum at the neutral axis. When horizontal and vertical shear, only, act at a point in a body, the body is said to be in a state of pure shear at the point.

Shear is not restricted to beams. It occurs wherever there is bending. Columns, which are subjected to bending caused by eccentric loads, or by inclined or lateral loads, must be designed to withstand the shearing stresses. Rivets and welds are also subjected to shear. If the riveted connection is made so that the shear occurs between two plates only, it is called a single shear. When the type of connection is such that the shearing force is opposed by resisting shears acting on two planes, as in the case of three plates riveted together, the condition is called double shear.

A shear diagram is a graphical representation of the variation of vertical shear on a beam. Figure 1 is an illustration of a shear diagram for an overhanging beam with a uniformly distributed load covering the entire length of the beam. The points where the shear changes sign are points of maximum bending moment. The area of the shear diagram between any two points is equal to the change of bending moment between these points.

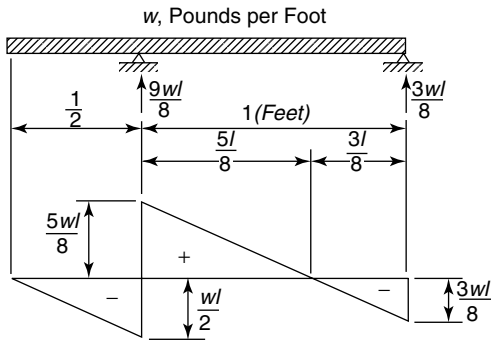

Fig. 1. Shear diagram.

SHEAR CENTER. The point through which the external shear must act at any cross section of a beam in order to eliminate torsional stresses is called the shear center of the particular cross section in question. The shear center coincides with the centroid of the internal shearing forces on the cross-section. If the beam is to bend without twisting, the loads must be applied in such a manner that the external shear at any section will pass through the shear center. The shear center has no meaning for sections where pure bending occurs because there is no shear and, therefore, no torsional stress can exist under these conditions.

SHEAR-GRAVITY WAVE. A combination of gravity waves and a Helmholtz wave on a surface of discontinuity of density and velocity. If the densities of the lower and upper layers respectively are and $'$ and the velocities U and U', the phase speed c of the shear–gravity wave is

$$c = \frac{\rho U + \rho' U'}{\rho + \rho'} \pm \left[\frac{gL}{2\pi} \frac{\rho - \rho'}{\rho + \rho'} - \frac{\rho\rho'(U - U')^2}{(\rho + \rho')^2} \right]^{1/2},$$

where g is the acceleration of gravity and L the wavelength. The motion is unstable if and only if the bracketed quantity is negative; the density difference thus contributes to stability and the velocity difference to instability. Applications have been made to atmospheric frontal surfaces and inversions; perhaps the most successful of these is to the phenomenon of billow clouds. Reasonable atmospheric values for the parameters yield stationary wavelengths of the order of 1 kilometer (0.6 mile).

SHEEP. See **Goats and Sheep**.

SHEEPSHEAD. See **Porgies**.

SHEEP TICK *(Insecta, Diptera)*. A wingless parasitic fly, *Melophagus ovinus* (Linne), that resembles a true tick only in its flattened body and leathery texture. Like the other flies, it has sucking mouth parts and hence draws blood from the skin of the host. Some scientists have described the insect as a degenerate, louse-like fly that has completely lost its wings. The insect is especially harmful to lambs. The tick is irritating to the sheep, causing it to rub and scratch, sometimes injuring the fleece and reducing its marketable value. It migrates from ewes to lambs at shearing time. It also attacks goats. Distribution is worldwide in all sheep-producing regions.

The adult sheep tick is about $\frac{1}{4}$ inch (6 millimeters) in length and has a covering of spiny hairs. The tick is also present on sheep in another stage of development, when it is somewhat like a brown seed, tenaciously fastened to the hair of the animal, especially inside the thighs, along the belly, and around the neck. This is the pupal stage of the fly. The sheep tick does not lay eggs, but is live-borne. The young are about $\frac{1}{8}$ inch (3 millimeters) in length, oval in shape, and off-white in color.

Numerous commercial preparations are available as sprays and dips for controlling the sheep tick. Such formulations may include lindane, malathion, rotenone, or toxaphene. The natural pyrethrins or allethrin are also effective. Care must be taken in applying control chemicals and to make certain that such applications are not made just prior to shearing or marketing. Sheared wool should not be kept near flocks for fear of infestation traveling from one to the other and, after dipping or spraying, the animals should be turned into an area that is considered free of ticks. Previous areas of infestation should be vacated for up to 6 weeks.

SHEET ICE. Ice formed in a smooth thin layer on a water surface by the coagulation of frazil through rapid freezing.

SHEET LIGHTNING. See **Lightning**.

SHELF CLOUD. See **Clouds and Cloud Formation**.

SHELL. A hard external covering secreted by folds of the body wall of many animals. The term applies properly to the shells of Brachipoda and Mollusca, although it is sometimes used in reference to the hard exoskeleton of crustaceans. Also a hard covering of eggs.

Brachiopod shells consist of two valves, one upper and one lower. They have an outer layer of organic matter known as the periostracum, under it a thin layer of calcium carbonate, and a thick inner layer of mixed organic and calcareous matter, deposited in prismatic form. The valves are opened and closed by a complex system of muscles.

Molluscan shells are usually spiral in form, like many common snail shells, or bivalve like those of mussels and the oyster. The valves of such shells are lateral in position. A third rarer form is the shell of nautilus, which is spirally coiled in one plane. Internal shells of slugs, chitons, and some cephalopods are in the form of plates of calcareous matter.

The external shells of mollusks have an external horny layer, the periostracum, a smooth lining of nacre or mother-of-pearl, and a thick calcareous middle layer.

Because of their permanence and beauty the shells of many marine mollusks have attracted the attention of collectors, and many have received common names. Among them the spiral staircase or wentletrap, periwinkle, conch, finger shell, cowry, coffee-bean, apple-seed, oyster drill, whelk, papal miter, cockle, gem, and others are to be found on the coasts of the United States.

The shells of eggs are calcareous or chitinous coverings secreted by a portion of the female reproductive ducts known as the shell gland. In the birds they are characteristically and often beautifully colored, and in the insects they may be beautifully sculptured. They are sometimes perforated by a minute opening or group of openings called the micropyle for the entry of the sperm. The egg shell of insects is also called the chorion, a term not to be confused with the chorion of vertebrate embryos. See also **Mollusca**.

SHELLAC. A secretion or excretion of the lac insect, *Coccus lacca*, found in the forests of Assam and Siam. Freed from wood it is called "seed lac." It is soluble in alkaline solutions such as ammonia, sodium borate, sodium carbonate and sodium hydroxide, and also in various organic chemicals. When dissolved in acetone or alcohol, shellac yields the familiar shellac varnish of superior gloss and hardness. Orange shellac is bleached with sodium hypochlorite solution to form white shellac. See also **Paints and Coatings**; and **Resins (Natural)**.

SHELL (Atomic). See **Chemical Elements**.

SHELLFISH. Any sea animal that is protected by a hard shell, such as crabs, lobsters, crawfish and crayfish, and shrimp of the class *Crustacea*; and clams, quahogs, oysters, and snails of the phylum *Mollusca*. See also **Crustaceans (Edible)**; and **Mollusks**.

SHELLFISH POISONING. See **Foodborne Diseases**.

SHELL MOLDING. The forming of a mold cavity for casting metals by placing sand bonded with a thermosetting resin against a preheated metal pattern (150 to 300 °C).

SHELL (Physical Chemistry). In physical chemistry, this tem is applied to any of the several sets of, or orbits of, the electrons in an atom as they revolve around the nucleus. They constitute a number of principal quantum path representing successively higher energy levels. There may be from one to seven shells, depending on the atomic number of the element and corresponding to the seven periods of the periodic table. The shells are usually designated by number, though letter symbols have been used, i.e., K, L, M, N, O, P, Q. The laws of physics limit the number of electrons in the various shells as follows: two in the first (K), eight in the second (L), 18 in the third (M), and 32 in the fourth (N). With the exception of hydrogen and helium, each shell contains two or more orbital, each of which is capable of holding a maximum of two electrons.

See also **Orbitals**; **Quantum Number**; and **Pauli Exclusion Principle**.

SHEPPARD'S CORRECTIONS. If a continuous frequency distribution is grouped, the moments derived by replacing each observation by the central value of the group into which it falls differ from those of the original distribution. Provided the distribution tapers smoothly to zero in both directions, average corrections to the grouped moments, known as Sheppard's corrections, may be applied as follows:

$$\mu_1 \text{ (corrected)} = \mu_1$$
$$\mu_2 \text{ (corrected)} = \mu_2 - h^2/12$$
$$\mu_3 \text{ (corrected)} = \mu_3$$
$$\mu_4 \text{ (corrected)} = \mu_4 - \tfrac{1}{2}h^2\mu_2 + 7h^4/240$$

SHERARDIZING. The process for applying an adherent protective coating of zinc to steel parts by heating at 700 °F (371 °C) in contact with zinc dust in a rotating-drum container.

SHERRINGTON, CHARLES SCOTT (1857–1952). Charles Sherrington was a British physiologist who elucidated the workings of the nervous system. Sherrington was born in London and died in Eastbourne, Sussex, England. Sherrington was attracted to the humanities. He matriculated at Gonville and Caius College, Cambridge, in 1881. While working with (Sir) Michael Foster, Professor of Physiology at Cambridge, Sherrington decided to dedicate himself to experimental physiology. Foster's laboratory also stimulated the development of many of Sherrington's contemporaries, including Walter Gaskell, John Newport Langley, Sheridan Lea and Newell Martin. After earning his Bachelor of Medicine degree in 1884, he spent three years in Germany where he worked with Rudolf Virchow and Robert Koch. Sherrington's first meeting with Santiago Ramón y Cajal occurred during this period, when he served as a member of a cholera commission in Italy and in Spain. When he returned to England in 1887 he was appointed to a lectureship in systematic physiology at St

Thomas's Hospital. In 1891 he succeeded Sir Victor Horsley as Professor-superintendent of the Brown Institute for Advanced Physiological and Pathological Research, a veterinary hospital at the University of London. During this period he carried out some studies of the activities of the central nervous system in collaboration with the physiologist Friedrich Leopold Goltz at Strasbourg. In 1895 he became Holt Professor of Physiology at Liverpool. His experimental work led to his appointment as Waynflete Professor of Physiology at Oxford in 1913. He remained at Oxford until his retirement in 1936. During his tenure as Professor of Physiology at Oxford he created what many scientists regarded as the best school of physiology in the world. See also **Foster, Michael (1836–1907)**.

Sherrington published more than three hundred papers concerning his experimental studies of the nervous system. His productivity, insight and influence have been so extensive that he has been called the William Harvey of the nervous system. His first paper, co-authored with John Newport Langley in 1884, dealt with experiments that had been performed by Goltz at an international congress of medicine in London in 1881. According to Goltz, the excision of a certain area of cerebral cortex of the dog had no effect on the animal. Goltz claimed that his experiment falsified the views held by (Sir) David Ferrier about the localization of function in the brain. Sherrington and Langley established that Ferrier had been correct. See also **Central and Peripheral Nervous Systems**.

Subsequent experiments by Sherrington mapped the motor nerve supply of the muscles, the pathways of the sensory roots, and the pathway of nerve fibres between muscles and the central nervous system. His first paper on the knee-jerk reflex was published in 1891. This study of a 'stretch reflex' helped elucidate the relationship between muscle tone and posture. Although he considered the 10 years from 1887 to 1897 he devoted to the painstaking work of tracing the pathways of the sensory and motor fibres of the spinal cord essentially tedious and mundane, he realized that it was essential to his understanding of neural anatomy and function. In 1897 he established the concept of the synapse (the points of contact between nerve cells where one nerve cell acts on another), and described reciprocal innervation and active inhibition. Ultimately, his researches led to the fundamental concept that he called 'the integrative action of the central nervous system'.

In addition to his experimental studies of the nervous system, Sherrington was actively interested in pathology and public health. Sherrington was the first doctor in Britain to use diphtheria antitoxin successfully. The desperately sick patient was his nephew. In 1916–1917 Sherrington was involved in the evaluation of antitetanus serum in battle casualties. During World War I, he served on various government committees charged with investigating the work environment in factories, industrial fatigue and alcoholism. Taking his responsibilities as chairman of the Industrial Fatigue Board very seriously, he worked as a labourer in a shell factory in order to understand the problems encountered by workers in munitions factories.

Sherrington received many honours. He was elected a Fellow of the Royal Society in 1893, received the Royal Society's Royal Medal in 1905, the Copley Medal in 1927, the Order of Merit in 1924, and was knighted in 1922. In 1932, he shared the Nobel Prize with (Lord) Edgar Douglas Adrian in recognition of their pioneering work on the physiology of the nervous system, most particularly for elucidating the transmission of nerve impulses between the muscles and the central nervous system. His work on the nervous system, especially his experimental studies of reflex action, has had a profound influence upon modern physiology. SHIELD (Geology). From a tectonics viewpoint, a shield is a large area of exposed basement rocks in a craton commonly with a very gentle convex surface, surrounded by sediment-covered platforms; e.g., Canadian Shield, Baltic Shield. The rocks of virtually all shield areas are Precambrian. See also **Craton**. From a paleontological viewpoint, a shield is: (a) a protective cover or structure on an animal, likened to or resembling a shield; e.g., an ossicle of an ophiuroid, or the carapace of a crustacean, or a large scale on the head of a lizard; (b) a float or curved, lateral outgrowth at one or more levels of a tangential rod or needle in the skeleton of an acantharian radiolarian and forming by fusion the lattice shell; (c) one of the discoidal elements of the placolith coccolith.

SHIPWORM *(Mollusca, Lamellibranchiata).* A peculiar marine mollusk that bores into submerged wood and apparently is among the few animals that can digest cellulose and related materials. The shipworms belong to several genera of which *Teredo* is most often cited. All are slender worm-like creatures but they have the characteristic structures of the bivalves. The valves of the shell are small separate parts, located at the anterior end of the worm, and are used for excavating the burrow.

Shipworms do great damage to wooden hulls and marine piling, consequently they have been subject to detailed studies to determine methods of avoiding their destructive attacks.

SHITTIMWOOD. See **Acacia Trees**.

SHOCK SYNDROME. In the simplest of terms, shock is the inadequate delivery of blood to the major organs of the body. Unless immediately treated, deprivation of blood supply causes disturbance of the metabolism (sometimes a shift from aerobic to anaerobic metabolism at the cellular level) of the organs with resultant damage. Because of these profound consequences, the treatment of shock is considered an emergency procedure. Cellular damage may be reversed with very prompt treatment, but is otherwise irreversible, leading to the ultimate death of the patient. Recovery from shock depends upon promptness of treatment and the age and general underlying health of the patient. Authorities suggest five broad categories of shock, based upon causation.

(1) *Hypovolemic shock.* Several conditions cause a massive loss of blood, plasma, or extracellular fluid from the body or intravascular compartment. The latter may be lost from the gastrointestinal tract from vomiting or diarrhea, abusive use of diuretics, in extensive burns, as well as acute pancreatitis. The most common loss of blood and plasma is encountered in hemorrhagic shock, as that which may result from serious trauma or severe gastrointestinal bleeding. The arterial blood pressure is lowered, causing a deficient supply of blood to tissues, as the result of loss of fluid volume from the vascular space.

(2) *Septic shock.* This may occur as the result of septicemia caused by a gram-negative bacterial infection. Bacterial endotoxin (a complex lipopolysaccharide) is released into the bloodstream. Septic shock is only infrequently a consequence of infections by gram-positive organisms, viruses, fungi, or rickettsias. Sequestration and pooling of blood in various vascular compartments lowers the availability of blood for the perfusion of other vital organs.

(3) *Cardiogenic shock.* This may result from a massive myocardial infarction caused by extensive damage to the myocardium. This sometimes occurs in connection with cardiac surgery; less commonly by severe myocarditis. Cardiogenic shock also may be caused by an arrhythmia in a patient with serious heart disease. In essence, the heart fails to pump, causing a reduction in cardiac output and arterial pressure.

(4) *Obstruction to cardiac filling.* Where cardiac filling is prevented or lessened, as by a massive pulmonary embolism or tumors or other space-occupying lesions, this type of shock may be precipitated.

(5) *Neurogenic shock.* In this type of shock, there is loss of vasomotor tone. This may arise from general or spinal anesthesia, an injury to the spinal cord, or from the massive intake of depressant drugs, such as certain narcotics and barbiturates. Respiratory arrest causing sustained hypoxia also may be a factor in this syndrome.

Depending upon the type of shock, various drugs are administered, including the catecholamines, such as norepinephrine, epinephrine, metraminol, dopamine, and isoproterenol. These drugs increase the arterial perfusion pressure. Vasodilating agents also may be used, particularly in connection with the treatment of septic shock and in some cases of hemorrhagic shock. These drugs, which include sodium nitroprusside, nitroglycerin, isosorbide dinitrate, phentolamine, and adrenal corticosteroids, must be administered with extreme care while the patient is constantly monitored. In cases of cardiogenic shock, circulatory assistance may be provided by the use of intra-aortic balloon counterpulsation. The balloon is inserted through a femoral artery and positioned, usually with the assistance of fluoroscopy, in the descending thoracic aorta. The balloon is programmed from the electrocardiogram such that it will deflate just prior to systole and inflate in diastole. Even though the use of intra-aortic balloon counterpulsation has been successful in many cases, it is estimated that to date it has increased the survival rate from cardiogenic shock by only 5 to 10% of cases. Where possible, if the patient has survived for 2 days with balloon counterpulsation and if other conditions are favorable, angiography and coronary artery revascularization will be attempted. See also list of entries given in the entry on **Heart and Circulatory System (Human)**.

SHOCK TUBE. A relatively long tube or pipe, in which very brief high-speed gas flows are produced by the sudden release of gas at very high pressure into a low-pressure portion of the tube; the high-speed flow moves into the region of low pressure behind a shock wave.

SHOCK WAVE. Infinitesimal disturbances in a fluid medium are propagated with a characteristic speed known as the sound speed. When the restriction on the amplitude of the disturbance is lifted, the linear approximation breaks down and the velocity of propagation becomes dependent on the amplitude of the disturbance. Another feature of this phenomenon is that the forward gradient of the disturbance rapidly steepens until it becomes a discontinuity and propagates as such. A *shock wave* is then a discontinuity in the physical properties of a fluid medium which propagates through the medium at supersonic velocity without further change. The strength of the shock is defined by the Mach number, the ratio of its velocity to the undisturbed sound speed. Such waves are generated by the detonation of explosive material, by high-speed aircraft and missiles, and by earthquakes. See also **Earth Tectonics and Earthquakes**.

Since all media are necessarily discrete, a true discontinuity is inconceivable, but, as the thickness of the shock transition corresponds to only a few mean free paths in a gas (or internuclear distances in a solid), the transition can be treated as a discontinuity to the same extent that the medium can be regarded as continuous. In comparison with an adiabatic or isentropic change, the shock wave is an irreversible process and hence leads to an increase in the entropy of the material. The pressure, density, and temperature of the medium are all raised on passage through the shock and the flow velocity is reduced. The latter is easily understood by observing that, with respect to the moving front, the molecules enter with an ordered flow motion at supersonic speed and the transport processes in the front transform a major fraction of this ordered flow into the random temperature or kinetic motions of the molecules.

The extent to which the various properties change through the transition depends on the magnitude or strength of the shock and on the thermodynamic properties of the fluid. For an essentially incompressible material, such as a liquid or solid, the major change normally occurs in the pressure variable, whereas for a gaseous medium the most significant change is in the temperature. Although shock waves in solid and liquid materials have been used to study physical properties at high pressures, the method is rather limited by the small test times available before the interaction of other wave phenomena that prevent the attainment of thermodynamic equilibrium, and it is in gases that shock waves have proved of most interest.

The detailed behavior of the shock transition is in itself a most important subject for study, since shock waves are associated with the flight of supersonic aircraft and with the reentry of ballistic missiles into the Earth's atmosphere. In addition to their own intrinsic interest, shock waves are important for other reasons. Since the transition involves the translational motions of the molecules, energy must eventually be transferred into other modes before the system reaches equilibrium. These subsequent relaxation processes involve the rotation, vibration, chemical reaction, electronic excitation, and even ionization of the molecules if the shock is sufficiently strong. The shock phenomenon thus provides an excellent method for studying energy transfer processes. For chemical reactions in particular, the shock wave provides a source of heat that is essentially instantaneous and is completely homogeneous. Also, provided the thermodynamic properties of the medium are known, the temperature is completely defined by a determination of the shock velocity.

Although shock waves can be created in many ways, including the detonation of high explosives and in wind tunnels, the simplest technique makes use of the *shock tube*, discovered in 1899 by Vieille. A long tube of uniform cross section is divided into two parts by a thin diaphragm and gas is admitted to these at different pressures. If the diaphragm is ruptured in some way, a shock wave is generated in the low-pressure gas and a corresponding rarefaction, or expansion, wave in the driver gas. Because the motion is restricted to a single dimension by the containing walls, the strength of the shock does not decrease with distance, as it would in a three-dimensional expansion, and the relaxation processes become simple functions of distances behind the front. This extremely simple piece of equipment can generate temperatures up to 20,000 K, since the strength (or velocity) of the shock depends only on the pressure ratio across the diaphragm immediately prior to rupture and on the thermodynamic properties of the gases in the two sections.

The disadvantage of all shock tube work is that the front moves so rapidly and subsequent wave interactions follow so soon afterwards that the available testing time is very short, often as little as 100 microseconds. Shock waves can also be created in highly ionized media where the forces are Coulombic in origin and the shocks are termed "collisionless." In this situation, shock waves lie more properly in the realm of plasma physics.

SHOOTING STAR. The popular term used to designate meteors. These objects bear little if any relation to the stars, aside from their being seen as bright, rapidly moving objects against the dark sky.

SHOOTS AND BUDS. The shoot represents the above-ground part of higher plants. It is composed of repeated units, the phytomers, which

consist of a node at which leaves and axillary meristems insert and the part of the stem between two nodes. The stem raises foliage and flowers for optimal light exposure and seed dispersal. The leaves are the main photosynthetic organs. They carry meristems in their axils that can give rise to side branches or flowers. The flowers themselves are modified shoots with specialized leaf-like organs: petals and sepals that mainly serve to protect the flower and in many cases to attract pollinators, and the male and female reproductive organs–stamens and carpels, respectively. See also **Flower**; **Leaf**; and **Petals**.

In the case of some trees the shoot can grow for more than a thousand years and elaborate an extensive organ system. This repetitive development is accomplished by the activity of a stem cell system, the shoot meristem. This review focuses on our current understanding of the mechanisms that govern shoot development.

The Shoot Meristem

The ultimate source of all above-ground organs is a small population of stem cells in the central zone of the shoot apical meristem (Figure 1). The stem cells are pluripotent in that they give rise to a variety of different cell types. Stem cell divisions result in two populations of daughter cells. The daughters that stay in the apical position remain pluripotent and renew the stem cell population. By contrast, daughter cells more distant from the apex ultimately undergo differentiation: in the peripheral zone of the meristem they initiate primordia for leaves, side branches and flowers, and in the rib zone they differentiate into the central tissue of the stem.

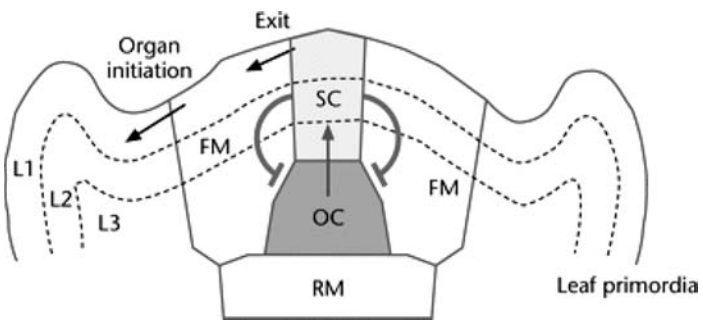

Fig. 1. Shoot meristem homeostasis. The stem cells are specified by yet unidentified signaling from the underlying organizing centre (OC). Cells that exit the stem cell region initiate differentiation and are recruited into organ primordia (RM, rib meristem; FM, flanking meristem; SC, stem cells; OC, organizing center).

The shoot meristem organization reflects specific patterns of cell divisions: the outermost cells typically divide perpendicular to the surface, resulting in separate cell layers. The number of the cell layers varies between species: many dicotyledonous plants have two, named L1 and L2 (together termed tunica). Cells underneath these layers divide in different orientations, and this region is named L3 (or corpus). Because the outer cell layers grow as sheets, cells of L1, L2 and L3 usually do not mix but behave as clonally independent compartments and contribute differently to the plant tissues: the L1 exclusively forms the epidermis, whereas the L2 and the L3 give rise to internal tissues. All cells within L1, L2 or L3 are ultimately derived from only 1–3 apical stem cells per cell layer. The fate of each shoot meristem cell, however, is only predictable in a stochastic way: if a daughter cell from one layer is displaced into another layer, this cell will adopt the fate of its new position. See also and **Epidermis (Plant)**; and **Plant Tissues**.

Cell Fate Specification in the Shoot Meristem

How is a cell's decision between pluripotency and differentiation regulated? Stem cell identity is restricted to the meristem center (Figure 1). However, if a stem cell becomes displaced from the centre, it enters differentiation. This indicates that stem cell identity is not a heritable trait, but that positional information defines a niche in which the cells maintain a pluripotent state. This specification process requires expression of the homeobox gene *WUSCHEL* (*WUS*) in the underlying cells. Mutations in *WUS* result in the misspecification of stem cells and the premature termination of meristem activity. The misspecified apical cells in *wus* mutants, however, do not become integrated into organs, indicating that *WUS* functions as a positive regulator of stem cell identity rather than as a repressor of organ formation. It has been suggested that the *WUS*-expressing cells act as an organizing centre that signals to its overlying neighbors, specifying them as stem cells.

By contrast, mutations in the *SHOOTMERISTEMLESS*, *ZWILLE* or *TERMINAL FLOWER* genes result in ectopic organ formation in the meristem centre, indicating that maintenance of shoot meristem activity also involves mechanisms that repress the formation of organs or flowers in the center.

Cells that become displaced from the meristem centre initiate differentiation (Figure 1). In a first step, they exit stem cell identity. This step is regulated by the CLAVATA receptor kinase signaling pathway: mutations in any of the three *CLV* genes result in a delayed entry of cells into differentiation and consequently in a gradual accumulation of meristem cells. In a second step, cells become recruited into organ primordia. This step requires the *MGOUN* genes, mutations in which result in defective organ formation.

The balance between the two processes of stem cell maintenance and differentiation, and thus the homeostasis of the shoot meristem, appears to be regulated by a feedback loop between stem cells and the *WUS* expressing cells underneath. It has been suggested that the latter act as an Organizing Center that signals to its overlying neighbors, specifying them as pluripotent stem cells. The stem cells in turn express CLV3, the putative ligand of the CLV1 receptor kinase, which functions as a feedback signal to repress *WUS* and thereby restricts the Organizing Center. By this regulatory feedback loop, the size of the stem cell population can continually be checked and kept constant during development.

Within each organ primordium, a number of different cell types are needed: for example, in a leaf, L1-derived cells form epidermal structures, whereas L2 and L3 progeny give rise to mesophyll and vasculature. Which differentiation pathway a cell follows depends on specific signals. Some of those signals may be derived from older, already differentiated, tissues in order to integrate the newly formed organ into the plant architecture.

Integration of Cell Fate Decisions by Cell-Cell Communication

How do cells communicate with each other to coordinate their development? There are two main routes by which plant cells can communicate and both appear to function in the shoot meristem. One way is to exchange molecules via cytoplasmic connections, the plasmodesmata. It has been shown that cells of distinct regions of the shoot meristem, e.g. the cells in the central zone, are effectively coupled via plasmodesmata, allowing facilitated exchange of molecules, whereas the exchange between cells of different domains may be less efficient. Studies of the maize Knotted 1 (KN1) protein suggest that the plasmodesmata are indeed used as molecular routes in the shoot meristem to exchange important regulatory molecules. The *KN1* gene appears to prevent apical cells of the shoot meristem from differentiating. Its mRNA is present in subepidermal cells, whereas KN1 protein is also detected in the epidermis. Injection of KN1 protein into mesophyll cells indicate that the KN1 protein itself can pass through plasmodesmata and can also promote selective plasmodesmal transport of its own mRNA.

A second way of communication between cells is signaling through the intercellular space, the apoplast. Mobile molecules secreted by one cell can be recognized by specific receptors on another cell's surface. The *CLV* signaling pathway is a candidate for this type of communication in the shoot meristem.

Position of the Shoot Meristem: Distal Organizer or Self-Regulatory Loop

What designates the shoot tip as the place where the shoot meristem resides? The shoot meristem receives signals from the rest of the plant that affect, for example, its maintenance, the position of new primordia or flowering time. Thus it is conceivable that the position of the shoot meristem itself could also be determined by distal information constantly provided to the shoot apex. This information could be a molecule transported towards and thus accumulating at the shoot pole, promoting stem cell identity. There is no evidence for such a mechanism in shoot

meristem regulation, but findings imply that a similar mechanism may be involved in regulating the root meristem. The growth factor auxin is transported basipetally and accumulates in a cell group at the root pole, which may function as a distal organizer of the root meristem.

An alternative mechanism is that once the shoot meristem is established, it is able to maintain itself without continuous information from the rest of the plant. Such an autonomous shoot meristem would simply stay at the apex through its polar mode of growth, whereby cells are given off towards the meristem base.

Shoot Meristem Formation

The primary shoot meristem is formed during embryogenesis and it only becomes apparent when the cotyledonary primordia are evident (Figure 2). The precise origin of the shoot meristem and the cotyledons is controversial. One view, based on comparative morphological analysis, holds that the apical half of the globular embryo represents the shoot meristem, which as its first products gives rise to the cotyledons, similar to the way true leaf primordia are initiated later. In an alternative view, a functional shoot meristem is the outcome of a gradual patterning process that is not completed until after the cotyledons have been formed. In this view, plants would have two different ways of making leaf-like organs: cotyledons made during embryo patterning, and leaves derived from the shoot meristem.

There is growing evidence in favor of the latter model: although expression of the *WUS* gene is already initiated in the apex of the 16-cell stage embryo, the *WUS* expression domain only gradually becomes confined to its prospective domain of function in the shoot meristem. Other shoot meristem genes, such as *STM*, *UFO* and *CLV1* are switched on successively and also display dynamic expression patterns.

Plants can also form shoot meristems in the axils of the leaves, which will give rise to side branches and flowers. In principle, axillary meristems could be derived either from cells of the main shoot meristem that have never entered differentiation but are locked in a meristematic state, or could arise *de novo* from already differentiated cells in the leaf axil. In any case, formation of axillary meristems appears to require information from the subtending leaf. In the *Arabidopsis phabulosa-d* (*phb-d*) mutant, the abaxial (lower) side of the leaf has features usually found on the adaxial (upper) side and axillary meristems develop ectopically at the lower side of the leaf. This has been taken as an indication that cells on the adaxial leaf side promote shoot meristem formation. An apparent contradiction to this proposal is that floral meristems in some species, e.g. in *Arabidopsis*, are formed in the absence of a subtending leaf. However, it is possible that in those cases a leaf primordium is present that does not grow out but may be sufficient to initiate a floral bud.

Programming the Shoot Meristem

At an appropriate time that depends on environmental stimuli and/or internal cues, the shoot meristem switches from the production of axillary shoot meristems to floral meristems. Genetic analysis in *Arabidopsis* has led to a model according to which flowering is repressed early in development until factors that promote flowering have accumulated to overcome this block. A central repressor of flowering is the *EMBRYONIC FLOWER* (*EMF*) gene. Mutation in *EMF* results in precocious flowering in the embryo. The *TERMINAL FLOWER* (*TFL*) gene and several early flowering genes prevent an early switch to flower formation before the normal vegetative program has been completed. This inhibitory block is gradually whittled away by the accumulation of flowering-promoting factors until the floral meristem identity genes *LEAFY* (*LFY*) and *APETALA* (*AP1*) have reached a critical threshold and specify axillary shoot lateral primordia as floral buds. One part of their function is to activate a set of floral organ identity genes that lead to the formation of floral organs instead of leaves. The antagonism between vegetative development and flowering is reflected in the reciprocal negative regulation of their key genes. *TFL*, for example, inhibits flower initiation by delaying the upregulation of *LFY* and *AP1* and by lowering the responsiveness of the meristem to these genes. *AP1* and *LFY* in turn repress *TFL* expression in floral primordia.

Perspectives

Shoot development requires the continuous production of undifferentiated cells and the integration of these cells into the growing plant. The first task is fulfilled by pluripotent stem cell populations that are being maintained by a neighboring organizing center. Studies of the underlying regulatory mechanisms will not only increase our understanding of shoot development but may reveal fundamental parallels between plant and animal stem cell systems. For example, the status of hematopoietic stem cells appears to depend on their cellular neighborhood, with the regulatory mechanisms being unknown. The similarity between ZWILLE and PIWI proteins, non-cell-autonomously required for maintaining stem cells in the *Arabidopsis* embryo and the *Drosophila* germarium, respectively, is consistent with regulatory mechanisms being conserved in different stem cell systems. The second task, differentiation of specific cell types, depends on a network of positional information. In this network each cell signals and perceives signals at the same time to integrate individual developmental choices into a meaningful context. This positional information can change with time, and –as at the flanks of the shoot meristem –may result in the formation of leaves early in development and floral buds later on.

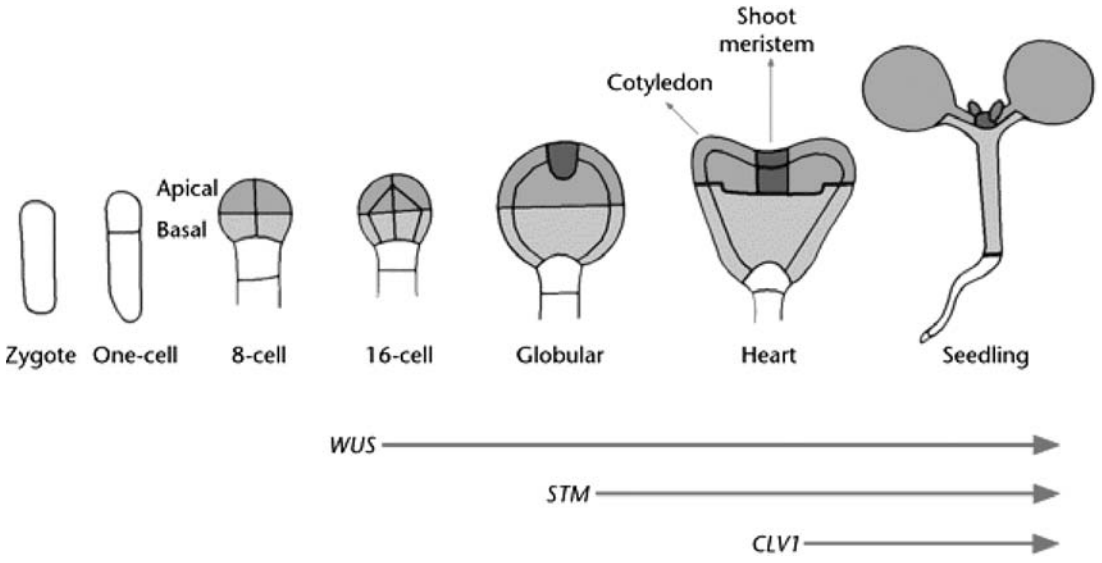

Fig. 2. Initiation of the shoot meristem. The shoot meristem is initiated early in embryo development as indicated by the onset of *WUS* expression. The expression domains of *WUS* and other genes undergo dynamic changes before the shoot meristem organization is in place.

THOMAS LAUX
Center of Plant Molecular Biology (ZMBP), Tübingen, Germany

SHORAN (Short-range Navigation). A precision electronic position fixing system using a pulse transmitter and receiver and two transponder beacons at fixed points. High-precision shoran is called *hiran*.

SHORE EFFECT. The change in the characteristics of an electromagnetic wave as it passes along a land-sea boundary, due to a difference in the propagation characteristics of the two regions. A source of error in radio direction-finders.

SHORT CIRCUIT. An electrical circuit is considered to be shorted when the terminals are connected directly together, with only the impedance of the short connecting leads between them. Thus, for all practical purposes, there is no resistance between them, hence no voltage can exist between them. While shorting a circuit that does not contain, and is not connected to, any source of voltage will produce no harmful effects, shorting a set of terminals across which a voltage normally exists will produce, in many instances, disastrous current flows. In power circuits, protection is often provided by circuit breakers or fuses which open the circuit under the high values of current that will flow on short-circuits. Even then, the transient effects that result from short circuits may cause generators to "arc over." A short obviously puts the circuit out of use.

See also **Circuit Breaker**; and **Fuse (Electric)**.

SHORTEN (SHN). See **Data Compression**.

SHORT-RANGE FORCE. A force between two particles which is essentially ineffective when the interparticle separation exceeds a certain distance; usually applied to nuclear forces which have a range of several times 10^{-13} centimeter.

SHORT WAVE (OR MINOR WAVE). With regard to atmospheric circulation, a progressive wave in the horizontal pattern of air motion with dimensions of cyclonic scale, as distinguished from a long wave. A short wave moves in the same direction as that of the prevailing basic current through the troposphere. The angular wavenumber of short waves ranges between eight and twenty. 2. A wave with a relatively short wavelength and period.

For ocean wind waves, this usually means waves with periods shorter than about 60 s.

See also **Long Wave**.

SHOVELLER. See **Waterfowl**.

SHOWER. See **Precipitation and Hydrometeors**.

SHREWS. See **Moles and Shrews**.

SHRIKE *(Aves, Passeriformes)*. This bird (*Lanius*) is chiefly known for its habit of catching other birds and small animals and impaling uneaten remnants on thorns. It is also known as the butcher bird. The beak is notched and in some species hooked. The numerous species occur on all continents but South America. The minivet is a brightly colored shrike (cuckoo-shrike), several species of which inhabit eastern Asia and India. The bird is about 6 inches (15 centimeters) long, is black along the back, with bright orange underneath and on the tail and wings. The female tends to be dark gray with a dull yellow coloration. Nests are cup-shaped and made of roots, pine needles, spider webs, and twigs. There are three to four green eggs with pale pink spots.

SHUGA. An accumulation of spongy, whitish chunks of ice a few centimeters (inches) across formed from grease ice or slush. It forms instead of pancake ice if the freezing takes place in seawater that is considerably agitated.

See also **Grease Ice**; **Pancake Ice**; and **Slush**.

SHUNT (Electrical). An electrical bypath so arranged that an electric current divides and flows partially through a second path (termed *shunt*). Shunts are employed in instrument circuits and other electrical equipment. For example, in the shunt-wound generator, the field coils are shunted across the armature circuit. The shunt resistance is very high and consequently only a very small portion of the current flows through the shunt winding.

A current bypass often is used with permanent-magnet moving-coil electrical instruments because only currents up to about 50 milliamperes can be taken into a moving-coil through the springs. Direct current instruments in excess of this range require the use of a parallel resistance circuit formed by one or several shunts. Where these ranges are moderate, the shunts usually are self-contained. On higher ranges, the shunts become physically large and convert more than a few watts into heat. One kilowatt for 50 millivolts, 20,000 amperes. Thus, they are used as accessories external to the instrument. Small or large, these devices consist of one or several manganin conductors terminating in copper blocks, which are provided with separate terminals for connection to the instrument, to avoid errors.

The manganin sections are soldered into the copper blocks. Shunt construction is such that heat is carried off at a rate sufficient to keep the operating temperature below the softening point of the solder. Adequate conductors tightly fastened, clean contact surfaces, and free air circulation are important.

Ammeters for use with external shunts are provided with special leads for shunt connection. Shunts are usually made to produce a standard potential drop, such as 50 millivolts at rated current. The associated DC mechanism is then built to give full scale deflection on a slightly smaller potential so as to allow for lead resistance. As the leads form part of the mechanism circuit, shown in Fig. 1, their resistance must not be altered.

Usually the current through the mechanism is a negligible portion of the total and the potential drop across the shunt terminals is nearly the same with or without the mechanism in the circuit. In instruments of moderate precision and fairly high current range, this difference can be neglected and shunts and instruments made interchangeable. In instruments of high precision and in instruments of low current range, the shunt adjustment must take into account the instrument current. Such combinations are usually not interchangeable.

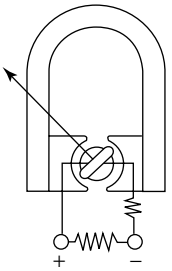

Fig. 1. Use of a shunt with a permanent-magnet moving-coil ammeter.

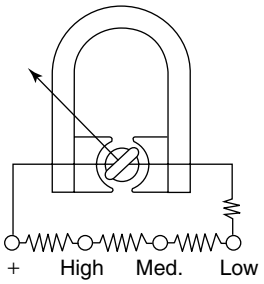

Fig. 2. Preferable manner for connecting a multirange shunt to avoid use of switch.

Multirange shunts should be connected as shown in Fig. 2 to avoid the use of a switch with its variable contact resistance between shunts and mechanism.

Because of the relatively high current consumption of alternating current instruments, shunts are not used either for obtaining multiple ranges or for extending the base range. The division of current between mechanism and shunt would become unfavorable and would invite inaccuracies due to the difficulty of obtaining good pressure contacts, as well as the fact that the current division would be a function not merely of the relative resistances of the parallel circuits, but also of their relative impedances. Moreover, AC mechanisms are not suitable for low millivolt ranges so that shunts would have to have large potential drops and would generate excessive heat. The ranges of alternating current ammeters are, therefore, extended with the aid of current transformers.

SHUTTLE RADAR TOPOGRAPHY MISSION (SRTM). See **Space Science Missions: Earth**.

SIAMANG. See **Anthropoids**.

SIBERIAN HIGH. See **Atmosphere (Earth)**.

SICKLE CELL ANEMIA. See **Anemias**.

SIDEREAL DAY. The duration of one rotation of the Earth on its axis, with respect to the vernal equinox. It is measured by successive transits of the vernal equinox over the upper branch of a meridian. Because of the precession of the equinoxes, the sidereal day thus defined is slightly less than the period of rotation with respect to the stars, but the difference is less than 0.01 second. The length of the mean sidereal day is 24 hours of sidereal time or 23 hours 56 minutes 4.09054 seconds of mean solar time. See also **Time**.

SIDEREAL HOUR ANGLE (SHA). Angular distance west of the vernal equinox; the arc of the celestial equator, or the angle at the celestial pole, between the hour circle of the vernal equinox and the hour circle of a point on the celestial sphere, measured westward from the hour circle of the vernal equinox through 360 degrees. Angular distance east of the vernal equinox, through 24 hours, is right ascension.

SIDEREAL MONTH. The average period of revolution of the Moon with respect to the stars, a period of 27 days 7 hours 43 minutes 11.5 seconds, or approximately $27\frac{1}{3}$ days.

SIDEREAL PERIOD. The sidereal period of any object is its period of revolution around its primary. In general, sidereal period may be defined as the time required for an object to move from a particular position among the stars back to the same longitude again, as seen from the sun.

SIDEREAL TIME. See **Time**.

SIDEREAL YEAR. The period of one apparent revolution of the Earth around the Sun, with respect to the stars, averaging 365 days 6 hours 9 minutes 9.55 seconds in 1955, and increasing at the rate of 0.000095 second annually. Because of the precession of the equinoxes this is about 20 minutes longer than a tropical year. See also **Time**.

SIDERITE. This mineral is a carbonate of iron, $FeCO_3$. It is hexagonal with rhombohedral crystals, and also occurs in various massive forms. It has a rhombohedral cleavage; uneven fracture; is brittle; hardness, 3.75–4.25; specific gravity, 3.96; luster, vitreous to pearly; color, gray, yellowish- or greenish-gray, green, reddish-brown and brown. Siderite is found as concretionary masses in the sedimentary rocks; as a replacement mineral from the action of iron solutions upon limestones; and in metalliferous veins as a gangue mineral. It is relatively common. Siderite is found in Austria, Saxony, the Czech Republic and Slovakia, France, England, Italy, Greenland, Australia, Brazil and Bolivia. In the United States important localities are in Connecticut, Pennsylvania, New Jersey, Ohio, and Washington. It is an iron ore. The mineral was at one time called chalybite.

SIDEWINDER. See **Snakes**.

SIFAKA. See **Lemur**.

SIGMA PARTICLE. A hyperon with a rest-mass energy of about 1193.4 MeV, an isospin quantum number 1, an angular momentum spin quantum number $\frac{1}{2}$, and a strangeness quantum number 1. Symbol, Σ.

SIGMA$_T$ (symbol σ_t). A conveniently abbreviated value of the density of a seawater sample of temperature t and salinity S:

$$\sigma_t = [\rho(S,t) - 1] \times 10^3$$

where $\rho(S,t)$ is the value of the seawater density in c.g.s. units at standard atmospheric pressure. If, for example, $\rho(S,t) = 1.02648$, then $\sigma t = 26.48$.

SIGMOIDOSCOPY. An instrumental technique for examining the rectum and sigmoid colon. The patient is placed in the knee-chest position, preferably on a motorized table that allows support of the knees below the level of the abdomen. After introduction of the sigmoidoscope, any liquid colonic contents are aspirated. A cotton swab may be pressed against the mucosa and rotated 360 degrees to remove mucus and debris. The physician then searches for ulcerations, a granular mucosal surface, polyps, friability (bleeding), and other conditions, depending upon the exact purpose of the examination. Where information beyond the reach of the sigmoidoscope is required and when this cannot be fully obtained through a barium-contrast x-ray, colonoscopy may be used. This involves an instrument employing fiber optics that permits examination of the colonic surface from the anus to the ileocecal valve.

SIGNAL. 1. An independent input variable.

2. A visual, audible, or other indication used to convey information.

3. The intelligence, message, or effect to be conveyed over a communication system.

4. A signal wave.

SIGNAL CONDITIONING. A process for modifying an input signal prior to introduction into an electronic system, such as a digital-data acquisition or instrumentation operation. The meaning of the term varies from one type of application to the next. Modification of an analog input signal prior to amplification may include: attenuation (scaling), filtering, conversion (current to voltage or voltage to current), impedance-level transformation, bridge or signal compensation, and in numerous instances specialized operations such as cold-junction compensation in the case of thermocouple inputs. Commercially available signal conditioning apparatus may include both amplification and conversion from analog to digital form. Because of the rather nebulous nature of this term, its use in procurement always should be accompanied by detailed specification of functions and operating parameters.

SIGNAL GENERATOR. In the development, calibration, and testing of electronic hardware, instruments, and systems, frequently it is required to simulate certain electrical signals. A signal source provides the stimulus that creates the response to be measured. This source usually is an oscillator or a standard-signal generator of known characteristics which can be adjusted to establish a known set of conditions. These characteristics include: (1) the frequency; (2) the output voltage and impedance; (3) the carrier-signal waveform, which typically may be sine wave, square wave, pulse, or random noise; and (4) the modulation that carries the system information through variation of phase, frequency, amplitude, or timing of the carrier waveform.

Signal sources can be classified functionally as to whether the information that they yield is readily usable in *frequency domain*, or in *time-domain* analysis. Sine wave techniques form the basis of power generation and transmission systems and most communication systems, leading to ready frequency domain analysis. Many developments in information transmission and data handling, such as radar systems, digital computers, telemetry, and wire telegraphy, are based upon pulse techniques which yield most easily to time domain analysis.

Common to all of these systems are ultimate performance limitations, determined by system bandwidths and noise. Bandwidth and transient performance are closely related. They convert one into the other and can be measured as phenomena in either the frequency or the time domain at the convenience of the analyst. Noise is most easily measured by comparison with a noise source of known characteristics.

Types of Signal Sources. These fall into five major categories:

1. *Oscillators*, or sine wave generators which embrace frequencies from 0.01 Hz to 7 GHz, with maximum output levels from a few milliwatts to 200 watts.

2. *Standard signal generators*, which are sine wave oscillators with accurately calibrated output voltage behind a standard impedance and with calibrated modulation capabilities. For wideband measurements, a sweep frequency instrument provides calibrated sweep bands as well as calibrated output. Mechanical sweep devices also are available for converting conventional signal generators and oscillators to sweep generators.

3. *Frequency synthesizers* generate output frequencies continuously adjustable over wide ranges, all coherently derived from a single quartz crystal oscillator. Commercial instruments are available with optional degrees of resolution from one part in 10^3 to one part in 10^9, with either manual or programmable control.

4. *Pulse generators* for time domain measurements. See also **Pulse Generator**.

5. *Random-noise generators* that produce wideband noise of known spectrum and energy distribution for noise and vibration testing in mechanical systems, noise measurements in communication circuits, and applications is psychological, probability, and information theory research. These devices are described under **Noise Generator**.

Oscillators

The variable frequency, sine wave oscillator is the basic general purpose signal source. With it one can make a series of measurements at specified frequencies which can be combined to specify performance in the frequency domain. These measurements may be made by manual settings, point-by-point, or by a frequency swept automatically over the desired range to display the system response on a chart recorder or a cathode ray oscilloscope.

Oscillators are of four basic types:

1. *LC Oscillators*. At radio frequencies where tuning can be accomplished with air capacitors, the LC circuit is the best and most economical frequency-determining system. They cover frequencies from 500 kHz to 1,050 MHz. At frequencies above 1,000 MHz, circuits with distributed constants are used.

2. *RC Oscillators*. The frequency is determined by resistive and capacitive elements in this type of instrument. These devices in various configurations cover a frequency range of 0.01 to over 1 MHz.

3. *Beat-frequency Oscillators*. In these devices, the output frequency is the difference between the frequencies of a variable-frequency and a fixed-frequency oscillator. Several decades of frequency can be covered in one band with a single control.

4. *Klystron Oscillators*. In these devices, the frequency is determined by a velocity-modulated electron stream, which excites a resonant cavity. In one form, a reflex klystron in a coaxial cavity with a noncontacting plunger is used to cover frequencies from 1.7 to 4.1 GHz. Internal square wave and frequency modulation are provided.

An automatic, audio frequency measuring system that combines a beat-frequency audio generator and a graphic level recorder for automatic plotting of frequency response data is shown in Fig. 1. This type of instrument is used widely for measuring the response of filters, attenuators, networks, loudspeakers, amplifiers, microphones, transducers, and complete acoustic systems.

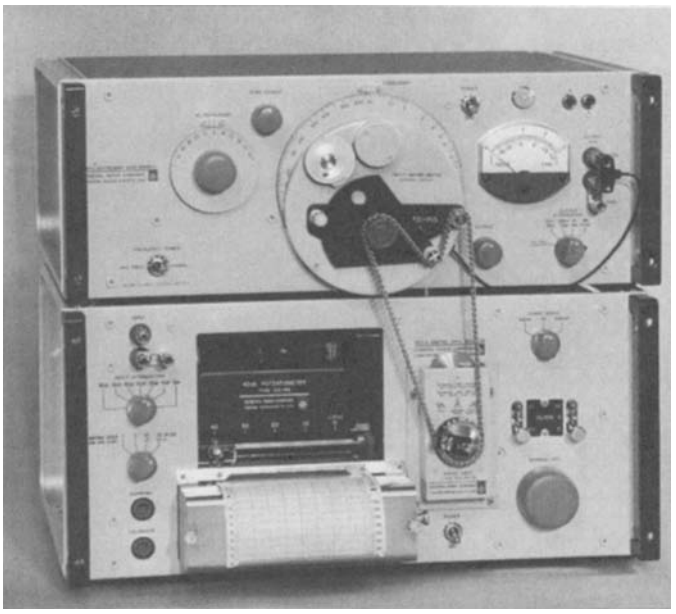

Fig. 1. Automatic audio-frequency measuring system.

Standard Signal Generators

These instruments provide a source of alternating current energy of accurately known characteristics. The carrier, or center frequency, is indicated by a dial setting, the output voltage by a meter reading and associated attenuator setting, and the modulation by a meter reading that is set by appropriate knobs. See Fig. 2.

Common types of modulation signals are sine wave, square wave, and pulse. The output signal either may be frequency or amplitude modulated by these signals. When the frequency modulation system produces a considerable excursion in frequency at a relatively low cyclical rate, the instrument is known as a sweep frequency generator and is particularly useful for automatic data display. Standard signal generators are used for testing radio receivers, as voltage standards over the range from a few microvolts to about one volt, and generally as power sources in measurement of gain, bandwidth, signal-to-noise ratio, standing wave ratio, and other circuit properties.

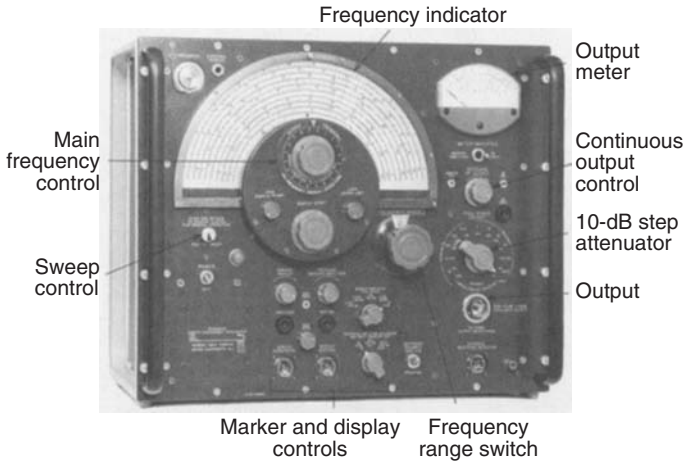

Fig. 2. Standard sweep frequency generator.

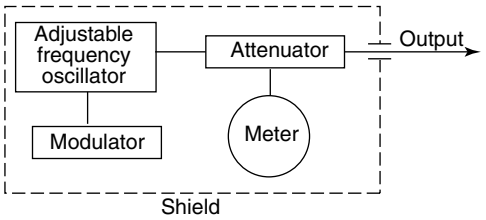

Fig. 3. Elements of a standard signal generator.

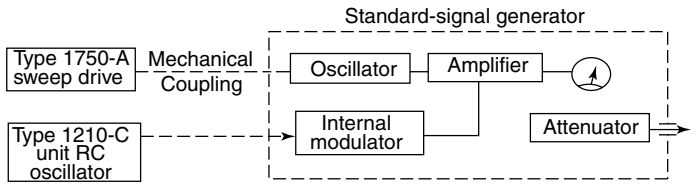

Fig. 4. Elements of an amplitude modulated standard signal generator with amplifier.

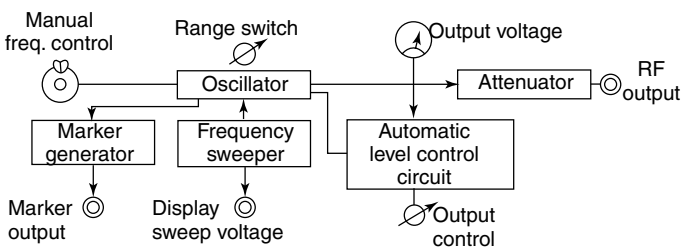

Fig. 5. Elements of a standard sweep frequency generator.

For use as a standard signal generator, the oscillator must be stable, have reasonably constant output over any one frequency range, have a good waveform, and have no appreciable hum or noise modulation. Careful overall shielding of the generator is essential to minimize stray fields.

The elements of an amplitude modulated standard signal generator are shown in Fig. 3. An amplifier may be added readily at lower frequencies, as shown in Fig. 4, to isolate the oscillator from the load and to minimize the incidental frequency modulation that usually results from amplitude modulation. The elements of a standard sweep frequency generator are shown in Fig. 5.

The specifications for three standard signal generators and for a standard sweep frequency generator are given in Table 1 to illustrate the overall performance parameters of these instruments.

Frequency Synthesizers

These devices are well suited for repeatable, high precision frequency response measurements on amplifiers, filters, transducers, and similar electronic devices. Either point-by-point or sweep techniques may be used. An instrument of this type is shown in Fig. 6 and the overall specifications of four configurations of it are given in Table 2 to illustrate the overall

TABLE 1. PERFORMANCE PARAMETERS OF SIGNAL GENERATORS

Instrument Type	Frequency Range	Open-circuit Voltage	Impedance Ohms	Output Modulation %
Standard signal generators	5 kHz–50 MHz	0.1 μV–200 μV	10.50	0–80
	67 kHz–80 MHz	0.1 μV–6 V	50	95
	9.5 MHz–500 MHz	0.1 μV–10 V	50	95
Standard sweep frequency generators	0.7 MHz–230 MHz	0.3 μV–1 V	50	Sweep all bands
	0.45 MHz–10.7 MHz	0.3 μV–1 V	50	

TABLE 2. PERFORMANCE PARAMETERS OF FREQUENCY SYNTHESIZERS

Characteristic	Example #1	Example #2	Example #3	Example #4
Frequency range	0–100 KHz	0–1 MHz	30 Hz–12 MHz	10 kHz–70 MHz
Smallest digital step	0.01 Hz	0.1 Hz	1 Hz	10 Hz
Smallest direct-calibrated continuously-adjustable decade increments	0.0001 Hz	0.001 Hz	0.01 Hz	0.1 Hz
Maximum bandwidth controllable by continuously adjustable decade module	100 kHz	1 MHz	1 MHz	1.2 MHz
Spurious frequency outputs:				
Harmonic (a^+ maximum output)	< -40 dB	< -40 dB	< -30 dB	< -30 dB
Nonharmonic	< -80 dB	< -60 dB	< -60 dB	< -60 dB
Output	(Coupling switch at ac) Adjustable, 0 to 2 V, rms (Coupling switch at dc) Adjustable, 0 to 0.8 V, rms 0 to 2 V, rms		(Output impedance switch at 50 ohms) 0 to 2 V, rms (Output impedance switch at zero)	0.2 to 2 V, rms, metered and leveled behind 50 ohms ± 5%

performance parameters obtainable in these kinds of instruments. The output frequency is synthesized directly by repetitive arithmetic manipulations of frequency in a series of identical modules. The synthesizers are equipped for direct, front-panel, digit selection.

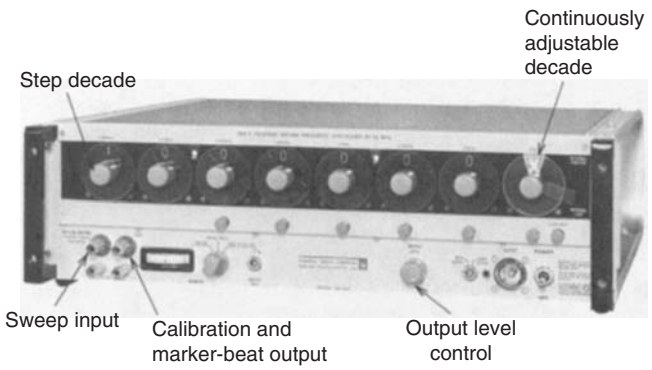

Fig. 6. Coherent decade frequency synthesizer.

Frequency synthesizers combine the advantages of tunable oscillators, which are not usually highly stable, with those of frequency standards, which though very stable, are not tunable. In addition, frequency synthesizers can be tuned like a decade box, i.e., in discrete steps for precision and repeatability; or they can be swept over bands as wide as the instrument's full frequency range, or as narrow as 0.001 Hz.

SIGNAL (Instrument). With reference to industrial and scientific instruments, the Instrument Society of America defines *signal* as information about a variable that can be transmitted.

Actuating-Error Signal. The reference-input signal minus the feedback signal.

Error Signal. In a closed loop, the signal resulting from subtracting a particular return signal from its corresponding input signal.

Feedback Signal. The return signal that results from a measurement of the directly controlled variable.

Input Signal. A signal applied to a device, element, or system.

Measured Signal. The electrical, mechanical, pneumatic, or other variable applied to the input of a device. It is the analog of the measured variable produced by a transducer (when such is used).

In a thermocouple thermometer, the measured signal is an emf, which is the electrical analog of the temperature applied to the thermocouple. In a flowmeter, the measured signal may be a differential pressure, which is the analog of the rate of flow through an orifice. In an electric tachometer system, the measured signal may be a voltage, which is the electrical analog of the speed of rotation of the part coupled to the tachometer generator.

Output Signal. A signal delivered by a device element, or system.

Reference-Input Signal. A signal external to a control loop which serves as the standard of comparison for the directly controlled variable.

Return Signal. In a closed loop, the signal resulting from a particular input signal, and transmitted by the loop and to be subtracted from the input signal.

Signal Transducer. A transducer that converts one standardized transmission signal to another.

Signal-to-Noise Ratio. Ratio of signal amplitude to noise amplitude.

SIGNAL LEVEL. At any point in a transmission system, the difference of the measure of the signal at that point from the measure of an arbitrarily-specified signal chosen as a reference. In audio techniques, the measures of the signal are often expressed in decibels, thus their difference is conveniently expressed as a ratio.

SIGN CONVENTION (Lens and Mirror). Since every distance involved in lens computations must be measured from some origin, a convention

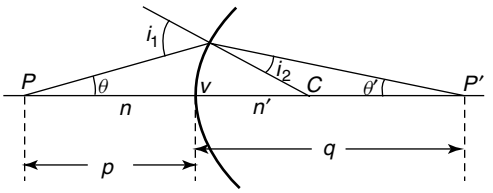

Fig. 1. Demonstration of sign convention.

of signs should be adopted to insure consistency in the derivation and use of formulas. Unfortunately, this has not been done by all authors. The following probability has the largest following: (1) Draw all figures with the light incident on the surface of reflection or refraction from the left. (2) Consider the object distance $p = PV$ positive when P is at the left of the vertex. (3) Consider the image distance $q = VP'$ positive when P' is at the right of the vertex. (4) Consider the radius of curvature $R = CV$ positive when the center of curvature lies to the right of the vertex. (5) Consider the slope angles positive when the axis must be rotated counterclockwise through less than $\pi/2$ to bring it into coincidence with the ray. (6) Consider angles of incidence and refraction positive when the radius of curvature must be rotated counterclockwise through less than $\pi/2$ to bring it into coincidence with the ray. (7) Consider distances normal to the axis positive when measured upward.

In Fig. 1, only θ' is negative. When the convention is followed, the simple thin-lens formula results.

SIGNIFICANCE TESTS. Suppose that a sample provides an estimate θ of a parameter t, and that a certain hypothesis specifies a certain value for θ, $\theta = \theta_0$ say. t will differ from θ_0 by a discrepancy $d = \theta_0 - t$, and it may be possible to deduce from the sampling distribution of t the probability P that a discrepancy as large as d would have arisen if the hypothesis $\theta = \theta_0$ were true. If this probability is small, the sample may be taken to provide evidence against the truth of the hypothesis. This procedure is called a test of significance. If P is less than some value α (commonly chosen to be 0.05 or 0.01), we say that t is significantly different from θ_0 at the level α, or simply that d is significant at this level. The hypothesis $\theta = \theta_0$ (i.e., $d = 0$) is called the null hypothesis.

Alternative tests of the same hypothesis are often available, based on different statistics. To choose between them, we introduce the notion of an alternative hypothesis, $\theta = \theta_1$ say. We may now calculate, for a given α, the probability β of obtaining a significant result at this level when the alternative hypothesis is true. This probability (a function of α and θ_1) is called the power of the test. A few tests can be shown to be at least as powerful as any alternative test for all values of θ_1. Such tests are said to be uniformly most powerful and are clearly to be preferred in cases where they exist.

If we imagine some action being taken based on the result of a significance test, this action may be referred to as accepting or rejecting the null hypothesis. Sampling fluctuations may then lead to two types of incorrect action:

1. We may reject the null hypothesis when it is true.
2. We may accept the null hypothesis when it is false.

These are referred to as errors of the first and second kind; their probabilities are respectively α and $(1 + \beta)$. A test for which $(1 + \beta) \geq \alpha$ for all values of θ_1 is said to be unbiased.

SIR MAURICE KENDALL, International Statistical Institute, London

SIGNIFICANT DIGITS. 1. The digits that determine the mantissa of the logarithm of the number beginning with the first digit on the left that is not zero and ending with the last digit on the right that is not zero.

2. The digits of a number that have a significance; the digits of a number beginning with the first nonzero digit on the left side of the decimal point, or with the first digit after the decimal point if there is no nonzero digit to the left of the decimal point, and ending with the last digit to the right. Note that the use of the final zero in the number 0.230 implies that the number is known to third place accuracy.

SIGNIFICANT WAVE. In ocean wave forecasting, a fictitious wave whose height and period are equal to the average height and period of the highest one-third of the actual waves that pass a fixed point.

SIKAS DEER. See **Deer**.

SIKES SCALE. See **Specific Gravity**.

SILAGE. A feedstuff resulting from the anaerobic preservation of moist forage crops or crop residues by acidification. This definition (M.E. McCullough, Georgia Experiment Station, University of Georgia) aptly confines silage to the production of a feedstuff and eliminates the confusion of nonagricultural uses. The definition confines the process to anaerobic conditions and excludes decomposition under aerobic fermentations in which the final result is the disposition of a waste product, such as sewage. The two important inclusions in the definition are the terms *forage* and *acidification*. This confines the definition to harvested farm products that are being stored for feed and limits the method of preservation to acidification. The latter limitation does permit the acidification process to include either or both the direct application of acids or the development of acids through fermentation within the silage mass. Silage must not be confused with simply wet grains in storage. McCullough points out that there are many terms in common use that have no scientific significance in silage terminology (such as *haylage*, *cornlege*, *oatledge*, etc. — all coined names used to designate a particular method for harvesting and storing forage). They are like brand names in the feed industry, such as *dairy feed* or *hog supplement*, which have no meaning by themselves. Other terms used in connection with silage, such as *wilted, direct cut*, or *recut*, have value only as being descriptive of the methods used in harvesting or storing the crop.

Advantages and Limitations of Silage. In terms of the dairy farm, there are several advantages to making and feeding silage, including:

1. Silage may be fed at any time of the year or year-round.
2. Silage may be harvested in adverse weather as well as in fair weather.
3. There is very little waste in silage feeding processes.
4. The silage crop can be readily harvested at the most favorable stage of maturity.
5. Silage requires less storage space than hay.
6. Silage crops are removed from the land earlier, thus facilitating a double cropping system.
7. The use of silage increases the carrying capacity of cows per unit of land and per farm by saving more feed per unit of land.
8. The fire hazard in storing silage is minimal.
9. Forage stored as silage is the most economical method of preserving the greatest amounts of nutrients (TDN, total digestible nutrients) per unit of land.
10. Silage is an excellent substitute for pasture.
11. The making and feeding of silage can be completely mechanized.
12. A few weeds will not seriously affect the quality of silage, since most weeds seem to lose off-flavors in the ensiling process. Wild onion is an exception; its flavor is usually retained in the silage.
13. Silage may be kept for many years, almost indefinitely, if it is properly made and well stored.
14. A silo saves feed that might otherwise be wasted.
15. When forage is stored in the form of silage, it has some values that other stored roughages do not possess, including palatability, laxative effect, and the fact that it can be fed free-choice (self-fed) without danger to dairy cattle.

Limitations of silage include:

1. Initial costs of silo and silage-making machinery are high.
2. After a silo is opened, some silage should be fed daily to prevent spoilage.
3. Sale of silage is generally impractical; hence it must usually be fed on the farm where it is stored.
4. Silage requires some skill and knowledge to be handled successfully, thus keeping spoilage, other losses, and reduction in quality to a minimum.

SILANES. See **Silicon**.

SILICA. [CAS: 7631-86-9]. The term silica denotes the compound silicon dioxide, SiO_2, and encompasses its various forms, including crystalline silicas, eg, quartz; microcrystalline silicas, eg, diatomaceous earth, vitreous silicas, which are essentially supercooled liquid glasses; and amorphous silicas. The amorphous forms vary over a wide range of hydration or hydroxylation. Silica sols (colloidal silicas) are nonsettling dispersions of amorphous silica particles in a liquid, generally water. Amorphous powders can be broadly classified as either wet process or pyrogenic silicas based on the mode of manufacture. Wet process types include precipitated silicas and silica gels. Pyrogenic silicas are made at high temperature rather than from aqueous solution, and are sometimes referred to as fumed silicas.

The earth' crust is almost exclusively made of siliceous minerals and silicon dioxide (~95%) in the form of approximately 800 crystalline minerals. In recorded history, there are numerous indications of the omnipresence of silicates in humanity's natural habitat. Siliceous minerals were either utilized by processing natural silicate deposits, e.g., clay, porcelain, glass or enamel, or obtained by means of chemical conversion (silica, silicones, ceramics). The properties of pure elemental silicon are now of pivotal importance in the manufacture of integrated switching circuits and, therefore, also form the basis for the age of electronics. Silica and silicates in the form of amorphous white powders can also be made synthetically, using a thermal or pyrogenic process (fumed silica) or a wet process (precipitated silica, silica gels). Amorphous silica is used in various industries, such as food, feed, personal care, paper, tires, plant protection and many others, and is an essential part of many everyday products.

Although siliceous minerals can appear in various structure types and stoichiometries, they can be classified using only a few relatively simple rules. The basic structural unit of most forms of silica and silicate minerals is a tetrahedral arrangement of four oxygen atoms surrounding a central silicon atom (SiO_4). The SiO_4 units can either be discrete and isolated or connected to each other via shared edges. The SiO_2 stoichiometry of silica requires that on the average each oxygen must be shared by silicons in two tetrahedral. Sharing of corners is the common mode of linkage of the coordination polyhedra; sharing of edges is rarely encountered; and sharing of faces never occurs because of the decrease in stability that would result from the close distance between silicon cations. Structurally, silica represents a limiting case in which an infinite three-dimensional network is formed by the sharing of all oxygen atoms of a given tetrahedron with neighboring groups. The possibility of linking tetrahedrons so that some corners remain unshared gives rise to a wide range of structural possibilities some of which are encountered in the silicates. Each unshared oxygen atom contributes a formal negative charge to the anionic groups thus formed, which is satisfied by the presence of other cations in the silicate structure.

Properties. Despite the fact that synthetic silica has been known for a long time, the question as to how they are best assigned characterization values has yet to be resolved. In a particular application, the behavior of products frequently differs from the expected on the basis of characterization values. There is, however, still hope that the accurate characterization of silica will allow conclusions to be drawn with respect to its mechanism of formation and its behavior in its intended application. Characterizing silica means describing its surface and structure, the morphology, as accurately as possible in an attempt to predict its behavior and performance in certain applications. Other analytical methods attempt to describe the surface chemistry; i.e., they describe the number of silanol groups and their arrangement, surroundings and reactivity, the chemical composition and degradation behavior of the silica structure. Furthermore, there are a number of methods that can collectively be termed bulk chemical analysis.

Manufacture. Amorphous, synthetic silica and silicates can be manufactured using a "thermal" or "pyrogenic" or a "wet" process. The thermal

process leads to fumed silica, the wet process to either precipitated silica or silica gels. See also **Silica Gel**.

Fumed or Pyrogenic Silica. The technical synthesis or production of fumed silica can fundamentally be described as continuous flame hydrolysis of silicon tetrachloride, $SiCl_4$[CAS: 10026-04-7]. Hereby, $SiCl_4$ will be converted into the gas phase ("evaporated") and then reacted with hydrogen and oxygen ("hydrocarbon flame"). The "intermediate" water, H_2O, will spontaneously react with the silicon tetrachloride to form silicon dioxide quantatively according to equations 1–3.

$$2H_2 + O_2 \longrightarrow 2H_2O \quad (1)$$

$$SiCl_4 + 2H_2O \longrightarrow SiO_2 + 4HCl \quad (2)$$

or

$$2H_2 + O_2 + SiCl_4 \longrightarrow SiO_2 + 4HCl \quad (3)$$

The chemical reaction is exothermic and therefore generates a lot of heat requiring cooling of the reaction products. The only by product of the reaction is hydrochloric acid, which needs to be separated from the fumed silica powder and can be recycled and used for the manufacture of silicon tetrachloride according to equation 4.

$$Si + 4HCl \longrightarrow SiCl_4 + 2H_2 \quad (4)$$

Ferrosilicon (FeSi) [CAS: 8049-17-0], which is widely used in the steel manufacturing process, is usually the source of silicon. The generated hydrogen is recycled and used in the burner to create the flame, so that the overall process is very environmentally friendly.

The physical-chemical properties, e.g., surface area, particle size distribution and structure, of the fumed or thermal silica can be controlled through variation of the concentration of the reactants, the flame temperature and reaction time. Instead of silicon tetrachloride or other silanes, eg, methyltrichlorosilane [CAS: 75-79-6], trichlorosilane [CAS: 10025-78-2] etc, can be used for the formation of fumed silica. The use of the above mentioned silanes instead of silicon tetrachloirde requires an adjustment of the process conditions to get the same final product.

Precipitated Silica. The raw materials used for the production of precipitated silica are alkali silicate solutions, preferably sodium silicate and acid.

In the first step (precipitation), the raw materials consisting of water glass (sodium silicate solution) and mineral acid, normally sulfuric acid is used, are dosed into a stirred vessel containing water. In many cases, once a defined pH value has been set, the components are fed continuously into the reactor, this process taking place simultaneously over a certain time interval. Typically, precipitated silica is manufactured at pH values >7, whereas silica gels are manufactured at pH values <7. Another possibility is to first supply a particular quantity of water glass and initially (first stage) dose just sulfuric acid followed by a second stage in which water glass and sulfuric acid are added simultaneously under defined reaction conditions. The chemical reaction is described in equation 5.

$$Na_2O \times 3.3SiO_2 + H_2SO_4 \longrightarrow 3.3SiO_2 + Na_2SO_4 + H_2O \quad (5)$$

After the chemical reaction (precipitation) has been completed, the obtained suspension is filtered, and the filter cake is washed to remove the sodium sulfate. The filter cake can then be resuspended and spray dried or directly fed to a term drying process. Depending on the drying technology and the required particle size of the silica, the product can be optionally milled to obtain a finer particle size or granulated to convert the powder into a low dust form. Precipitated silica too can be converted from hydrophilic to hydrophobic using a chemical after treatment.

Silica Gels. Silica gels are generally being manufactured using the same feedstock that is used for precipitated silica: an alkali silicate solution, preferably sodium silicate ("water glass") and acids, mostly sulfuric acid [CAS: 7664-93-9]. The same chemical reaction as shown in equation 5 is followed. Different from precipitated silica in the process of making silica gels, the two raw materials are not reacted and precipitated in huge vessels for up to several hours, but are brought together in relatively small mixers. The raw materials are passed through the mixers within a couple of seconds and are intensively mixed forming silica hydrosols. The silica hydrosol is then collected in containers where rapid gelation of the mixture occurs. Silica hydrosols are typically formed at pH $<$ 7. At a given silica concentration and temperature, the rate of gelation strongly depends upon pH. As pH of formation increases, the surface area of silica gels becomes lower. The gelation of the silica gels is usually followed by an aging step to further modify the performance of gels. The resultant gel block must be crushed before further processing. After gelation and aging, the silica gel is washed to remove the soluble salts. The conditions of washing affect the gel properties as well. If the product is dried only enough to remove excess surface water, the product is called a hydrogel. If the washed gel is further dried, xerogels are obtained. Milling may accompany drying to achieve a desired particle size distribution. The drying of hydrogels and xerogels usually causes a partial collapse of the silica gels structure and a loss of pore volume and porosity.

The final category of silica gels of commercial importance is the aerogels, first reported by Kistler in the 1930s. See also **Aerogels**. Aerogels, like xerogels, are dry gels, but they are made in such a way as to prevent pore collapse upon drying. In order to do so, the water in the hydrogel is replaced with a liquid of lower surface tension, eg, alcohol or acetone. The liquid is then removed by heating the silica gel to above the critical point and then releasing the pressure. This way a liquid-vapor interface never forms, so surface tension forces never have the opportunity to collapse the pore structure.

Health and Safety. Silica, produced in a thermal (fumed silica) or precipitation process (precipitated silica, silica gels), is characterized by the absence of any sharp peaks in X-ray powder diffraction scans, and considered totally amorphous. Exposure to synthetic silica is most likely to occur due to dust ingestion, dermal contact or inhalation, with inhalation being by far the most important route of contact. When handling synthetic amorphous silica and observing the TLV (Threshold Limit Value) for total dust, no negative or harmful effects were detected. If the TLV is exceeded, the respiratory tract may be mechanically overloaded as with other nuisance dusts. After contact with skin and mucous membrane (eye, respiratory tract) no symptoms of irritation have been noticed up to now. Synthetic amorphous silica is essentially non-toxic when ingested. Always consult the manufacturers Material Safety Data Sheet (MSDS) for details prior to using the silica.

Uses. Silica is widely used in various products of daily life such as food, feed, plant protection, coatings, toothpaste, tires, and mechanical rubber goods, and unsaturated polyester resins, etc.

Food and Feeds. Powdered ingredients play an increasingly important role in the food industry due to the customer's need for convenient, easy to handle products with a consistent quality. Fruit powders, sea salt, dairy products, or vegetable powders as well as ground spices or spice mixtures are only a few of many examples. Many of those ingredients tend to pick up moisture, become sticky over time and start to cake or loose there ability to flow freely. Tailor made silica products have a very high absorption capacity for water or oil, thus are capable of drying the surface of the food ingredients, preventing them from sticking together and help to keep them as free flowing powders.

Animal feeds and premixes are blends of many ingredients needed by a particular species for good nutrition. Generally included are grains, fats, proteins, sugars, amino acids, vitamins and minerals. Many of these ingredients flow poorly, or cake during storage. Some are in liquid form, therefore are difficult to add accurately to a dry blend. Due to its unique absorption capacity, silica is used as a carrier medium for, e.g., Vitamin E. Silica helps turning liquids into free flowing powders and facilitates dosing feed additives for livestock. Some silica can absorb liquids up to three times their own weight and still remain free flowing powders. Many feed ingredients are hygroscopic, that is possess a high affinity to absorb moisture from air. This causes them to change chemical state during processing or storage. An ingredient which begins as a free flowing powder can quickly become caked depending on the ambient temperature and humidity and the quality of packaging. Silica is very effective in solving these problems and assuring, the powder ingredients remain free flowing over extended periods of time.

Agriculture. The food stuffs produced worldwide is 97% of agricultural origin, only 2% come from fishing and 1% from pasture farming. The world's supply depends on the crop yields. More than one third of the potential crop yields throughout the world are lost as a result of diseases and pests. A well balanced pest control is required in order to protect nature and life cycles. Synthetic silica greatly contributes towards optimizing the formulations for plant protection and pest control. Silica, fumed and precipitated, is widely used in different formulation types, powder or granulated formulations and liquid formulations. Silica, mainly precipitated, in powder formulations regulates and maintains the flow properties during storage, is used as a grinding additive or carrier to absorb and carry the active ingredient of the formulation. Silica, mainly fumed, is used in liquid formulations to stabilize the suspension containing a variety of liquid and solid ingredients. Due to its unique structure, fumed silica forms a three-dimensional network when suspended in a liquid system, thus preventing any solid components from settling. Solid substances can be "stored" within the three dimensional network enhancing the shelf life of the formulation significantly.

Coatings. The increasing demand for matt-finish paint systems, either as a fashionable trend or as means of increasing safety by preventing glare or in course of general product improvements, led to an increasing demand for silica. Changing trends in coatings technology have forced many formulators to re-examine their requirements for matting agents' performance. As the industry moves from conventional solvent-based systems to high solid and water based technology, the matting agent's performance becomes more critical for uniform and consistently matted finishes. Fumed, precipitated silica and silica gel, vary in average particle size, particle size distribution, oil absorption, moisture content and surface treatment. All of these characteristics play an important role in how well the matting agent will perform in each system.

Defoamers. Foam occurs in many natural and industrial processes as well as in everyday life. Food products like ice cream, whipped cream of cappuccino are some examples. On the opposite, the formation of stable foams can cause major problems in industrial processes such as in the manufacturing of paints and coatings, textiles, paper, detergents, and in the chemical industry. Here, foam can either affect the quality of the final product or impede the manufacturing process by reducing the capacity of tanks or containers or by causing pumping problems. For this reason, foam control processes have been developed. Highly effective foam control systems, with no negative impact on the manufacturing process or final product, are dispersions made of oils and hydrophobic, pre-treated, silica with a great variety of silica being used. In addition to their use as highly effective active component in foam control systems, silica also finds use as anti-settling agent in the manufacture of defoamers thus stabilizing the defoamer system providing a longer shelf life and consistent quality. See also **Defoaming Agents**; and **Foam**.

Personal Care. Oral care and oral health is continuing to gain importance globally. Synthetic silica as a major component in toothpaste significantly contributed to the progress in personnel oral hygiene. Silica in toothpaste serves one of two functions –they provide abrasivity and therewith cleaning, and they act as rheology modifier or thickening agent. Abrasive silica grades in toothpaste provide efficient cleaning of the teeth when brushing without causing damage to the teeth surface. Different grades of abrasive products have been developed covering a wide range of abrasiveness from very mild in toothpaste for children, to medium in adults' everyday toothpaste, to very strong abrasivity for use in whitening or smoker toothpastes. Silica serves the following functions: structuring toothpastes of gels and stabilizing dentifrices against separation through adding thixotropy and viscosity. Silica is also used in personal care products such as shampoos, body washes, creams, and lotions and sun lotions. Silica in these products helps to control viscosity and thixotropy and to stabilize the formulations improving storage stability and shelf life.
